- Symptoms experienced by the patient reflect the location of the cancer. Common symptoms include pain, rectal bleeding, altered bowel habits, and tenesmus. Pain may be the result of direct nerve (sacral nerve roots and sciatic nerve), muscle (levator, piriformis, and obturator internus), or bony (sacral) infiltration or the result of referred pain, usually to the buttock or hamstring.
- As the tumor gets larger, mass effect may ensue with ureteric or bowel obstruction. Advanced cancers of the pelvis may also present with malignant fistulae between the small or large bowel and an adjacent viscera such as the vagina or bladder. Occasionally, patients may present as an offensive fungating tumor or lymphedema of the lower limb because of venous compression.
- Asymptomatic local recurrences may be detected on routine follow-up with elevated carcinoembryonic antigen (CEA), surveillance computed tomography (CT), or colonoscopy. Asymptomatic anastomotic recurrence following low rectal

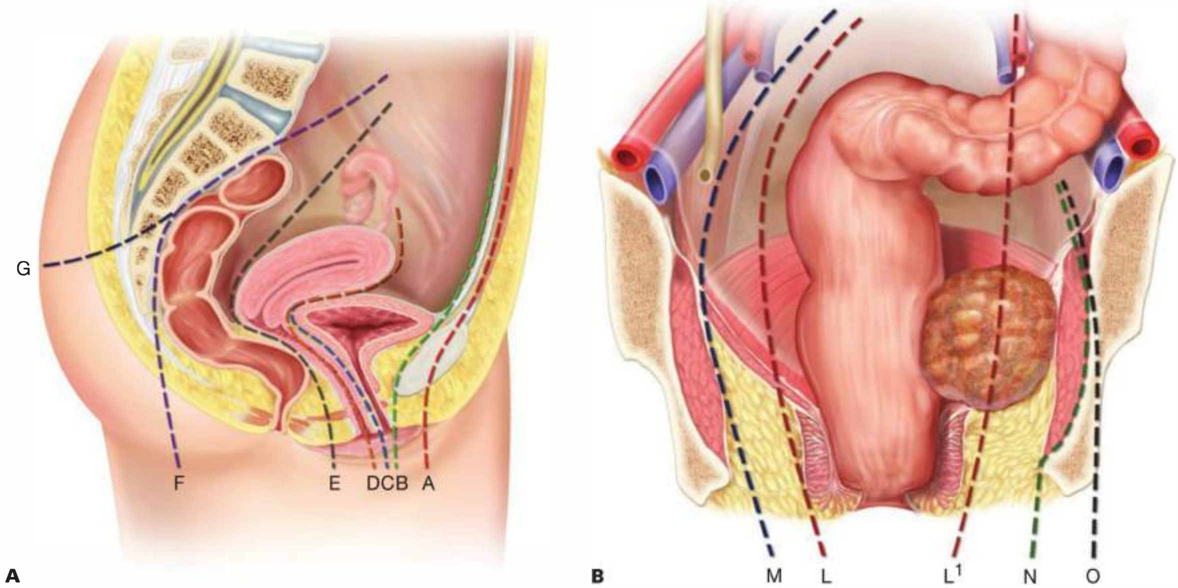

FIG 2 ● **A.** This is the sagittal section of a female pelvis. *Planes A* and *B* are the dissection planes for complete or partial exenterations involving the anterior compartment with and without en bloc pubic excision, respectively. *Planes C* and *D* are dissection planes for partial exenteration involving the central compartment with total or subtotal vaginectomy and posterior vaginectomy, respectively. Note that *planes C* and *D* do not exist in men. *Planes E* and *F* are the anterior and posterior total mesorectal excision planes, respectively, whereas *plane G* is the plane for en bloc sacrectomy. **B.** Coronal section of the pelvis. There are four possible lateral dissection planes. *Plane L* represents the total mesorectal excision plane and is the lateral plane for a partial exenteration not involving the lateral compartment. *Plane M* represents the extravascular plane, which is a plane lateral to the iliac vasculature but medial to obturator internus. *Plane N* involves excision of the entire lateral compartment including obturator internus, whereas *plane O* includes en bloc bony resection such as the ischial spine or ischial tuberosity. The right hand side of Figure 2B shows a tumour that involves the lateral compartment. Dissection in the lateral mesorectal plane depicted by *plane L1* will invariably result in an involved surgical margin. In order to achieve R0 resection margins, dissection should follow *plane N*.

resection may be readily palpable with digital rectal examination or be visible on rigid sigmoidoscopy.

- As pain frequently accompanies LARC or LRRC, clinical assessment may require an examination under anesthesia, which will also permit biopsies and other investigations to be undertaken concurrently such as a completion colonoscopy or cystoscopy where ureteric stents may also be inserted at the same time if necessary.
- In patients with a previous abdominoperineal excision, clinical findings are often limited.
- A general assessment for obvious systemic metastasis such as hepatomegaly or inguinal lymphadenopathy should also be performed to rule out the presence of metastatic disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- CT scan of the chest, abdomen and pelvis is a useful first step to rule out systemic metastasis. In general, CT scans do not provide adequate soft tissue delineation in the pelvis to permit accurate staging of LARC for decision making on neoadjuvant therapy. In patients with potential LRRC, CT scans have are limited in its ability to distinguish between post-surgical fibrosis and tumour recurrence.
- Positron emission tomography (PET) scans complement CT scans in detecting the presence of metastatic disease (**FIG 3A,B**). By detecting metabolically active tissue, it has the advantage of being able to distinguish between postoperative fibrosis and metabolically active local recurrence. PET in LARC or LRRC has been shown to alter clinical decision making by 20% to 40% by detecting occult metastatic disease.
- Magnetic resonance imaging (MRI) is currently the gold standard to determine the local extent of tumor, to assess resectability, and to determine the potential need of neoadjuvant (for LARC) therapy (**FIG 4A,B**). The accuracy of MRI in

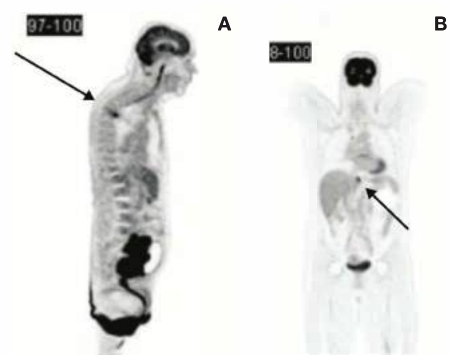

FIG 3 ● **A.** PET scan of a patient with locally advanced rectosigmoid cancer referred for pelvic exenteration. PET scan was consistent with metastatic disease *(arrow)*. **B.** PET scan of a patient with an anastomotic recurrence after a previous sigmoidectomy who presented with an asymptomatic recurrence manifesting with an elevated CEA. The patient was being considered for pelvic exentertation. PET scan showed a small liver metastasis otherwise undetected on CT scan *(arrow)*.

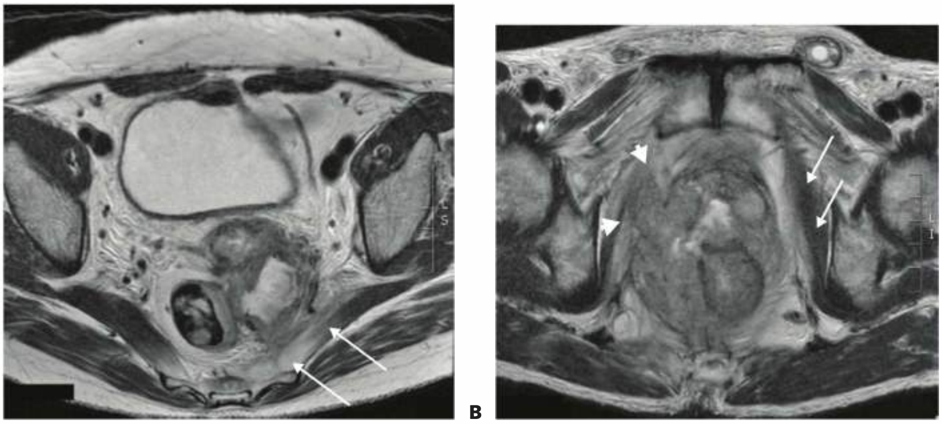

A B

FIG 4 ● **A.** MRI of the pelvis showing locally advanced cervical cancer. The cancer is seen to the left of the rectum and is invading the left piriformis muscle *(arrows)*. This patient has pain in the left S2-S3 nerve root territory consistent with sacral plexus infiltration. **B.** MRI of the pelvis of a patient with a large LRRC abutting the left obturator internus muscles *(arrows)* and directly infiltrating the right obturator internus muscle *(arrowheads)*.

confirming anterior compartment, pelvic sidewall and sacral involvement ranges between 60% and 100%. The major limitation of MRI with LRRC resides in its inability to accurately diagnose pelvic sidewall involvement.

- Tissue diagnosis, although easily obtained in LARC, is a contentious issue in patients with LRRC when the lesion may be inaccessible luminally and a biopsy would necessitate a percutaneous route that could lead to tract seeding. However, without tissue diagnosis, patients in whom the final pathology report shows no recurrence of cancer may have been subjected to an unnecessary major operation with significant morbidity. It is our practice to accept a diagnosis of LRRC when there is a positive PET scan provided that there is corroborative history, MRI findings, and elevated CEA level.
- CEA level is helpful for ongoing disease surveillance in patients with LARC. The sensitivity of CEA for detecting recurrent disease is low but the specificity is 85%.
- A complete colonoscopy is performed to obtain tissue diagnosis and to rule out synchronous colon cancer prior to embarking on a major resection.
- CT or magnetic resonance angiography may be useful to ensure the patency of inferior epigastric arteries if a rectus abdominis myocutaneous flap is being considered for perineal reconstruction in a patient who previously had or currently has stoma(s). They may also help to determine if a vascular surgeon may be needed if there is major arterial involvement of the common iliac or external iliac vessels.
- Cystoscopy can help diagnose bladder involvement and may allow ureteric stenting to relieve ureteric obstruction and prevent impending renal failure.

SURGICAL MANAGEMENT

Preoperative Planning

- All patients should be discussed preoperatively at a multidisciplinary team meeting to determine resectability and operative strategy.
- Patients who are radiotherapy naive should be considered for preoperative long-course chemoradiation prior to pelvic exenteration.
- A detailed informed consent is obtained. Because studies have shown that patients often underestimate the magnitude of the procedure, we encourage family members to participate in the discussions and we schedule at least two separate consultations.
- A preoperative review by the cancer coordinator and psychooncologist is obtained. Further, as most patients will require the creation of at least one, if not two, stoma, it is essential that the patient receive stomal education prior to the procedure.
- Bowel preparation is usually necessary for patients without an existing colostomy.

Positioning

- Depending on the location and the extent of the cancer, the patient may require surgery from the abdominal and the perineal compartment. In patients where a high sacrectomy is required, repositioning in a prone position after completion of the abdominal and perineal components of the operation is also necessary.
- Patients are placed in a modified Lloyd-Davies position directly on a gel mat with both arms tucked by their sides and protecting all pressure areas (**FIG 5**). In patients who require major perineal resections, the buttocks should be elevated with a rolled towel and overhang the end of the operating bed by up to 5 cm to permit access into the natal cleft if needed.
- To avoid muscle compartment syndrome, the legs should not be elevated more than 30 degrees during abdominal phase and only elevated for the perineal phase.
- Patients will require an arterial line, a central line, and a large-bore intravenous cannula. These lines need to be well secured prior to be being tucked away by the patient's sides.
- Patients should also receive prophylactic antibiotics, subcutaneous heparin, mechanical venous thromboprophylaxis in the form of graduated compression stockings and calf compressors.
- An indwelling Foley catheter is inserted. The anterior thigh is prepped and draped if a vascular graft using the great or common saphenous veins needs to be harvested. The vagina should also be included in the preparation.

FIG 5 ● The patient is positioned in modified Lloyd-Davies position with both arms tucked by their sides. The previous midline scar is marked. In this patient, a high sacrectomy and rectus abdominis myocutaneous is planned. The rectus abdominis myocutaneous flap is to be harvested from the patient's right where there has not been a previous stoma and this has also been marked out with the ileal conduit site being lateralized to *A′* by the same distance as that between the midline and the first stoma site *A*.

- A purse-string suture at the anal verge is used to prevent fecal spillage during the procedure.
- Prior midline incisions or scars should be marked so that the same incision can be used. In patients where a rectus abdominis myocutaneous flap is planned, this should also be premarked prior to prepping and draping (**FIG 5**). The colostomy is prepped and covered with a swab, which is then held in place by an impervious adhesive plastic dressing.
- Insertion of bilateral ureteric stents is not routinely done in all cases.

ABDOMINAL PHASE

- We start with a meticulous adhesiolysis to mobilize all small bowel loops from the pelvis. Avoiding enterotomies in pelvic small bowel loops which may have been damaged by previous radiotherapy is important to prevent a postoperative enterocutaneous fistula.
- The abdominal cavity is inspected for peritoneal carcinomatosis or unresectable metastatic liver disease not identified during pre-operative staging. Presence of either usually precludes curative resection and is likely to alter the surgical plan.
- Pelvic small bowel loops invaded by cancer should be resected en bloc using linear staplers. The remaining small bowel loops are packed into the upper abdomen using moist sponges held in a fixed table retractor such as the Omni-Tract®.
- If the colon is still intact, it should be mobilized along its anatomic planes. Reflection of the sigmoid and descending colon on its mesentery medially will expose the left ureter. Identification of the ureter is important to avoid inadvertent ureteral injury.
- For a LARC, a high ligation of the inferior mesenteric artery is performed. The colon is divided at a point of convenience that remains well vascularized. The proximal divided colon can then be packed into the upper abdomen, isolating the pelvis from the abdominal contents.
- The appendix is prophylactically removed in patients who require a conduit as dense adhesions and mesh closure of the abdomen would make a future appendectomy difficult.

Lateral Compartment Dissection

- There are four possible planes of dissection in the lateral compartment (**FIG 2B**). *Plane L* is the conventional total mesorectal excision plane that is familiar to all colorectal surgeons. This plane is used for partial exenterations not involving the lateral compartment or in small anastomotic recurrence that only requires a reoperative anterior resection.
- For dissections in *plane M*, *N*, or *O*, the procedure begins with identification and mobilization of the ureters with a cuff of connective tissue to preserve their blood supply (**FIG 6**). Both ureters are mobilized as distal as possible into the pelvis. If en bloc cystectomy is planned, the ureters are divided without compromising resection margins and to provide adequate ureteric length for urinary reconstruction with an ileal or colonic conduit. Ureters should be anastomosed to the conduit out of the field of prior radiotherapy when possible. Even if en bloc cystectomy is not required, mobilizing the ureters along their entire length allows them to be mobilized off the pelvic sidewall such that the next layer of structures under the ureter (the common, external, and internal iliac arteries) can be accessed (**FIG 7**).
- Other than an early anastomotic recurrence, complete pelvic lymphadenectomy, starting at the level of the aortic bifurcation, is routinely performed for most other LRRC. **FIG 7** also demonstrates the appearances of the iliac vasculature after complete pelvic lymphadenectomy.
- Dissecting in *plane M* will require ligation and excision of the internal iliac vasculature so as to get into and to

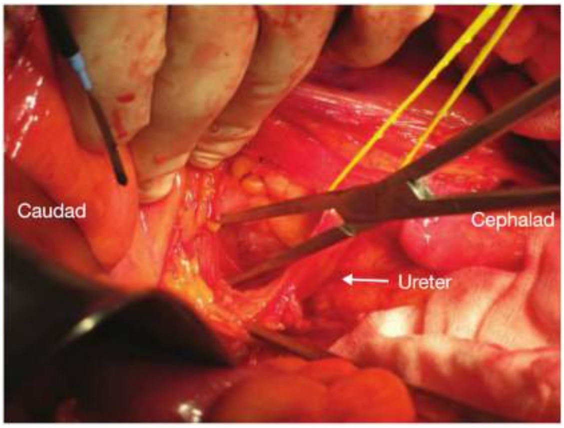

FIG 6 ● Mobilization of the right ureter with a cuff of connective tissue around the ureter so as to preserve its blood supply. We use yellow vessel loops for ureters (blue for veins and red for arteries). Ureterolysis is performed with the operator dissecting using right-angle forceps and the assistant dividing tissue between the forceps using diathermy.

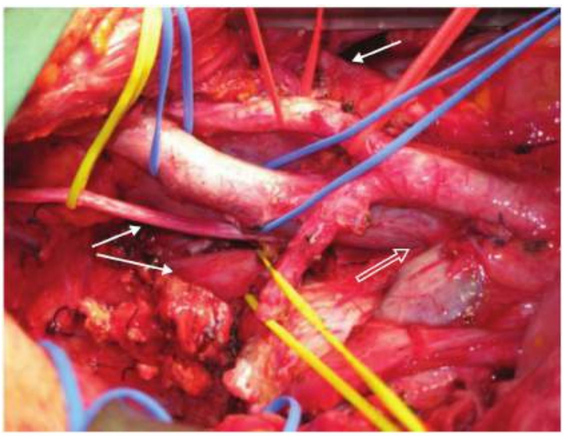

FIG 7 ● Right pelvic sidewall. The ureter has been fully mobilized, divided and is placed in the right iliac fossa away from the pelvic sidewall while further dissection of the right pelvic side wall continues *(top arrow)*. Pelvic lymphadenectomy has been performed from the bifurcation of the aorta and the common iliac artery (CIA). This exposes the common iliac vessels and the confluence between the external and internal iliac vessels *(block arrow)*. The right external iliac artery (EIA) is held in red vessel loops and the right internal iliac artery (IIA) has been ligated and divided. The external iliac and common iliac veins are held in blue vessel loops with the internal iliac vein ligated and divided. The two yellow vessel loops demonstrate two nerves. The smaller nerve is the obturator nerve and the larger nerve is the lumbosacral trunk *(left sided arrows)*. Note the "layered" arrangement of the pelvic sidewall where the iliac arterial system lies superficial to the iliac venous system which in turn lies superficial to the lumbosacral trunk. Note that after ligation and division of the internal iliac artery or vein, the external iliac artery and vein can then be "floated off" the pelvic sidewall.

remain in the extravascular plane. Even if formal excision of the internal iliac vasculature is not required, in situ ligation of the internal iliac artery and vein can be helpful to provide vascular control to limit blood loss as the dissection continues, especially if sacrectomy is planned. In LRRC, previous total mesorectal excision and radiotherapy usually cause tissue fibrosis and obliterate tissue planes making dissection difficult. Even if extra-vascular dissection is not necessary, the plane is typically virginal and may be comparatively easier to dissect.

- To get into plane M, after ureterolysis is performed, the internal iliac artery is dissected. When an adequate segment of internal iliac artery has been mobilized, it can be suture ligated and divided.
- Continued mobilization of the common iliac and external iliac arteries, which do not have any branches within the pelvis, will allow the common and external iliac arteries to be "floated" out of the operative field using two vessel loops held apart to prevent acute kinking of the artery. This exposes the next layer of structures—the common, external, and internal iliac veins. The combination of ligation of the internal iliac venous system and lymphadenectomy will result in progressive exposure of the sacral nerve roots on the piriformis muscle (**FIG 8**).
- Next, the internal iliac vein can then be ligated and excised en bloc together with the specimen, allowing the operator to get progressively more lateral within the lateral compartment. Variable venous anatomy and tributaries coupled with thin-walled veins make dissection of the venous system particularly challenging. Once the internal iliac vein is ligated, the external iliac vein and distal common iliac vein can be similarly mobilized (as with the common and external iliac arteries) to allow these veins to be floated out of the pelvis providing access to the deeper structures—the lumbosacral trunk (**FIG 7**). Lumbosacral trunk is derived from L4 and L5 nerve roots and joins the sacral plexus on the piriformis muscle to

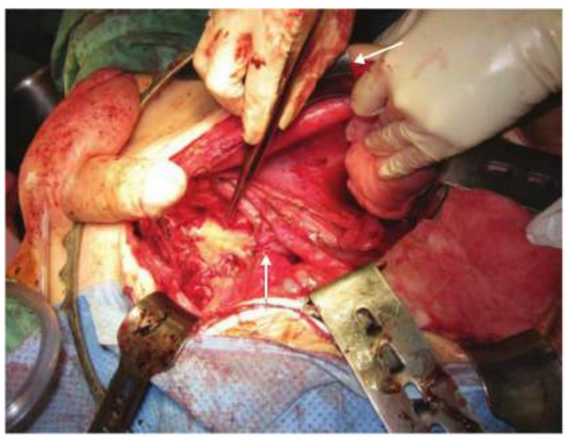

FIG 8 ● By dissecting and ligating the internal iliac vasculature and performing a lymphadenectomy, the lumbosacral trunks and the sacral plexus (S1, S2, and S3 nerve roots) are displayed. The internal iliac artery and internal iliac vein stumps are seen *(arrows)*. The DeBakey forceps points to the S1 and S2 sacral plexus nerve roots. (S3 has been divided.)

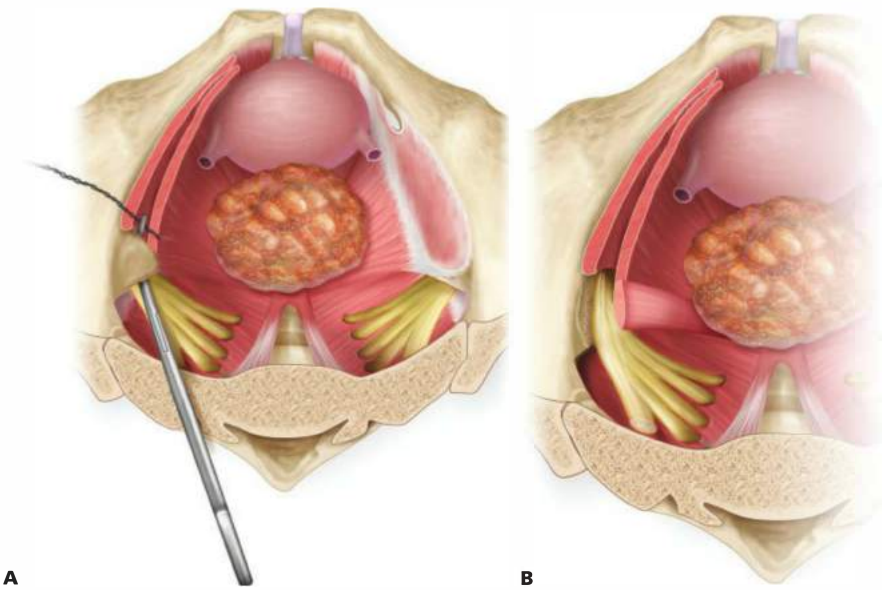

FIG 9 ● **A.** Curved large right-angle forceps passed around ischial spine in preparation to its excision. The end of a Gigli saw is grasped and pulled through. The sciatic nerve under the saw is protected by a malleable retractor while the ischial spine is being divided. **B.** View of the pelvic sidewall after ischial spine has been excised. This exposes the entire intrapelvic course of the sciatic nerve.

form the sciatic nerve, which exits the pelvis by coursing posterior to the ischial spine via the greater sciatic notch.

- Identification of the lumbosacral trunk is an important step as this ensures the nerve is preserved for lower limb function and serves as an anatomic gatekeeper that helps guide the operator to the obturator internus muscle and ischial spine.
- Continued lateral dissection staying within the extravascular plane (*plane M*) will stay medial to the obturator internus muscle within the lateral compartment. While dissecting in *plane M*, numerous small branches and tributaries of the internal iliac vessels will be encountered that will need to be individually ligated to ensure hemostasis is secure. Continued dissection within *plane M* will lead to the origin of the levator ani, which can then be divided to enter the perineal compartment (**FIG 2B**).
- For complete excision of the lateral compartment (*plane N*), the lumbosacral trunk is traced distally to the obturator internus muscle and ischial spine. The entire obturator internus muscle can be excised by detaching it at its origin from the medial aspect of the pelvis (pubic bone) using diathermy. The ischial spine may also be excised en bloc to gain wider exposure. To do this, a large curved right-angle forceps is passed from the posterior to anterior around ischial spine (**FIG 9A**). The free end of a Gigli saw is pulled through. Using a malleable retractor to protect the sciatic nerve, which is immediately deep to the ischial spine, the Gigli saw may be used to saw off the spine at its origin from the remainder of ischium (**FIG 9B**). The combination of dividing the ischial spine and the obturator internus exposed the entire pregluteal, pelvic course of the sciatic nerve (**FIG 8**) and releases the sacrospinous ligament exposing the sacrotuberous ligament.
- For wider excision of the medial wall of the ischium or of the ischial tuberosity (**FIG 2B**, *plane O*), the origin of the obturator internus is mobilized as described earlier. The perineal surgeon commences perineal dissection to gain wide exposure of the perineal aspect of inferior pubic ramus, leading to ischial tuberosity. Soft tissue attachments (origin of adductor magnus and semimembranosus muscles) are mobilized from the inferolateral aspect of ischial tuberosity, which then allows the ischial tuberosity to be excised using either an electric or Gigli saw while protecting the sciatic nerve using a malleable retractor. In some cases, the ischium can be removed through an abdominolithotomy approach.

Anterior Compartment Dissection

- The anterior plane of dissection for complete exenteration or partial exenteration involving the anterior compartment is depicted by *planes A* and *B* in **FIG 2A**.
- To dissect *plane B*, the peritoneum overlying the bladder is incised to enter the retropubic space of Retzius (**FIG 10A**). This incision continues laterally to open the endopelvic fascia. This is largely a bloodless plane, although anterolaterally, the superior vesical pedicle, vas deferens in a male patient, and the inferior vesicle pedicle will be encountered, which will require suture ligation. Laterally, the obturator neurovascular bundle will be seen and obturator lymphadenectomy is also performed with preservation of the obturator nerve.
- Anteriorly, the dorsal venous complex is the next to be encountered which will require suture ligation (**FIG 10B**). Division of the dorsal venous complex will allow the bladder to be reflected more posteriorly.

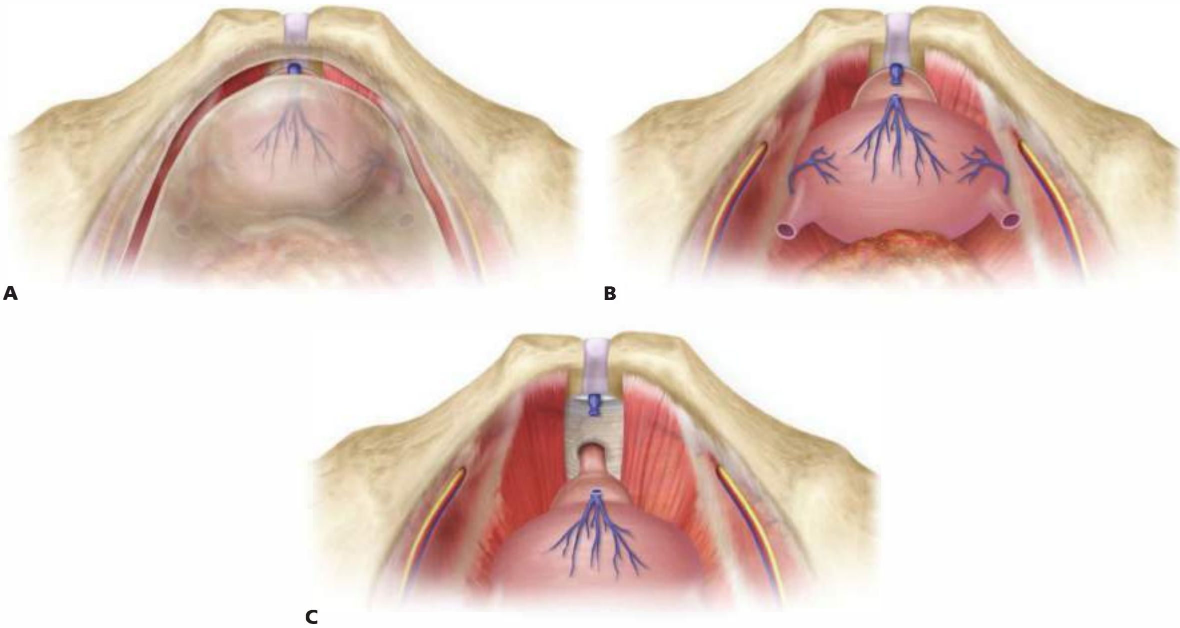

FIG 10 ● **A.** Anterior dissection plane for complete exenteration or partial exenteration involving the anterior compartment. This step involves incising the peritoneum over the bladder anteriorly. This enters the space of Retzius and is largely bloodless. However, the superior and inferior vesical pedicles and vas deferens (in men) will need to be ligated and divided. Laterally, the endopelvic fascia is also released. **B.** The dorsal venous complex has been ligated, which allows the bladder to be mobilized further. In males, this exposes the prostate. **C.** Continued mobilization of the anterior plane exposes the urethra as it exits the prostate. The presence of urethra can be confirmed by palpating the indwelling urinary catheter.

- In a male patient, the prostate will be encountered next (**FIG 10C**). Further mobilization of the prostate from the pelvic floor will lead to the urethra as it exits the prostate and traverses the urogenital diaphragm to become the penile urethra (**FIG 10C**). Presence of the urethra can be confirmed by palpation of the indwelling urinary catheter.
- The urethra is first partially incised to allow the catheter to be completely divided and removed before completely transecting the urethra and suture ligating the distal end of urethra. This completes the abdominal dissection in *plane B*.
- If restoring intestinal continuity is not possible, the perineal surgeon then begins dissection from the perineum to join the abdominal dissection similar to an abdominoperineal excision. In LRRC, if the tumor invades the prostate or membranous urethra (e.g., after previous abdominoperineal excision), then the urethra can be transected more distally from the perineal approach often with a cuff of pubic bone (see the following text).
- Dissection in *plane A* involves the first step in anterior plane mobilization, which is incision of the peritoneum overlying the bladder to enter the retropubic space of Retzius immediately deep to pubic symphysis and superior pubic rami. This incision is extended laterally to incise the endopelvic fascia. Mobilization of the bladder and ligation of the superior and inferior vesical vessels and the vas deferens (in a male patient) as described earlier are also carried out but ligation of the dorsal venous complex is not performed.
- In order to perform en bloc pubic excision, the pubic symphysis and pubic ramus will need to be defined and widely exposed both from the abdominal as well as perineal compartments. Thus, once the abdominal surgeon enters the retropubic space of Retzius, the perineal surgeon commences perineal dissection working toward defining the pubic symphysis, inferior pubic ramus up to the ischial tuberosity widely (**FIG 11**).

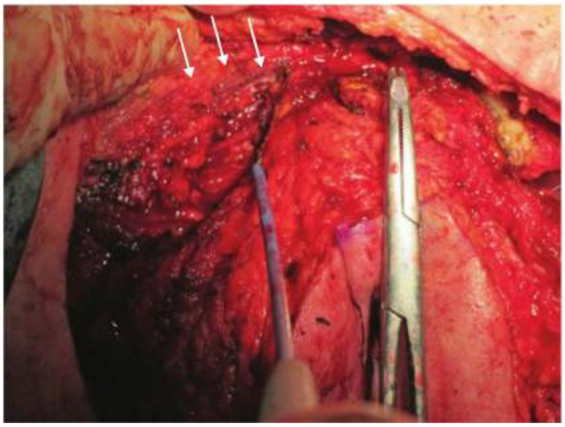

FIG 11 ● Perineal dissection with wide exposure of the pubic symphysis, inferior pubic ramus, and ischial tuberosity in preparation for en bloc pubic bone excision. The inferior pubic ramus bony edge is illustrated by the *arrows*.

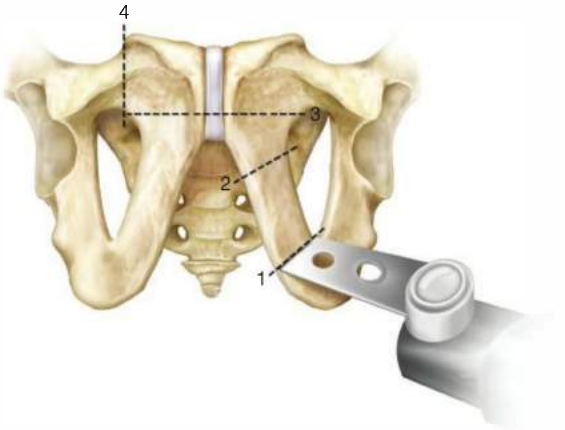

FIG 12 ● Diagram of the bony pelvis with *lines 1* to *4* demonstrating possible excision planes. Dividing pubic bones between *lines 1* and *2* will resect the inferior pubic ramus; between *lines 2* and *3* will cause central partial pubic excision; between *lines 2* and *4* bilaterally will result in central pubic excision.

- The anterior levator plane is not excised but is also defined widely. The origins of the adductor and gracilis muscles as well as the obturator fascia deep to the adductors are divided to expose the anteroinferior surface of the inferior pubic ramus. Depending on the site of tumor involvement, different extent of bony resections can be performed ranging from unilateral or bilateral pubic ramus excision (**FIG 12**, *lines 1* and *2*), partial pubic symphysis excision (**FIG 12**, *lines 2* and *3*), or central pubic excision (**FIG 12**, *line 2* and *4*) using either a Gigli saw or a handheld electric saw (**FIGS 13** and **14**).
- Internal fixation following pubic symphysis excision is generally not required even when it has been completely excised. Mesh reconstruction using polypropylene mesh to the cut ends of all four pubic rami and flap closure is usually all that is required.

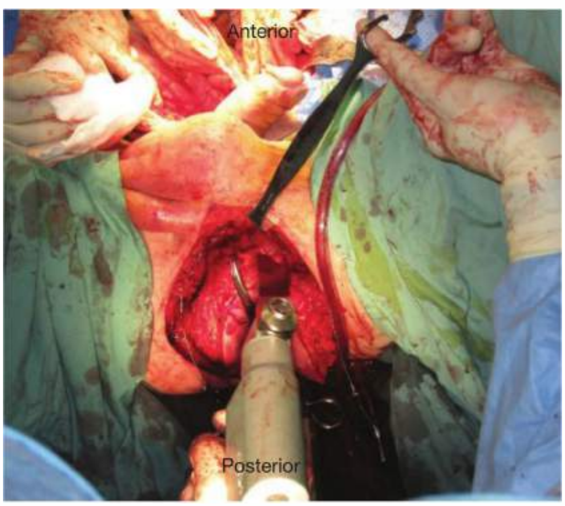

FIG 13 ● A handheld oscillating saw being used to divide the inferior pubic ramus.

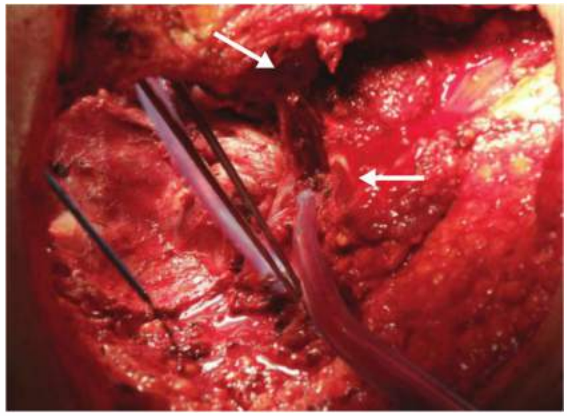

FIG 14 ● This patient has had en bloc excision of the left inferior pubic ramus. The picture demonstrates an oblique caudal to cephalad view into the pelvis. The divided ends of the pubic ramus can be seen in the photo *(block arrows)*.

- *Plane C* is the anterior dissection plane for a partial exenteration not involving the anterior compartment. Dissecting in this plane is dissecting in the vesicovaginal plane for en bloc radical hysterectomy and bilateral salpingo-oophorectomy.
- The procedure begins by grasping each uterine cornu for retraction (**FIG 15**). Gonadal vessels are ligated at the level of pelvic brim and the broad ligament is incised with ligation of the round ligament. The peritoneum between the uterus and bladder is incised (**FIG 15**) to permit placement of a lipped St. Mark's retractor to maintain retraction of the bladder anteriorly.
- Bilateral ureterolysis should be performed in order to mobilize the ureters from the lateral aspects of lower uterus and cervix to prevent inadvertent injury.
- Whether or not an en bloc hysterectomy is required depends on whether or not the uterus is involved more proximally.
- Whether a total vaginectomy or subtotal vaginectomy is required depends on the location of the cancer. When only posterior vaginectomy is required, dissection is carried out in *plane D*. Using a swab-on stick or a vaginal retractor is useful so that the operator is able to confidently incise the posterior wall of vagina without damaging the anterior wall.
- Vaginal reconstruction can be achieved using the skin paddle from a rectus abdominis myocutaneous flap to reconstruct the posterior and lateral walls of vagina.
- Note that *planes C* and *D* do not exist in men.

Posterior Compartment Dissection

- *Plane E* is the anterior dissection plane for a partial exenteration involving the central and posterior compartments or the posterior dissection plane for a partial exenteration involving the central and anterior compartments. This is also a plane familiar to all colorectal surgeons and is the anterior mesorectal plane.

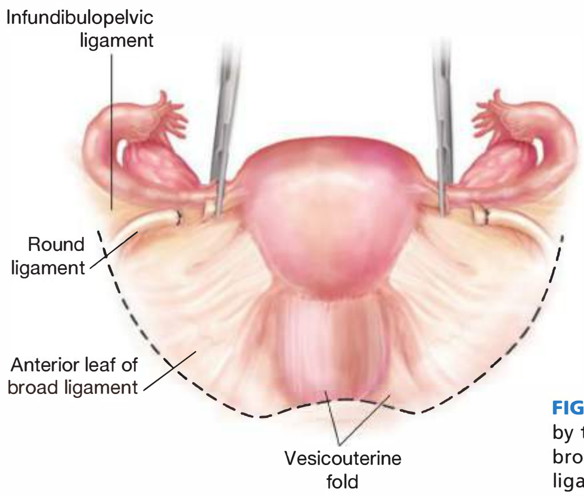

FIG 15 ● Uterine dissection. Two Kocher forceps grasp the uterus by the uterine cornu so as to provide retraction. The base of the broad ligament is incised as shown. The round ligament is also ligated and divided.

- Dissection proceeds in the usual manner using a total mesorectal excision technique with an assistant retracting the uterus and/or the bladder forward using a lipped St. Mark's retractor while the operator provides backward and downward countertraction on the rectum.
- This dissection continues to the pelvic floor. If a low rectal anastomosis is to be fashioned, the rectum is stapled at the level of the pelvic floor, but if an anastomosis is inappropriate, then an abdominoperineal excision can be performed with the abdominal surgeon guiding the perineal surgeon about the point of entry into the pelvis.
- *Plane F* is the surgical plane for a complete exenteration or partial exenteration without sacral involvement. Rectal mobilization begins by incising peritoneum over the left or right mesorectal fold. This plane, which is usually bloodless, is dissected using sharp dissection. Retrograde dissection in this plane joins the mesocolic plane and allows inferior mesenteric artery to be ligated if this is not ligated yet. With an assistant providing traction on the rectum and retracting the rectum forward using a St. Mark's retractor, the surgeon can continue to dissect in this bloodless plane until the coccyx is reached, where Waldeyer's fascia is incised in order to mobilize the rectum down to the pelvic floor.
- When an en bloc sacrectomy is necessary, plane G is the suggested plane of dissection. Depending on the level of sacrectomy (high vs. low), a different surgical approach is needed. Further, sacral resection is usually the last step in the procedure after completion of abdominal (anterior, lateral dissections) and perineal phases.
- A low sacrectomy involving S3, S4 and S5 can usually be performed with the patient in modified Lloyd-Davies position via an abdomino-lithotomy approach whereas a high sacrectomy (excision of S1 or S2) generally requires a prone approach.
- Surgery begins as described earlier with the abdominal phase of dissection. Lateral compartment dissection with vascular ligation and exposure of the lumbosacral trunk so as to preserve lower limb function is performed. The ischial spine may also need to be excised laterally.
- Dissection in the appropriate anterior plane is performed and posterior dissection stops about 2 cm above the site where the tumor is adherent to the sacrum. Overlying S3, S4, and S5 in the midline is the anterior longitudinal ligament, which is often abnormally thickened in patients with LRRC as a result of previous radiotherapy and surgery. Lateral to this at S3 level is piriformis medially and sacral nerve roots laterally. These may also need to be disconnected depending on the level of sacral resection.
- Perineal dissection should also be completed before attempting en bloc distal sacrectomy (see "Perineal Phase"). To perform abdominal sacrectomy, the perineal surgeon will have to extend the posterior dissection to first get to the coccyx. Once the coccyx is defined, the perineal surgeon continues dissection immediately posterior to the coccyx mobilizing the posterior aspect of the coccyx and sacrum from surrounding attachments of gluteus maximus and ligamentous attachments.
- By tunneling to the appropriate level of sacral excision, a malleable retractor or osteotome can then be inserted to protect the natal cleft tissue as the abdominal surgeon performs sacrectomy using a 20-mm osteotome and mallet (**FIG 16**). Once all bony attachments are divided, the specimen can then be delivered from the perineal wound.
- Where a high sacrectomy (excision of S1 and S2) is necessary, abdominal and anterior compartment perineal phases of the operation have to be completed before the patient is turned prone for posterior compartment excision. This includes completion of all aspects of abdominal and perineal procedures such as visceral reconstruction, drain placement, abdominal wound closure and temporary perineal wound closure, harvest of rectus abdominis flap as well as formation of a colostomy.
- To ensure the appropriate sacral segments are excised from a prone approach, an orthopedic pin or staple is secured into the sacrum about 1 to 2 cm above the desired point of transection (11 × 15 mm, Smith & Nephew™ fixation staple). The position of this stapler is checked with an intraoperative x-ray to confirm the point of transection (**FIG 17A**) when commencing the prone approach.

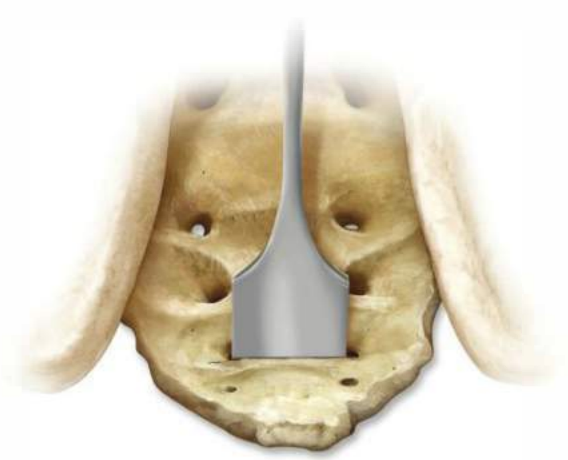

FIG 16 ● Diagram showing how low sacrectomy is performed by using an osteotome and a mallet.

- It is also useful to leave both lumbosacral trunks marked with a yellow vessel loop and to have a suture to orientate a rectus abdominis myocutaneous flap to avoid flap malrotation. Abdominal sponges may also be left just anterior to the sacrum to prevent small bowel from coming into contact with the anterior aspect of sacrum, which may be inadvertently injured as the sacrum is being transected from the prone approach.
- Prone approach to high sacrectomy is usually performed in collaboration with orthopedic surgeons or neurosurgeons and begins with a longitudinal incision in the natal cleft that extends from the posterior aspect of the perineal incision.
- The incision is deepened until the sacrum is reached. Attachments of gluteus maximus are released bilaterally so as to provide access to the sacrum (**FIG 17B**). Deep to gluteus maximus are the sacrococcygeal, sacroiliac, and the sacrotuberous ligaments, which are also released. Dividing these soft tissue attachments frees the lateral borders of the sacrum. Deep to the sacrotuberous ligament is the sacrospinous ligament, which is divided exposing the underlying piriformis muscles. Immediately deep to

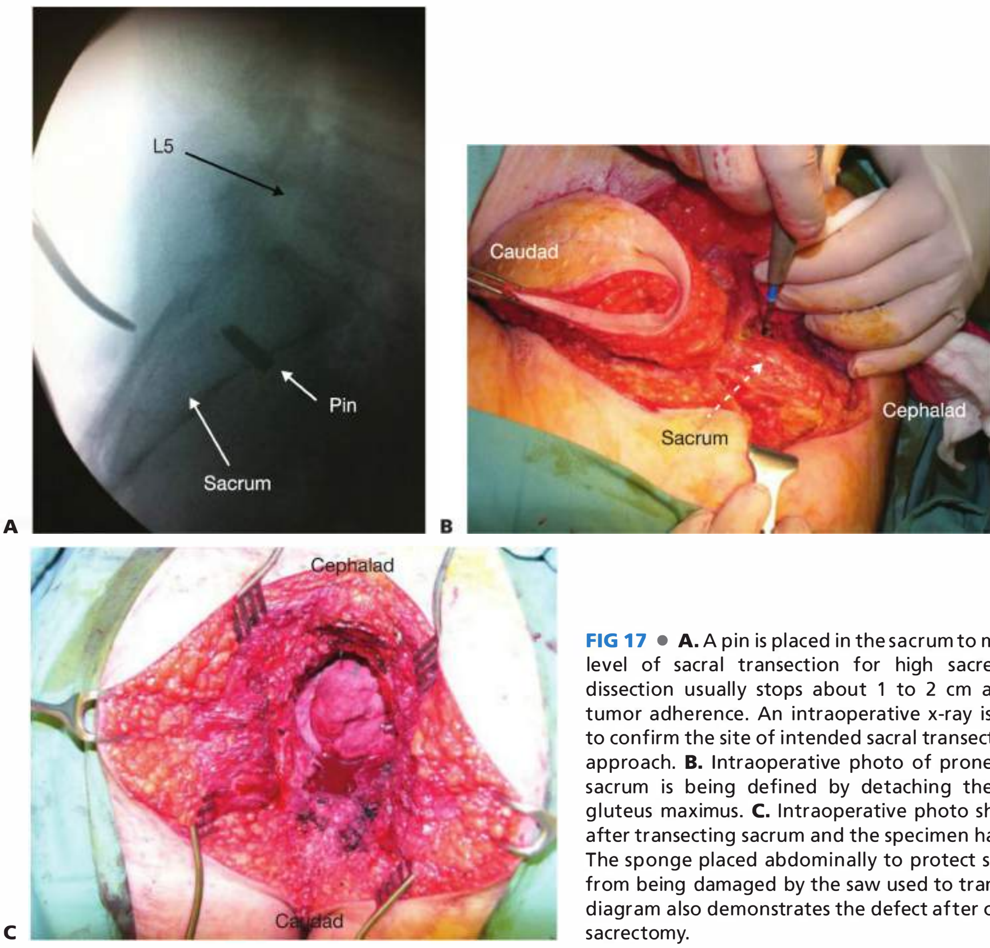

FIG 17 ● **A.** A pin is placed in the sacrum to mark the intended level of sacral transection for high sacrectomy. Posterior dissection usually stops about 1 to 2 cm above the site of tumor adherence. An intraoperative x-ray is then performed to confirm the site of intended sacral transection from a prone approach. **B.** Intraoperative photo of prone sacrectomy. The sacrum is being defined by detaching the attachments of gluteus maximus. **C.** Intraoperative photo showing the result after transecting sacrum and the specimen has been retrieved. The sponge placed abdominally to protect small bowel loops from being damaged by the saw used to transect sacrum. This diagram also demonstrates the defect after completing a high sacrectomy.

piriformis are the sacral nerve roots. It is imperative that the operator remains close to the lateral border of the sacrum to avoid any injury to these nerve roots.

- The level of transection is confirmed by a cross-table x-ray to check the position of the pelvic staple placed above the tumor (**FIG 17A**). This enables the sacrum to be transected with the staple in situ so as to ensure adequate bony margins.
- Once the level is determined, the sacral crest between the median and intermediate sacral crest is resected to expose the dural sac, which is ligated to prevent ongoing leakage of cerebrospinal fluid.
- Sacrectomy is then completed by using a handheld oscillating saw. The specimen is removed, exposing the abdominal pack protecting small bowel loops (**FIG 17C**). Hemostasis is secured; bone wax may be necessary to stop bleeding from exposed cancellous sacrum. The vessel loops around lumbosacral trunks should be intact and need to be removed. The preinserted abdominal drain needs to be repositioned and the preorientated rectus abdominis flap can then be retrieved and secured in place.

Perineal Phase

- The perineal phase is carried out with the patient in wide lithotomy position. This phase is usually only commenced when abdominal dissection is near completion.
- The extent of perineal excision required depends on the location of the cancer. The wider the perineal excision, the more likely the patient is to require closure using a pedicled myocutaneous flap to avoid tension closure, which will only predispose to perineal wound breakdown and prolonged healing due to previous irradiation.
- An elliptical skin incision is made. Using Lone Star retractor, the incision is deepened into ischiorectal fossa fat. Depending on the planned dissection plane from the abdominal compartment, the incision is deepened to approximate the dissection plane from the abdominal compartment. Wide excision of levator muscle is usually performed even if the amount of perineal skin excised does not have to be excessive.
- When en bloc distal sacrectomy is required, the perineal surgeon continues dissecting immediately posterior to the coccyx to the proposed level of sacrectomy, detaching gluteus maximus from the lateral and posterior aspects of coccyx and lower sacrum. A malleable retractor blade or second osteotome is then placed into the space to protect natal cleft soft tissue which the abdominal surgeon divides the sacrum using an osteotome and mallet.
- When a proximal sacrectomy is required, the perineal wound is temporarily closed so that the patient can be turned prone for the posterior dissection.

Urinary Reconstruction

- When an en bloc cystectomy is required, reconstruction using ileal or colonic conduit is usually performed. The decision for an ileal or colonic conduit is surgeon dependent and although ileal conduits are usually preferable in the urologic literature, in patients with LRRC where pelvic small bowel loops may have been previously irradiated, isolating a segment of ileum may be associated with increased risk of postoperative complications including anastomotic leak from the ureteroileal anastomosis and the ileoileal anastomosis.
- A colonic conduit is usually out of the radiation field and a study from our institution found a higher leak rate with ileal conduits as opposed to colonic conduits. Further, to minimize the risk of ileoileal anastomotic leaks, the segment of ileum isolated should be such that the subsequent ileoileal anastomosis is at least 10 to 15 cm away from the ileocecal valve so that it is away from the back pressure exerted by the valve.
- The use of orthotopic neobladder reconstruction is popular within the gynecologic oncology literature but few, if any, are considering the technique in LARC or LRRC.
- When en bloc partial cystectomy is required, double-layered suture repair of the bladder in conjunction with leaving the indwelling urinary catheter in situ for a minimum of 7 days with a check cystography prior to catheter removal is usually sufficient.
- When a segment of ureter is involved unilaterally, depending on the extent of ureteric excision and preexisting renal function in the kidney involved, the options are to consider a ureteric reimplantation with a psoas hitch, reimplanting the resected ureter to the contralateral ureter, or if renal preserving options are not available, a nephrectomy. Anastomosing the resected ureter to the contralateral ureter is avoided where possible as any anastomotic problem or surgical complication can have repercussions on both kidneys instead of one.
- To perform ureteric reimplantation and psoas hitch, the bladder has to be adequately mobilized bilaterally. Once the bladder is mobilized, a transverse cystostomy is performed. By inserting a finger through the cystostomy, an assessment is made to determine the best position for the ureter to be anastomosed to the bladder without excessive tension. A separate small cystostomy is created and the ureter is pulled through and anastomosed to the bladder using fine absorbable sutures over a ureteric stent. Reinforcing sutures are placed between the bladder and the psoas tendon to avoid traction injury on the newly created ureterovesical anastomosis. The cystostomy is then closed longitudinally in two layers, completing the reconstruction.

Intestinal Reconstruction

- When an ileal conduit is fashioned and when a segment of small bowel is resected en bloc with the main specimen, intestinal continuity needs to be restored, either using a hand-sewn or stapled anastomosis.
- Most patients with LRRC will require an end colostomy.
- Patients with LARC or selected patients with early anastomotic recurrences may be suitable for a colorectal anastomosis provided there are no other contraindications for the anastomosis. Even if a colorectal anastomosis is performed, in view of the complex surgery and previous irradiation, these patients should be at least temporarily defunctionalized with a proximal stoma.

Abdominal and Perineal Closure and Reconstruction

- In patients where a wide perineal excision, high sacrectomy, or complete pelvic exenteration has been performed, consideration needs to be given to flap reconstruction. Although our preference is for rectus abdominis myocutaneous flap, other perforator flaps based on the inferior gluteal artery perforator (I-GAP) or anterior thigh flaps may be necessary when the rectus abdominis is not available due to previous stomas.
- Rectus abdominis on the side where there are no prior stomas is preferable. In our practice, a vertical elliptical skin paddle (used for simplicity and ease of abdominal skin closure) with a maximum diameter of 5 cm is harvested (**FIG 5**) with the underlying anterior sheath and rectus abdominis muscle but leaving the posterior sheath intact. We avoid excessively wide skin paddles as this may introduce donor site morbidity with difficult abdominal skin closure and tension on stomas.
- The flap can then be rotated into the pelvis after harvesting. There are two possible ways of rotating the flap. The first is to rotate the flap with the pedicle acting as a pivot and the second is to roll the flap downward like a "Swiss roll."
- After harvesting the flap, it is important to raise skin flaps either on the ipsilateral side alone or bilaterally (if there are no existing stomas) prior to fashioning stomas. Broad-based skin flaps are raised on the external oblique with hemostasis of perforators as they penetrate the anterior abdominal wall to supply the overlying skin.
- Prior to abdominal and perineal wound closure, a thorough lavage of the abdomen, pelvis, and perineal wound is carried out. Hemostasis is checked to ensure there is no active bleeding. Minor oozing is not uncommon but should be controlled with electrocautery, clips, or sutures where possible. Ongoing oozing may require topical hemostatic agents such as Gelfoam®, Surgicel®, or Nu-knit®. At least one large-bore drain is placed in the pelvis, making sure that it drains the most dependent part of the pelvis.
- The myocutaneous flap is usually secured in the perineum using a combination of absorbable dermal and nonabsorbable skin sutures.
- When myocutaneous flaps are not required, the perineal wound is closed in layers. Due to wide excision of levator ani, muscle closure is generally not possible and closure is generally that of subcutaneous fat and skin using a braided suture such as Vicryl.
- There has been an increasing interest in prophylactic mesh repairs of the perineal wound to prevent subsequent perineal hernias. Currently, the safest and cost-effective method remains unclear, with some authors reporting the use of flaps and others the use of biologic mesh. Considering the high prevalence of postoperative pelvic septic complications and low prevalence of perineal hernias in our practice, we have not found prophylactic perineal mesh repair beneficial.
- Abdominal closure when a rectus abdominis flap is not required is relatively straightforward using mass closure with either a no. 1 polydioxanone (PDS) suture or nylon suture. However, when a rectus abdominis flap has been harvested, the abdominal wall will require mesh reconstruction to prevent a future incisional hernia. In these patients, closure of the posterior sheath on the ipsilateral side of harvest to full thickness of the abdominal wall on the contralateral side is performed using no. 1 PDS suture. It is important to remain mindful of the inferior aspect of the midline laparotomy wound where closure should be loose to prevent strangulating the arterial supply or impeding venous drainage of the flap particularly when edema sets in after surgery.
- An onlay mesh repair using polypropylene mesh is then carried out to reinforce the abdominal wall, securing it to the linea semilunaris laterally and the linea alba in the midline wound using 2.0 Prolene suture (**FIG 18**). A drain is also placed to prevent wound seromas.
- Abdominal skin closure is performed using a combination of skin staples and nonabsorbable interrupted vertical mattress sutures.

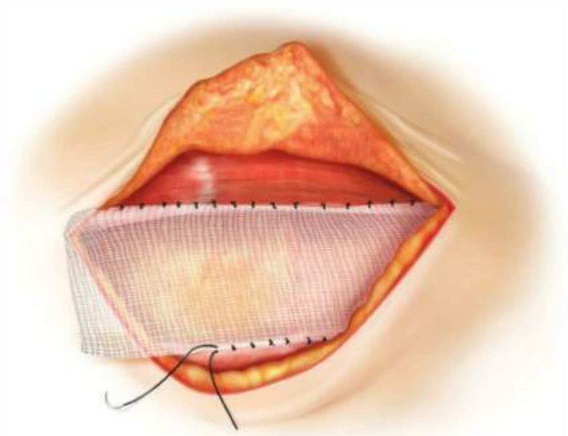

FIG 18 ● Abdominal wall reconstruction using polypropylene mesh.

PEARLS AND PITFALLS

Intraoperative surgical management	■ Meticulous adhesiolysis to avoid inadvertent enterotomies will prevent future complications. A trial of dissection is permissible but if the tissue is very adherent, consideration should be given to en bloc excision of that structure to avoid an involved surgical margin.
Lateral compartment dissection	■ The pelvic sidewall is organized in a "layered" structure. The layers are the ureter, the iliac arteries, the iliac veins, the lumbosacral trunk, and pelvic sidewall muscles.

Meticulous venous dissection	■ Although highly variable, there is an underlying pattern to venous drainage. ■ Usually, there is at least one spinal, gluteal, and visceral tributary entering the main trunk of internal iliac vein at each level. ■ Dissection of each tributary such that there is an adequate cuff before ligation of each tributary is advisable to prevent ties from slipping due to a short cuff. ■ Suture ligation is preferred over clips as it is not unusual for clips to slip or be inadvertently dislodged. ■ When suture ligation fails to control bleeding, adjacent muscle tissue can be used as a pledget and provides additional bulk for providing direct pressure for hemostasis.
Visceral reconstruction	■ In patients with LRRC, heavily irradiated small bowel loops are poor candidates for ureteroileal or ileoileal anastomosis. In these patients, a colonic conduit may be considered as the colon is typically beyond the irradiation field. ■ Mixed colostomies (combined urine and stool stomas) are not routinely advised.
Perineal reconstruction	■ Most recurrences do not require wide perineal excision. However, in patients with wide perineal excision and/or with a sacrectomy, a rectus abdominis myocutaneous flap reconstruction provides well-vascularized tissue in the pelvis to fill the "dead space" and to additional skin paddle to facilitate tension-free skin closure. ■ Alternatively, a pedicled omental flap is also very useful to fill the space within the pelvis to prevent infected fluid collections.
Postoperative management	■ Prolonged ileus is common. Early commencement of total parenteral nutrition should be considered. ■ In view of high complication rates, a high index of clinical suspicion is required for early recognition and treatment to prevent further morbidity.

POSTOPERATIVE CARE

- All exenteration patients are routinely admitted to an intensive care unit for postoperative care. The patient is often left intubated overnight.
- Aggressive fluid and blood product replacement and correction of coagulopathy is often required after a complete exenteration with en bloc sacral resection.
- Prolonged ileus is common; early initiation of total parenteral nutrition is recommended.
- Mechanical venous thromboprophylaxis is vital.
- Patients who have had a flap reconstruction are usually required to rest in bed for the first 5 to 7 days after surgery. It is important that these patients are turned regularly to minimize pressure on their flaps. Flap observations should also be performed regularly to ensure the flap remains well perfused.
- In patients with a urinary conduit, it is imperative to ensure that the patient is well hydrated to maintain a good urine output. Regular drain fluid creatinine check (1 to 2 days) also helps to detect urinary leaks early so that intervention can be readily instituted to avoid further morbidity.
- Septic complications are also particularly common in this group of patients; thus, it is common to continue prophylactic antibiotics for 5 days after surgery. Most causes of sepsis originate from urinary sepsis, infected abdominal or pelvic collections, and hospital-acquired pneumonia. Early mobilization and chest physiotherapy are helpful.
- Infected pelvic collections are common and are usually diagnosed on CT performed for persistent fevers with no obvious source. One of the challenges with interpreting CT scans after such surgery is distinguishing between infected and noninfected fluid collections as postoperative fluid collections are also very common. Postoperative inflammatory changes also take a longer time to dissipate; hence, interpretation of the CT by an experienced radiologist in conjunction with the surgeon is helpful. Keeping an abdominal drain in situ for a longer period of time may allow the drain to be rewired for abdominal drain replacement as opposed to a transgluteal approach for drain insertion, which is usually uncomfortable.
- In patients who have undergone a high sacrectomy, early documentation of neurologic deficit in lower limbs is helpful before swelling of nerves. Neuropathic pain in this group of patients is common and early input from the acute and chronic pain teams with early consideration for gabapentin may be helpful to facilitate pain management.
- Most patients will require ongoing input from dietitians, stomal therapists, and psychooncologists. Further, most patients will require a period of inpatient rehabilitation at a rehabilitation center. Thus, early involvement of all allied health specialists is important. As follow-up plans are often complex, clear written instructions and contact persons should be provided.

OUTCOMES

- The main aim of surgery is to achieve a clear resection margin (R0) as this is the single most important predictor of long-term survival.
- R0 rates within the literature vary between 38% and 85%. In as much as R0 is the most important surgical outcome, R0 is by no means an accurate reflection of a recurrent cancer unit's experience and performance because, as alluded to early in the chapter, different units have different resectability criteria. Without an understanding of the types of exenterations offered, units performing only limited exenterations on patients with good prognostic features may be seen to outperform higher volume and more established units.

Table 1: Complications from Pelvic Exenteration

Septic complications
- Urinary tract infection
- Wound infection
- Pneumonia
- Deep-seated intraabdominal/pelvic collections
- Osteomyelitis

Gastrointestinal complications
- Prolonged ileus
- Small bowel obstruction
- Enterocutaneous fistula
- Anastomotic leak
- Colovaginal fistula

Cardiorespiratory complications
- Atrial fibrillation or other cardiac arrhythmias
- Myocardial infarction
- Pulmonary embolism (deep venous thrombosis)

Wound complications
- Wound dehiscence
- Persistent perineal sinus
- Perineal flap necrosis
- Infected prosthetic mesh
- Hematomas

Urologic
- Urinary retention
- Urologic leak
- Colovesical fistula

Neurologic
- Sciatic nerve palsy

Stomal complications
- Stomal dehiscence
- Ischemia

- Pelvic sidewall recurrence was traditionally considered a formidable challenge because of the difficult dissection, risk of major bleeding, and concerns for involved surgical resection margins, and, therefore, often considered incurable. However, with improved surgical techniques, pelvic sidewall as a site of recurrence is no longer considered a contraindication for surgery and provided clear margins can be obtained, comparable survival with recurrence at other sites can be achieved.
- Quality of life in patients following pelvic exenteration is an area that remains understudied. Although much remains unknown, it is known that quality of life following exenteration is comparable to that of patients after total mesorectal excision for primary rectal cancer.

COMPLICATIONS

- Reported mortality rates range between 0.3% and 8%, although larger series in recent years have tended to report mortality rates of less than 1%.
- Published complication rates range from 21% to 72%, with major complication rates within contemporary literature originating from high-volume centers at about 25%.
- Common complications published are listed in Table 1.

Chapter 40

Transanal Excision of Rectal Tumors

Ryan M. Thomas *Barry Feig*

DEFINITION

- Transanal excision (TAE) of rectal tumors refers to the complete resection of a benign or malignant neoplasm of the distal rectum such that negative surgical margins are achieved while avoiding the morbidity of transabdominal resection procedures.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Not all patients are candidates for TAE of rectal tumors and many factors may prove to be a contraindication to such treatment. The surgeon must take into account physiologic, anatomic, and pathologic factors in order to deem a patient an appropriate candidate for TAE of a benign or malignant rectal tumor (Table 1).
- A full history must be performed with special focus on any changes in bowel habits including stool caliber, the presence of melena or hematochezia, personal or family history of colorectal cancer, and the use of any antiplatelet or anticoagulant medications in preparation for surgical excision.
- Physiologic factors and patient desires may make TAE a viable option, namely in patients who physiologically cannot tolerate an extensive transabdominal resection or have a short life expectancy because of metastatic disease yet have a bleeding tumor in need of palliation. In addition, some patients may not desire an abdominoperineal resection and resultant permanent colostomy or the possibility of sexual dysfunction. Given appropriate physical and pathologic criteria, these patients may be appropriate candidates for TAE as well.
- A thorough physical examination must be performed with special focus on rectal tone, location of the rectal tumor, distance of the tumor from the anal verge, and mobility/fixation of the tumor to underlying structures. These physical factors are critical to determine the feasibility of resection as the criteria for resection demands that the lesion:
  - Be within 8 to 10 cm of the anal verge in order to technically reach the lesion
  - Must be mobile and not fixed to underlying tissue
  - Must involve less than 30% of the circumference of the rectal wall on endoscopic evaluation, as anything greater risks nodal involvement or narrowing the rectal lumen after excision is performed.
- Often, patients are referred for TAE of a rectal tumor after having undergone endoscopic evaluation that diagnosed a malignant mass or a benign mass not amenable to endoscopic resection.
- Established pathologic criteria for TAE of a malignant lesion include T1 lesions, no evidence of lymphovascular invasion (LVI) or perineural invasion (PNI), moderately to well-differentiated tumors, or an endoscopically removed polyp with indeterminate pathology.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Endoscopy plays an essential role in the management of mid- to low rectal lesions in patients who may be candidates for TAE. Endoscopy defines the anatomy of the lesion and special attention should be made to the anatomic location, as this will affect surgical positioning. The tumor diameter, location from the anal verge, and degree of circumferential involvement are noted as they dictate the appropriateness of TAE as well.
- Assuming that a malignant lesion is technically resectable via a transanal approach, one must ensure that the lesion is a T1 stage and without nodal involvement. The transanal approach for rectal tumors has garnered support because of the decreased morbidity compared with a transabdominal approach but lymph node metastasis has been reported in 10% to 18% of T1 lesions.
- Imaging therefore plays an essential role in the preoperative planning for patients considered candidates for TAE of rectal tumors. In the case of malignancy, staging imaging should include the following:
  - A chest x-ray and computed tomography (CT) of the abdomen and pelvis to assess for metastatic disease
  - Critical to the determination of the local resectability of a rectal lesion is the assessment of the T stage and N stage of the tumor. The accuracy of determining the depth of invasion by CT scan, magnetic resonance imaging (MRI), and endoscopic rectal ultrasound (ERUS) is 73%, 82%, and 87%, respectively. Nodal metastases are accurately assessed by CT scan, MRI, and ERUS in 66%, 74%, and 74% of cases, respectively. The use of endorectal coils during MRI has been found to be equivalent to ERUS for T stage determination but superior in terms of nodal status.

Table 1: Criteria for Transanal Excision of Rectal Tumors

Patient Factors	Anatomic Factors	Pathologic Factors
• Comorbidities that preclude transabdominal resection • Short life expectancy in need of surgical palliation • Refusal of abdominoperineal resection and resultant permanent colostomy	• Lesion ≤8–10 cm from the anal verge • Lesion involves ≤30% of rectal circumference • Lesion ≤3cm in diameter • Mobile and not fixed to underlying tissue • Negative margins achievable depending on pathology of primary lesion (0.3–1 cm)	• Moderately or well-differentiated tumor • T1 tumor • No lymphovascular or perineural invasion • Indeterminate pathology on polypectomy • No evidence of lymphadenopathy on preoperative imaging

- Any biopsies that are performed of the rectal tumor prior to definitive excision should be re-reviewed to confirm the tumor depth of invasion, differentiation, and the presence of LVI or PNI.

SURGICAL MANAGEMENT

Preoperative Planning

- In most cases, patients should be instructed to discontinue anticoagulation and antiplatelet medications 7 to 10 days prior to the planned procedure if medically feasible.
- A specific bowel preparation does not have to be performed except that the patient should self-administer a sodium phosphate enema the evening prior to the procedure in order to evacuate the rectal vault.

Patient Positioning

- Positioning of the individual depends on the anatomic location of the rectal tumor to be excised, which should be determined on preoperative physical examination and endoscopy.
- Because it is technically easier to visualize and resect rectal tumors when they are located closer to the operating room (OR) table, patients with a rectal tumor along the posterior rectal wall should be positioned in high lithotomy such that their coccyx can be easily palpated (**FIG 1**). In contrast, patients with lesions located along the anterior rectal wall should be placed in the prone jackknife position.
- For patients placed in the prone position, heavy tape should be applied to the buttocks so that they can be retracted laterally and secured to the OR table. A 2-in–wide tape should be used and secured to the buttocks with benzoin ointment to prevent the tape from slipping during the procedure.
- Once in position with pressure points appropriately padded, a digital rectal exam is performed to confirm tumor location and the rectum is irrigated with saline until all solid material has been removed. The perineum is then prepped with Betadine and appropriately draped.

FIG 1 ● Patient positioning. For posterior lesions, the patient is placed on a high lithotomy position. It is important that the coccyx can be palpated, which ensures that they are low enough on the bed and adequate exposure to the lesion can be obtained.

EXPOSURE OF THE LESION

- Because of the limited working area, exposure is key to safe TAE with adequate margins.
- The operating surgeon must have a high-intensity headlight to aid visualization and a long, narrow suction apparatus is helpful for both smoke evacuation and fluid removal.
- The goal of exposure for TAE is to bring the lesion closer to the anus and avoid retractors that tend to push the lesion away. There are several methods and instruments that are available to achieve this goal.
- A Lone Star retractor may be used to help evert the anus and gain better exposure. Alternatively, a series of nylon sutures placed circumferentially in a simple fashion from the internal sphincter to the thigh can achieve a similar result. The use of these techniques is particularly helpful for posterior lesions when the patient is in the lithotomy position.
- For men in the lithotomy position, it may be helpful to secure the scrotum to the inner thigh with a 2-0 silk or other similar suture in order to remove it from the operative field. This is not necessary in the prone jackknife position as gravity provides the necessary retraction.
- A Parks self-retaining retractor, with the option of the additional center blade, is then placed in the anus to provide exposure, with an assistant using an appropriately sized lighted Hill-Ferguson retractor for additional exposure (**FIG 2**). A variety of other self-retaining and handheld retractors may be considered depending on the patient's anatomy.

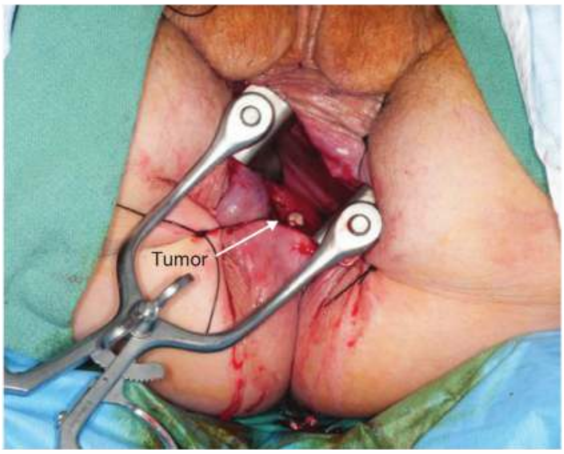

FIG 2 ● Exposure of the lesion. A self-retaining retractor, such as the Parks retractor, is placed into the anus and rectum and gently opened. A Lone Star retractor or a series of 2-0 nylon sutures placed around the periphery of the anus can be used to evert the anal canal and bring the lesion closer to the field prior to placing the Parks retractor. This is especially useful in obese individuals or for lesions that are at the maximum extent of reach (8 to 10 cm from the anal verge).

DEFINING THE SURGICAL MARGIN

- Once the lesion has been identified, electrocautery is used to score the mucosa circumferentially around the mass. This step is critical to define the appropriate margin: 1 cm for malignant lesions and at least 0.3 cm for benign lesions or those with indeterminate pathology on preoperative pathologic evaluation (FIG 3).
- It is important to flatten the surrounding mucosa with the use of the Hill-Ferguson retractor or a flat right-angle (Haney) retractor as the margin is being scored. The back end of DeBakey forceps is especially useful for this purpose as well (FIG 3). Failure to flatten the mucosa may result in a margin that is far greater or lesser than the intended margin because of mucosal folding.

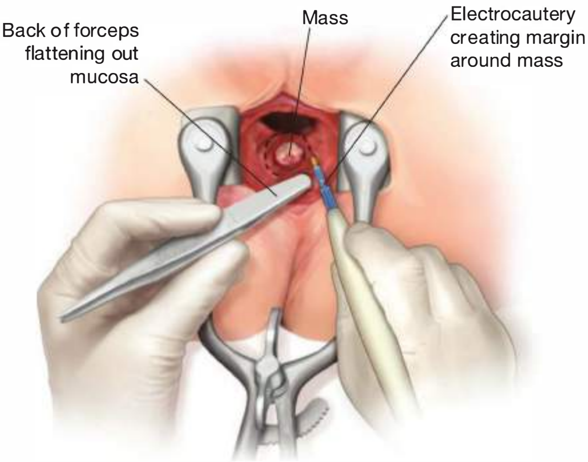

FIG 3 ● Defining the surgical margin. Once adequate exposure is obtained, electrocautery is used to mark out the surgical margin: 1 cm for malignant lesions and 0.3 cm for benign lesions or those of indeterminate pathology. Because mucosal folds can obscure the true margin and lead to a margin that is lesser or greater than intended, using the back of a DeBakey forceps or a handheld retractor such as the Hill-Ferguson retractor can help flatten the mucosal folds so an appropriate margin can be defined.

PLACEMENT OF RETRACTION AND ORIENTATION SUTURES

- For proximal lesions or in patients where visualization is less optimal, a 2-0 Vicryl retraction (stay) suture can be placed at the apex of the surgical specimen outside of the scored margin, tied into place, and used to bring the lesion closer to the operator, if necessary, during resection (FIG 4A).
- Next, sutures should be placed within the outlined margin to serve as orientation sutures once the specimen has been removed. A short proximal suture with one suture end cut and a long left lateral suture leaving both suture ends long avoids confusion and will ensure proper orientation of the specimen should additional margins need to be removed (FIG 4B).

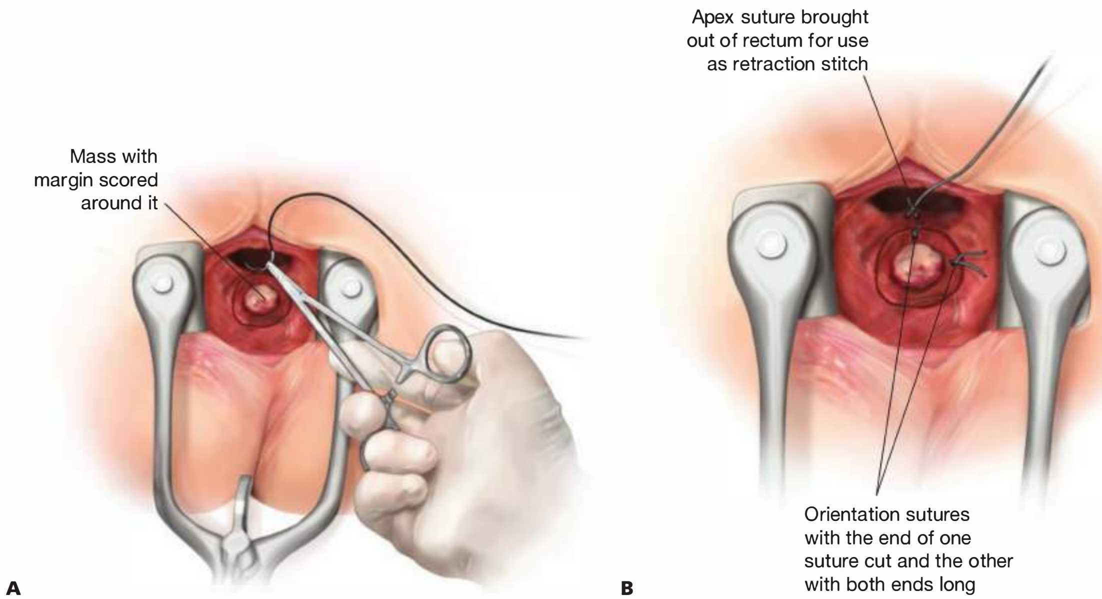

FIG 4 ● Placement of retraction and orientation sutures. **A.** Just outside of the most proximal extent of the surgical margin, a 2-0 Vicryl suture is placed and tied. The suture is left long and is brought out of the rectum and secured to the surgical drapes. This suture can be used during the excision for retraction and to help bring the lesion closer to the operator. **B.** Sutures of different length are then placed within the surgical margin that will serve as orientation sutures. As an example, a single short suture may be used for the proximal margin and a long suture for the left lateral margin. These sutures should be placed early in the case to maintain orientation for pathologic margin assessment.

FULL-THICKNESS EXCISION OF THE MASS

- Using electrocautery, a full-thickness excision of the mass is performed down to the deep perirectal tissue. A long needle-tip electrocautery device can often be helpful in providing access without obstructing visualization. It is easier to begin the dissection distally and work around the margins proximally; this allows for a more apparent identification of the perirectal tissue as it is encountered and helps to guide the rest of the proximal and deep extent of the excision (**FIG 5**).
- Special attention should be taken to create the electrocautery line of excision perpendicular to the rectal wall to avoid undermining the edges of the specimen and compromising the margins.

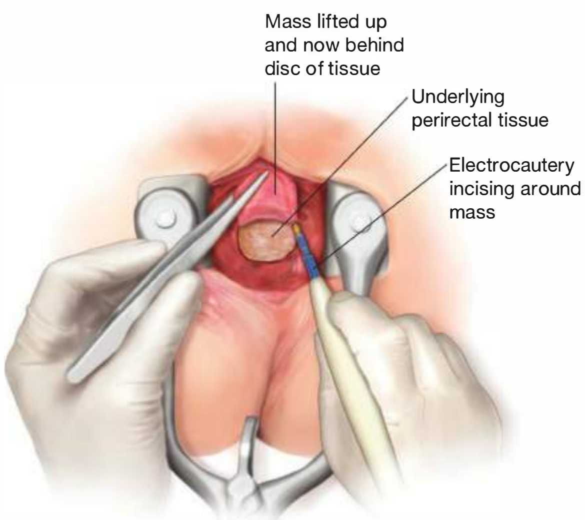

FIG 5 ● Full-thickness excision of the mass. Electrocautery is used to create a full-thickness defect through the rectal wall until the perirectal fat is identified. It is easier to begin at the most distal aspect of the lesion because visualization is better. Once the full-thickness defect is created, the free edge of tissue or a retraction suture is grasped to lift the mass and normal tissue away from the underlying perirectal fat as the excision proceeds proximally along the lateral aspects of the lesion, leaving the most proximal part of excision for last.

- Once the perirectal tissue is encountered, the mass is continually lifted away from this underlying tissue and detached from it using the electrocautery. The goal is to remove a disc of tissue that contains the mass, adequate margins, and a portion of tissue deep to the mass to ensure adequate full-thickness excision and pathologic evaluation. Special attention must be taken during the full-thickness excision of anteriorly located lesions because injury to the vagina or prostate can occur if the excision is carried too deeply.
- As the excision proceeds, gentle traction of the orientation and stay sutures can provide additional tension to facilitate the excision or to bring the tissue closer to the operator.

SUBMITTING THE SPECIMEN TO PATHOLOGY

- An important part of the TAE of a rectal mass is specimen orientation for the pathologist. After the mass has been excised, it should be fixed to a wax board with 22-gauge needles and hand delivered to the pathology suite so that the surgeon can speak directly to the pathologist for specimen orientation and margin assessment (**FIG 6**).
- The margins are inked and assessed. If tumor cells are present at any of the margins, additional tissue must be removed.

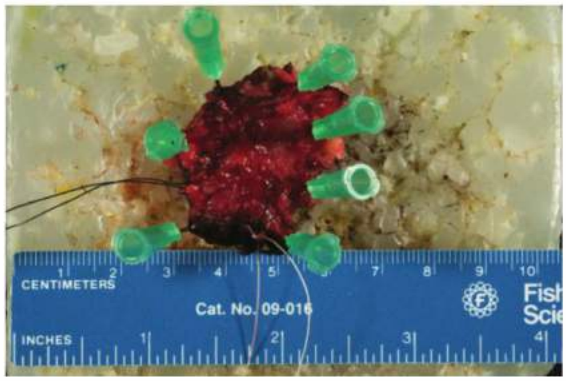

FIG 6 ● Submitting the specimen to pathology. The resected specimen is then secured to a wax board with 22-gauge needles for proper orientation. Because orientation sutures were placed early in the case, there should be no confusion about the specimen orientation. The surgeon then brings the specimen to the pathology suite to confirm orientation with the pathologist and the margins are inked and assessed. If tumor cells are present at any of the margins, additional tissue must be removed.

CLOSURE OF THE RECTAL WALL DEFECT

- Once appropriate hemostasis is obtained and no additional margins need to be taken, attention is turned to the closure of the resultant rectal wall defect (**FIG 7**). Interrupted Vicryl sutures are used to approximate the mucosa and submucosa. The sutures should be slightly spaced to allow for drainage to occur and to prevent hematoma formation (**FIG 8**). If there is difficulty obtaining adequate hemostasis, a running, locking suture can be used.
- The running suture is tied just before the end of the defect is reached, leaving a small opening for drainage to occur.
- Alternatively, the defect may be closed over a ¼-in Penrose drain secured into place with the final pass of the

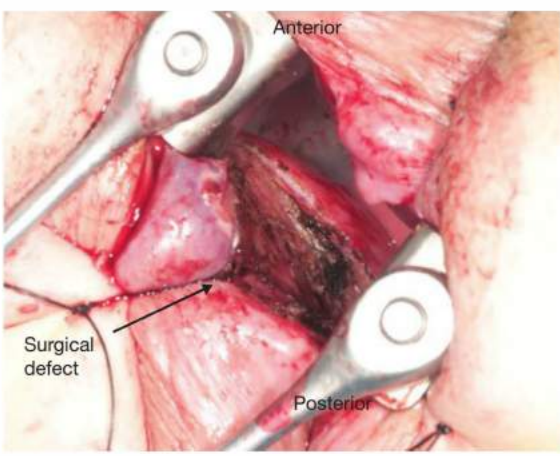

FIG 7 ● Hemostasis of rectal defect. The resultant rectal defect is irrigated and hemostasis is obtained prior to closure.

chromic suture to allow fluid to drain. The patient will eventually pass the drain once the chromic suture has dissolved.

- In the case of a large defect in which there is too much tension to reapproximate the mucosa, the defect may be left open to heal by secondary intention.
- After the defect has been closed, the retractors are removed and a digital rectal exam is performed to confirm patency of the rectum.
- A rolled-up piece of hemostatic agent (Fibrillar, Gelfoam) may be placed into the rectum, overlying the suture line, to provide additional hemostasis.

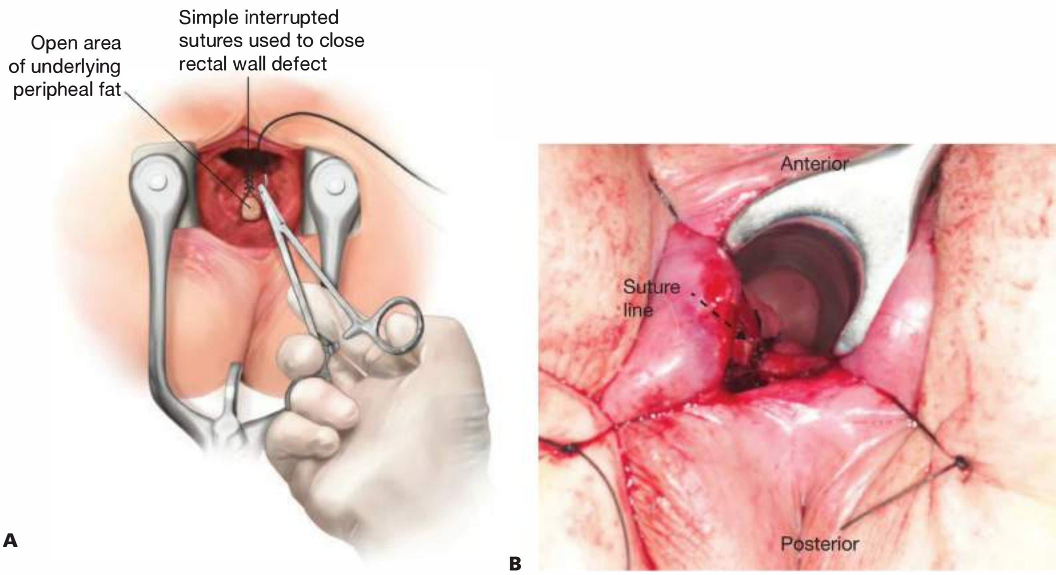

FIG 8 ● Closure of the rectal wall defect. **A.** After appropriate hemostasis is obtained, the rectal wall defect is closed with a 2-0 Vicryl suture. **B.** Beginning at the most proximal aspect of the defect, the full-thickness rectal wall is reapproximated in a running fashion. The sutures are locked to provide better hemostasis and the suture is tied just before the end of the defect is reached, leaving a small opening to allow drainage.

PEARLS AND PITFALLS

Preoperative	■ It is often more difficult to obtain adequate exposure in obese patients because of body habitus. Take extra time retracting the buttocks laterally with tape for prone cases, as well as using a Lone Star retractor to help evert the anus and create better exposure. ■ High recurrence rates occur with lesions greater than T2 or other aggressive pathology (PNI, LVI). Re-review the pathology to ensure the lesion is appropriate for TAE.
Intraoperative	■ Avoid retractors that "push" the lesion away and use sutures if necessary to help bring the lesion more distal. ■ Avoid grasping the typically friable mass but instead use sutures to provide traction. ■ Place marking sutures early so as to not lose the specimen orientation. ■ Full-thickness excision is confirmed by identification of perirectal fat. Pay special attention not to perform a partial thickness excision. ■ Excision of anterior lesions runs the risk of injury to the vagina or prostate. ■ Defects, especially when posterior, may be left open without reapproximating the rectal wall.
Postoperative	■ A consistent and aggressive bowel regimen is most important to prevent suture line disruption and keep the patient comfortable.

POSTOPERATIVE CARE

- Patients usually have minimal, if any, pain immediately after a TAE. Patients may have spasms of the anal sphincter that can be treated symptomatically with muscle relaxants but these are typically self-limited.
- Because of the fresh suture line, it is important that the patient be placed on an aggressive bowel regimen postoperatively to prevent suture line disruption. This should include a combination of stool softeners and fiber bulking agents, as well as mineral oil to lubricate the stool. Using such a bowel regimen will increase the postoperative comfort for the patient as well.

OUTCOMES

- Five-year survival rates after TAE for patients with a T1 rectal cancer without nodal metastasis, LVI, and PNI are comparable to surgical resection and range from 70% to 87% for TAE compared to 80% to 93% for standard surgical resection.
- Local recurrence rates have been shown to be statistically higher when TAE is performed versus standard surgical resection with local recurrence rates of 6% to 12.5% after TAE versus 2% to 7% after standard resection.
- Salvage surgery in the form of a standard resection (low anterior or abdominoperineal resection) can be performed in cases of tumor recurrence after TAE, but R0 resection rates are typically low and survival is poor unless immediate salvage is performed at the time of recurrence diagnosis.
- Treatment of T2 lesions with TAE is still controversial but a recent phase II trial (American College of Surgeons Oncologic Group [ACOSOG] Z6041) treated 90 patients with uT2N0 lesions by ERUS with preoperative chemoradiation followed by local excision. The margin-negative rate was 98%, with 44% of patients having a complete pathologic response. More data is still needed to support the local excision of T2 lesions but may be warranted in patients with multiple comorbidities who are unable to tolerate a large surgical resection.
- TAE for the treatment of T3 lesions is not considered standard of care. There are case reports of successful outcomes using TAE for locally advanced tumors after downstaging with neoadjuvant chemoradiation therapy. Further prospective evaluation is needed to establish patient/pathologic criteria that will predict for successful outcome using TAE in more advanced tumors.

COMPLICATIONS

- Bleeding
- Infection/pelvic sepsis
- Injury to the prostate or vagina for anteriorly located lesions
- Pain (if resection involves the dentate line) or from postoperative scarring
- Stenosis of the anus or rectum
- Incontinence
- Urinary retention

Chapter 41 Transanal Endoscopic Microsurgery

Margaret V. Shields   John H Marks

DEFINITION

- Transanal endoscopic microsurgery (TEM) is a minimally invasive technique that was originally developed by Dr. Gerhard Buess in 1983 to extend transanal access to benign and select malignant tumors. It is used to treat a variety of rectal lesions including benign adenoma, low-risk carcinoma, and more advanced cancers after neoadjuvant therapy.
- This procedure is performed transanally with specially designed microsurgical instrumentation. This surgical approach is both a single-port surgery and a natural orifice transluminal endoscopic surgery (NOTES).
- TEM is preferable over radical resection in select patients due to the ability to safely eradicate the disease with a wide full-thickness local excision while simultaneously sparing the morbidity of a major transabdominal surgery and preserving sphincter function.

DIFFERENTIAL DIAGNOSIS

- Adenomas and other types of polypoid lesions found in the colon and rectum include hyperplastic polyps, serrated adenomas, flat adenomas, hamartomatous polyps, and inflammatory polyps.
- Most colorectal cancers are adenocarcinomas (90% to 96%), but other rare malignancies include signet-ring cell carcinoma, squamous carcinoma, undifferentiated neoplasms, neuroendocrine tumors, gastrointestinal stromal tumors (GISTs), carcinoids, and melanoma.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The TEM procedure is primarily used to treat benign or malignant rectal lesions. In order to determine if TEM is the appropriate procedure for the patient, a full history and physical examination must be performed to evaluate both the general health of the patient and the extent of disease. Patients that are medically compromised may not be able to tolerate a radical procedure, making a local excision the only option.
- Ideal candidates for TEM are patients with early, nonextensive tumors. This procedure can be used for patients in good health and is also a wonderful option for those who are medically compromised, as the approach is less invasive than radical abdominal surgery and extends the transanal approach up to the level of the rectosigmoid.
- The fundamental objectives of rectal cancer management are complete tumor control and patient survival. However, perhaps in no other cancer are quality-of-life issues of such importance as the need for a permanent colostomy hangs in the balance.
- There are several secondary goals that are desirable and must be considered when deciding upon the best treatment option for rectal cancer. These include preserving sphincter function, minimizing patient morbidity and mortality, minimizing patient trauma, maintaining bladder and sexual function, and avoiding a permanent colostomy. The primary goal of cancer control along with the secondary goals can be achieved with TEM surgery under appropriate conditions.
- It is important to inquire about bowel habits, anal sphincter function, bladder and sexual function, past medical history, and past surgical history. It is important to discuss the genetic risk of colon cancer with the patient so that they can inform their relatives to get proper surveillance colonoscopy. Suspicious symptoms include change in bowel habits, rectal bleeding, rectal pain, or mucous discharge.
- A thorough digital rectal exam is the single most important component of the preoperative evaluation for lesions in the bottom half of the rectum. The status of sphincter tone must always be checked as this impacts significantly on treatment decisions.
- We recommend using both flexible sigmoidoscopy and rigid proctoscopy as part of the physical examination. Rigid proctoscopy offers a more accurate localization of the lesion's position, whereas the flexible sigmoidoscope provides a much clearer image of the lesion. The most important tumor characteristics to evaluate are level in the rectum (from the anorectal ring and the anal verge), mobility/fixation, position of mass (midpoint), size of the tumor, circumference involvement, obstruction, ulceration, and the estimation of the clinical stage of disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A full colonoscopy should be performed to assess the remainder of the rectum and the entire colon for potential synchronous lesions.
- In malignancy, a computed tomography (CT) of the chest, abdomen, and pelvis along with serum testing for carcinoembryonic antigen (CEA) are obtained.
- Patients should also get an endoscopic rectal ultrasound (ERUS) to view the depth of invasion of the tumor and to evaluate for lymph node involvement (**FIG 1**). ERUS can predict mesorectal adenopathy (N status) with 70% accuracy and can assess depth of invasion (T status) in early stage rectal cancers with 90% accuracy. The ability to assess lymph node involvement is essential because it could be a cause of locoregional treatment failure.
- Rectal protocol magnetic resonance imaging (MRI) is increasingly used in rectal cancer staging due to its ability to assess, in addition to T and N stages, potential adjacent

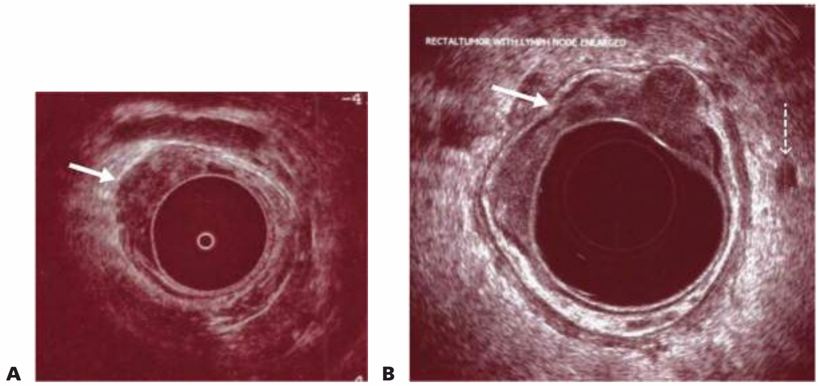

FIG 1 ● ERUS in rectal cancer. **A.** This tumor *(block arrow)* extends into but not beyond the muscularis propria with no evidence of nodal disease (ERUS T2N0). **B.** This tumor extends through the muscularis propria *(block arrow)* and exhibits nodal disease in the mesorectum *(dashed arrow)*. Therefore, it is an ERUS T3N1 tumor.

organ involvement and the relationship with the mesorectal margin (**FIG 2**). However, MRI, like ERUS, is challenged in trying to differentiate between T1 and T2 stages due to the limited resolution in delineating the layers of the rectal wall.

- If the patient has a malignant lesion that is unfavorable (≥T3 or N+) at any level in the rectum or a favorable cancer in the distal one-third of the rectum (0.5 to 6.0 cm above the anorectal ring), neoadjuvant chemoradiation is recommended. Surgical decision making is based on the evaluation of the tumor at 8 to 12 weeks after completion of neoadjuvant chemoradiation in order to maximize the effect of tumor downstaging.

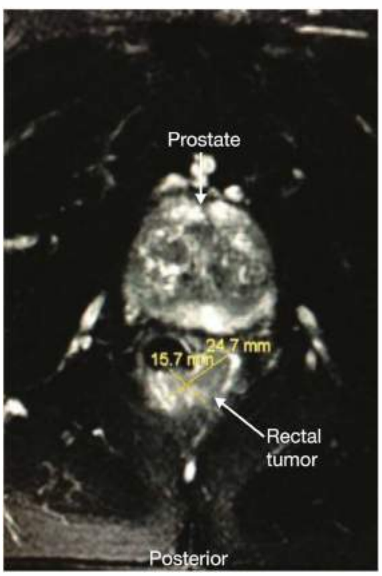

FIG 2 ● Rectal-protocol MRI showing a rectal tumor involving the posterior and lateral rectal walls. There is a clear plane of separation from the prostate anteriorly, ruling out a T4 lesion.

- Table 1 summarizes the ideal TEM candidates as well as the absolute contraindications for TEM. In general, local excision is the preferred option for patients with adenoma, or cancer with favorable features (≤3 cm in diameter; T1, grade I or II, and no venous or lymphatic invasion; and no evidence of lymph node metastasis) after chemoradiation. An ideal patient for local excision has a tumor that is small, mobile, located in the distal rectum, and posteriorly based.
- Contraindications for patients to undergo a TEM procedure after completion of neoadjuvant radiation include lymph node involvement, T3 or greater cancer after neoadjuvant chemoradiation, or tumors that remain fixed, deeply ulcerated, or have adjacent visceral organ involvement. In general, a maximum size of 4 cm is considered the limit for TEM after chemoradiation. Tumors greater than 3 to 4 cm in size can be challenging to excise transanally after neoadjuvant therapy due to the difficulty in closing the large defect that might be greater than one-half the circumference of the rectal wall.

Table 1: Candidates and Contraindications for Transanal Endoscopic Microsurgery and Lymphovascular Invasion

Candidates	Contraindications
Adenomas (and other benign lesions)	After chemoradiation:
Rectal cancer:	• N+
• <3 cm in diameter	• T3 or greater
• T1	• Fixed tumors
• Grade I or II	• Deeply ulcerated
• No LVI	• >4 cm in size
• N0	• >½ of rectal circumference
• Mobile	

LVI, lymphovascular invasion.

SURGICAL MANAGEMENT

Preoperative Planning

- Patient preparation for TEM is the same for benign or malignant lesions.
- The patient will undergo standard bowel preparation.
- Standard preoperative antibiotics are administered.
- It is important to have a conversation with the patient preoperatively to discuss the potential need for laparoscopy or laparotomy and a possible diverting stoma.

Patient Positioning

- The positioning of the patient depends on the tumor location. In general, the patient is positioned so that the tumor is in the dependent position during the procedure.
- The tumor should be at the center of the operating rectoscope throughout the procedure; the bevel of the TEM scope should face down at the tumor. This is essential as the optics reside in the upper portion of the operating proctoscope, limiting the reach of the instruments to the bottom 180 to 210 degrees of the lumen. Therefore, patient positioning becomes very important.
- Patients with posterior lesions are placed in the modified lithotomy position (**FIG 3**). Patients with anterior lesions are placed in the prone position (**FIG 4**). Patients with left or right lateral lesions are placed in the left or right decubitus position, respectfully.

Operating Team Setup

- The surgeon should be in a seated position in between the patient's legs (**FIG 5**). The assistant should be seated to the left of the surgeon. The scrub nurse is to be positioned opposite the endosurgical unit. The monitors are placed in front of the surgeon.

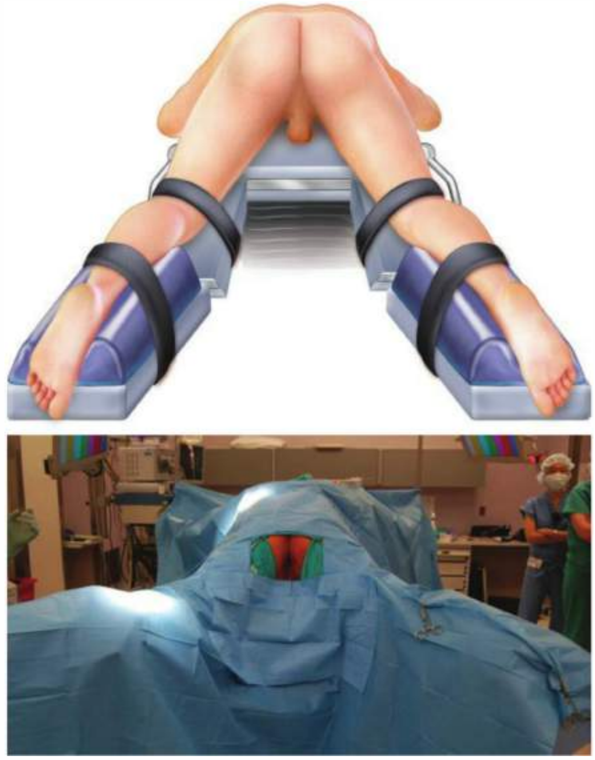

FIG 4 • Prone position: ideal for patients with anteriorly located lesions. The arms are resting without straining on arm boards. The lower extremities are resting on a split-table configuration. The patient is firmly secured to the table position changes during the procedure. All pressure points are padded to prevent nerve and/or vascular injuries.

FIG 3 • Modified lithotomy position: ideal for patients with posteriorly located rectal lesions. The legs are placed on Yellofin or Allen stirrups. The patient is firmly secured to the table to allow table position changes during the procedure. The arms are tucked and all pressure points are padded to prevent nerve and/or vascular injuries.

FIG 5 • Surgical team setup. The surgeon *(1)* is in a seated position in between the patient's legs, with the assistant *(2)* positioned to his or her left side and with the scrub nurse *(3)* positioned to his or her right side. The monitors are placed in front of the surgeon. The operating rectoscope is fixed to the operating table with a Martin arm for stability.

TRANSANAL ENDOSCOPIC MICROSURGERY SETUP

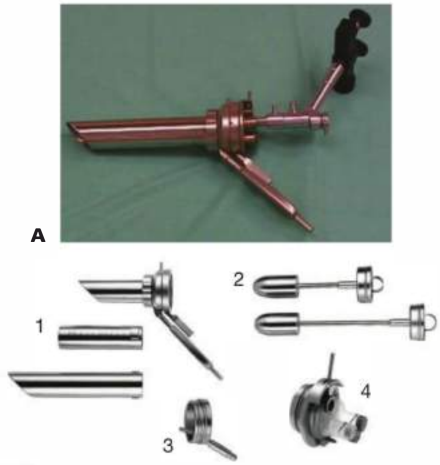
- All of the instruments that we use during the TEM procedure are from the Richard Wolf TEM Instrument System. Some of the instruments used to do the dissection are displayed in **FIG 6**. However, similar instruments and equipment are offered by Karl Storz and others use standard laparoscopic instruments.

A

B

C

FIG 6 ● **A.** Important TEM instruments. From *top* to *bottom*: curved monopolar grasping forceps for left and right hands, straight monopolar grasping forceps for left and right hands, suction tube, suture clip forceps, articulated monopolar knife, and straight monopolar knife. All black instruments are insulated so that they may be used for cautery. The angle at the end of the instrument allows a range of motion in the TEM lumen. **B.** Close-up of curved forceps. **C.** Close-up of straight forceps.



A

B

FIG 7 ● Richard Wolf TEM rectoscope. **A.** Assembled rectoscope. **B.** Rectoscope components. *(1)* Three different length shafts are available for different tumor locations. *(2)* Different length obturators allow for atraumatic rectoscope insertion. The working adapter *(3)* and the working insert *(4)* allow for connection to insufflator, camera, and working instruments.

- The operating rectoscope has a rectoscope tube that is 4 cm in diameter (**FIG 7A**). There are three different lengths of shafts (with their correspondent obturators; **FIG 7B**) that can be used during the surgery, depending how far the tumor is from the anal sphincter. The rectoscope tube is attached to the adapter and working insert (**FIG 7B**) and is then fixed to the operating table with a Martin arm (**FIG 5**).
- Once the patient is prepped and draped, the anus is gently dilated and the rectoscope (with the obturator) is inserted into the patient's anus (**FIG 8**). There is a 20-cm shaft with an oblique edge for higher lesions, a 12-cm

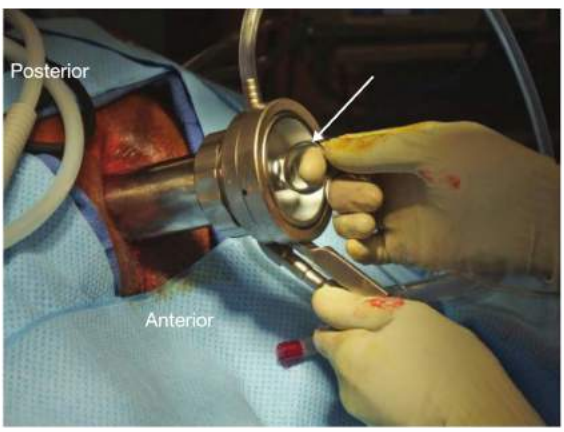


FIG 8 ● Insertion of the TEM rectoscope. After gentle dilation of the anus, the rectoscope is inserted with an obturator *(arrow)* in place for an atraumatic entry.

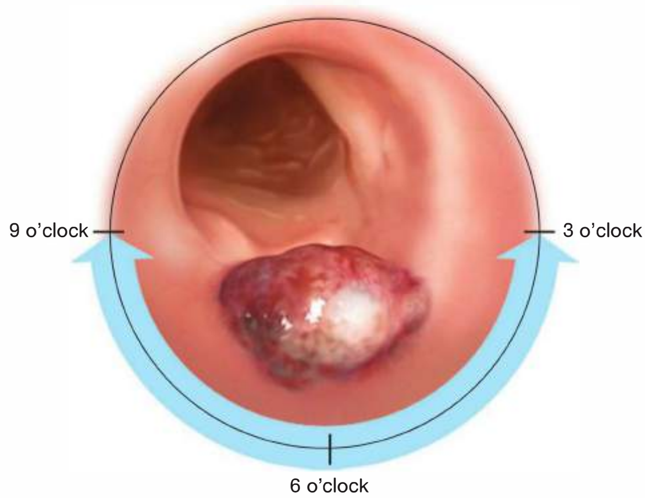

FIG 9 ● Ideal location of the target lesion. The scope and the patient are adjusted so that the lesion is positioned in the center of view at the 6 o'clock position. This ensures that the positioning is ideal and that the surgeon will have proper reach with the instruments.

shaft with an oblique edge for masses lower in the rectum, and a 13.7-cm shaft with a flat edge for lesions that extend into the anus (**FIG 7B**). The flat-edged shaft is ideal for very low lesions, as it allows access without losing insufflation extending down to the upper anus. The obturator can be removed and the working faceplate is secured.

- The light source is then connected and the rectum is insufflated. At this point, the TEM is functioning as a large rigid proctoscope. The scope can then be adjusted so that the lesion is positioned in the center of view at the 6 o'clock position (**FIG 9**). This assures that the positioning is ideal and that the surgeon will have proper reach with the instruments.
- After the ideal view of the lesion is found, the TEM scope is then secured to a Martin arm (**FIG 5**), and this arm is connected to the operating table. The application of the Martin arm is one of the most important aspects of the operation, as the arm is frequently repositioned to keep the lesion in the lower middle of the field, as explained earlier. It is essential to make certain that each of the three joints on the Martin arm is not maximally angled so as to maintain flexibility of positioning. If they are maximally flexed, the arm needs to be adjusted.
- All of the rubber sleeves and caps can then be lubricated with mineral oil to reduce the chances of drying and cracking. If the caps tear, it will lead to air leaking and loss of rectal distention. After lubrication, the sleeves and caps are placed into the ports on the faceplate.
- Lastly, the four pieces of tubing can be placed into their respective ports in the apparatus (**FIG 10**). The four ports are used for continuous insufflation, irrigation, suction, and the light source. The connecters are all different to avoid attaching the tubes to the wrong location.
- TEM equipment gives access to lesions at any location in the rectum from the anal canal up to the rectosigmoid region and sometimes even higher.

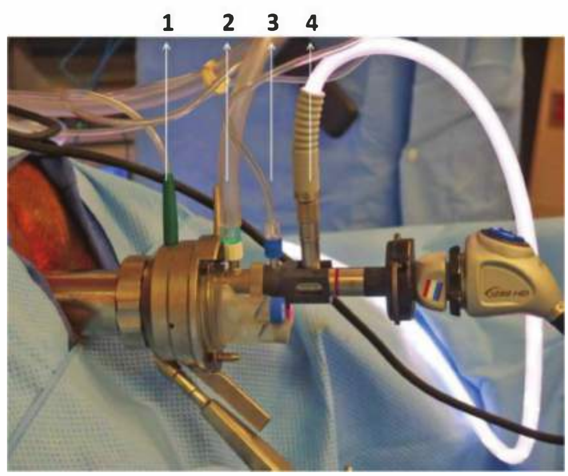

FIG 10 ● Finalized assembly of the TEM rectoscope. The four pieces of tubing are connected into their respective ports in the apparatus. The four ports are used for suction *(1)*, continuous insufflation *(2)*, irrigation *(3)*, and for the light source *(4)*. The connectors are all different to avoid attaching the tubes to the wrong location.

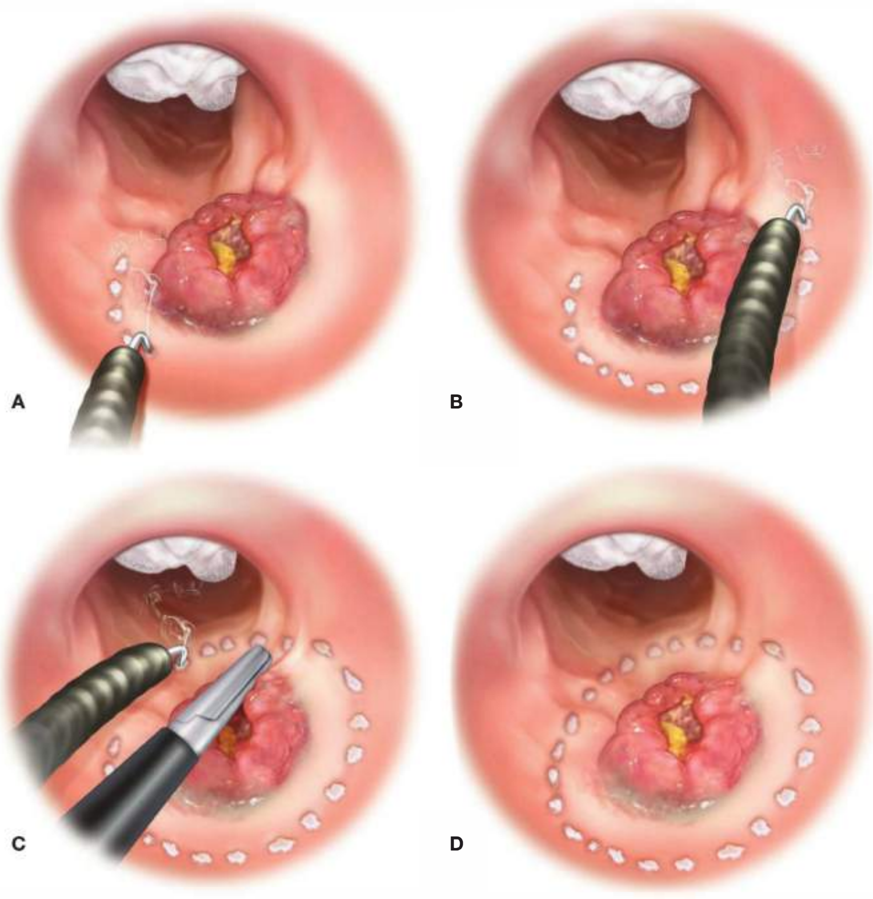
MARKING THE LESION

- Once proper setup is complete, the area around the lesion can be infiltrated using local anesthetic with epinephrine. The purpose of this step is to aid in hemostasis.
- The margin of the lesion can then be marked circumferentially using electrocautery (**FIG 11**). Marking the lesion is an important initial step in this surgery. It ensures the reach with the instruments to get an adequate margin circumferentially around the lesion and, most importantly, it aids in the visualization of the proper margin at all times. The latter is important because cautery artifact, blood, and smoke may obscure the edges of the lesion later in the procedure, which can impair the ability to have a negative margin.
- Although TEM can be performed safely by an experienced surgeon for lesions anywhere in the rectum, a less experienced surgeon should avoid performing TEM for lesions in the upper rectum and for higher lesions that are based anteriorly due to the potential of entering the peritoneal cavity, which leads to a challenging closure.



A B C D

FIG 11 ● **A–D.** Marking of the lesion. The margin of the lesion is marked circumferentially using electrocautery. This ensures the ability to reach with the instruments to get an adequate margin circumferentially around the lesion and, most importantly, it aids in the proper visualization of the margins of resection at all times.

DISSECTION

- Using the markings made circumferentially, electrocautery is used to "connect the dots" to dissect around the entire lesion (**FIG 12**). Malignant lesions must have a full-thickness excision into and/or including the perirectal fat. Adenomas only need to be excised submucosally. However, often it is difficult to avoid a full-thickness excision. It is essential to have at least a 10-mm margin for suspected malignancy and at least a 5-mm margin for adenomas.
- Ideally, the area around the lesion is connected circumferentially and then the base of the lesion is excised. For larger lesions, the inferior hemicircumference is incised and the dissection is brought around and under the lesion and then the superior aspect can be reached.
- A marking suture is placed at the inferior border of the specimen prior to removal to ensure the maintenance of proper orientation of the specimen (**FIG 13**).

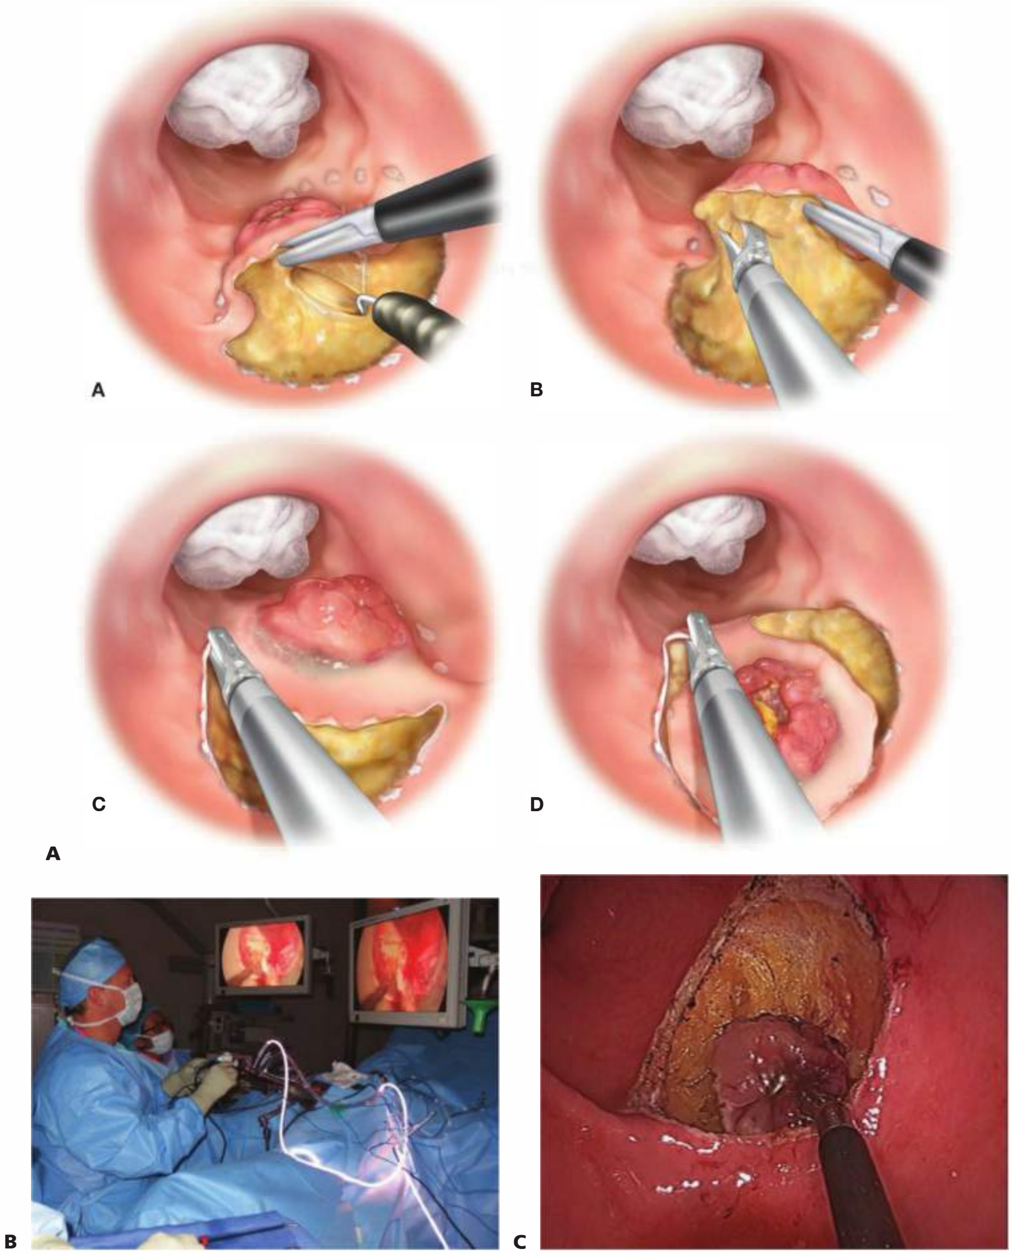


FIG 12 ● Dissection of the target lesion. **A.** It is easier to start the dissection distally, then laterally, and finally proximally (*A* through *D* in the illustration). **B.** The operative team during the dissection phase. **C.** The operative picture shows the full-thickness circumferential dissection of a malignant lesion with a 1-cm margin all around. Notice that the dissection is carried through the entire rectal bowel until the yellow fat of the perirectal tissues is reached.

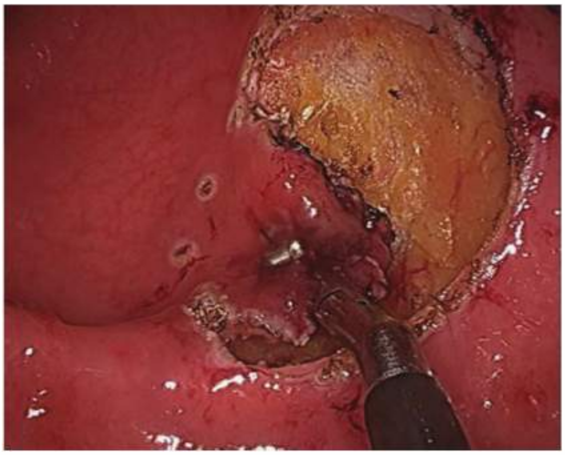

FIG 13 ● Placement of a marking suture. Prior to complete excision, a marking suture is placed in the distal margin of the target lesion for orientation.

CLOSURE

- After the lesion is dissected and ready to be removed, the insufflation is turned off and the tumor is grasped and pulled into the operating proctoscope. The faceplate is removed and the specimen is delivered.
- Two steps are taken to reduce the risk of tumor implantation/local recurrence. First, the defect, the faceplate, and the instruments are washed and irrigated with dilute Betadine, and second, the gloves must be changed after removal of the specimen.
- Following these protective steps, the closure of the rectal wall defect is performed in a running, full-thickness fashion with a 2-0 polydioxanone (PDS) suture (**FIG 14**). Closure begins at the proximal aspect of the defect and is then advanced in a full-thickness fashion from proximal to distal.
- Sewing within the confines of the TEM operating system represents a significant challenge originally. Because of the length and diameter of the operating proctoscope, there is no movement in a left to right fashion. The suture is advanced by inserting the needle driver into the lumen of the rectum and pulled out in a pistonlike motion. The closure progresses to the left. The upper left aspect of the wound closure always represents the most challenging aspect of the anastomosis.
- For large lesions, a 2-0 PDS monofilament suture is used to bisect the defect during the procedure (**FIG 15A**). If the defect is very large, it is beneficial to use two sutures to trisect it (**FIG 15B**). This can be helpful because it functions as a handle during the dissection and it also facilitates the closure process by keeping the edges of the wound closer together. Without these sutures in place, there is tension on the suture line, pulling it apart. Because there is no one holding the suture for you as the closure is performed, these stay sutures are a great help to take pressure off the suture.
- Once the closure is complete, any slack in the suture line can be fixed by gently pulling up on one end of the suture and applying another clip to tighten it.

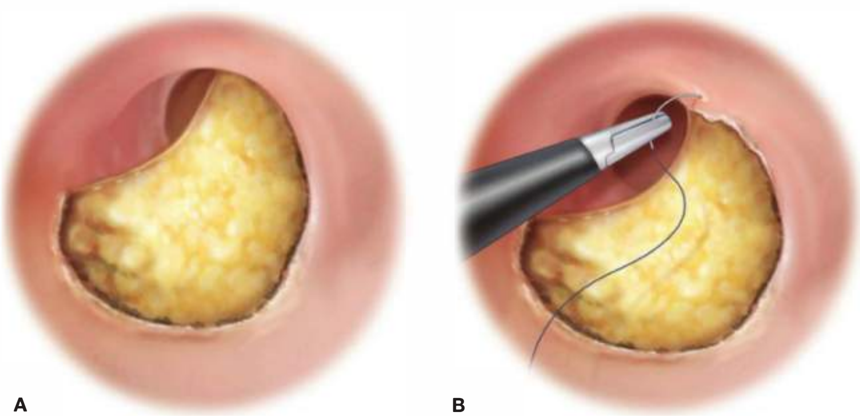

FIG 14 ● Closure of the defect. For smaller defects, a running suture with 2-0 PDS, progressing from proximal to distal (*A* through *D* in the illustration) is performed. The operative picture shows the completely closed defect. *(continued)*

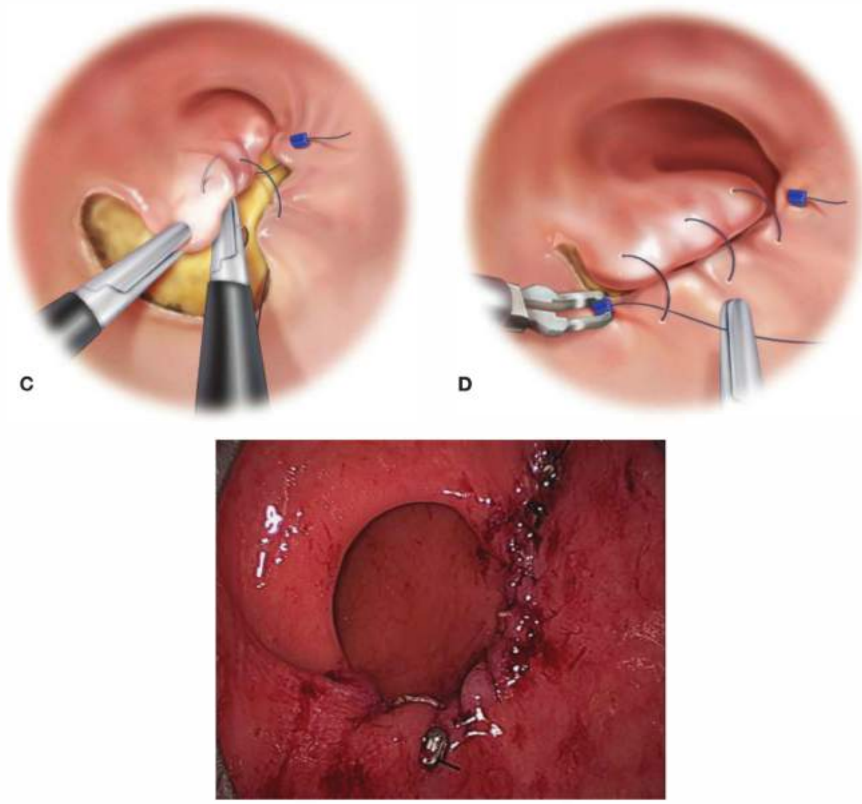

FIG 14 ● *(continued)*

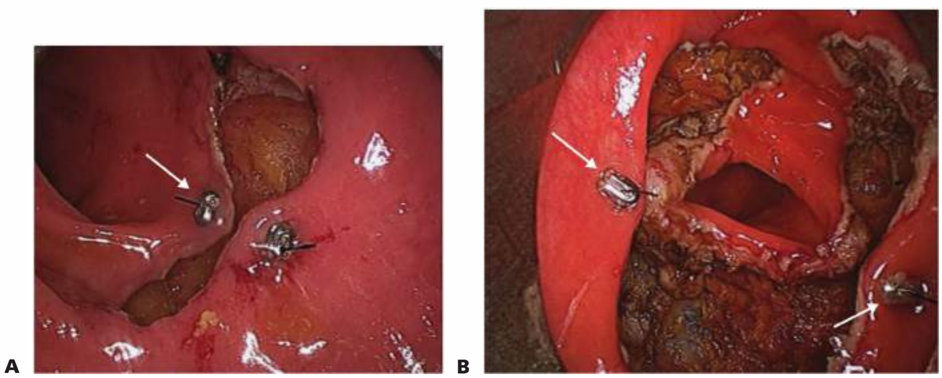

FIG 15 ● Closure of the defect. For larger lesions, it is easier to bisect **(A)** or even trisect **(B)** the defect with interrupted sutures *(arrows)* to approximate the edges, creating smaller defects in order to reduce the tension, and to facilitate the placement of the running sutures.

SPECIMEN SENT TO PATHOLOGY

- On the back table, the specimen is pinned to a corkboard (FIG 16) and the sides are labeled superior, inferior, left, and right for orientation of the lesion in the rectum.
- This is an important step, as the edges will otherwise roll in and result in an indeterminate read of the margins, or worse yet, a false-positive margin reading.

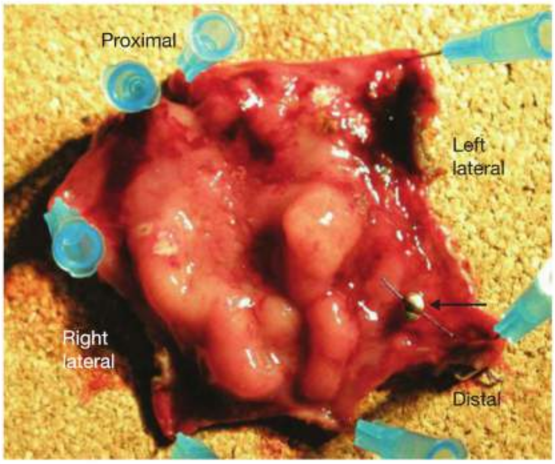

FIG 16 ● Specimen orientation. After resection, the specimen is pinned to a corkboard, oriented, and sent to pathology. This is critical to adequately evaluate the margins in cancer patients. Notice the clip placed on the distal margin for orientation prior to resection *(arrow)*.

PEARLS AND PITFALLS

Patient positioning	■ One of the most important steps of the procedure ■ Placing the lesion properly centered beneath the scope facilitates the dissection and closure. ■ The location of the tumor (anterior, posterior, or right/left lateral) must be carefully noted in the preoperative evaluation and rechecked the morning of surgery.
Using TEM instruments: key factors	■ Instruments should always remain in parallel and can only be moved in and out. There is no up and down or left and right movement. Rotating to the left and right adds significantly to the reach and mobility of the angled instruments. ■ All instruments should be well lubricated to reduce friction and decrease wear and tear of caps on the faceplate. A tear here will lead to loss of the air seal, which can lead to loss of visibility. ■ It is beneficial to keep the suction catheter in the proximal neck of the rectoscope so that it is out of view, does not interfere with the reach of the operating instruments, and increases the mobility of working instruments.
Measures to prevent tumor implantation/local recurrence	■ The defect, the faceplate, and the instruments are washed and irrigated with dilute Betadine. ■ The gloves must be changed after specimen removal. ■ Additionally, the use of neoadjuvant chemoradiation along with TEM surgery reduces local recurrence.
Facilitating suture closure	■ Keep the suture material short in length to reduce the amount of time taken to pull the suture through the tissue. We recommend a 10-cm suture length. ■ For larger lesions, bisect or even trisect the defect by placing interrupted sutures. This reduces the tension facilitating the placement of running sutures.

POSTOPERATIVE CARE

- Patients with smaller incisions can be sent home the same day of surgery.
- Full-thickness excision patients should be admitted overnight for intravenous (IV) antibiotics and observation. Patients receive Ancef and Flagyl for 24 hours and then doxycycline for 2 weeks.
- Clear liquids are given on the day of the surgery; advance to a soft diet later that day or the following day.
- We give 1 oz of milk of magnesia beginning on the day after surgery through postoperative day 5 in order to keep the stool loose without causing excessive diarrhea. Patients are instructed to take fiber supplements. The goal is to avoid a large hard bowel movement that can disrupt the suture line.
- In order to avoid potential wound complications, patients are discharged home with instructions to avoid heavy lifting and straining.
- Long-term postoperative care includes the following:
  - A surveillance exam at 3-month intervals for the first 12 months
  - A flexible sigmoidoscopy is performed at months 6, 18, and 24.
  - A full colonoscopy is obtained at the 1-year marker.
  - It is important during these examinations to carefully evaluate the suture line to rule out any potential suture line recurrence.
  - CEA tests should be monitored on the same schedule as office visits.
  - CT scans should be performed annually or as necessary to follow cancer patients depending on symptoms or findings during examinations.

OUTCOMES

- One of the major benefits of the TEM procedure is the decrease in postoperative morbidities compared to radical transabdominal surgery due to the minimally invasive nature of the TEM procedure, the lack of incision, and the avoidance of a diverting stoma.
- In our experience of more than 300 TEM procedures, we have only had two patients with transient incontinence after the surgery. These patients likely had decreased capacitance of the rectal wall after a large resection, but the urgency improved over time.
- Local recurrence after TEM remains a conflicting topic for many colorectal surgeons. In a study where we compared our experience with a total of 72 patients with T2 rectal cancers treated with neoadjuvant chemoradiation and either a TEM or a total mesorectal excision (TME), we found that there was no significant difference in local recurrence (3.3% vs. 2.3%, respectively). Five-year survival was also not significantly different with 95% in the TEM group and 97% in the TME subset. Saclarides and Floyd performed a larger study looking at 221 patients with T1 rectal cancer treated with TEM and found a local failure rate of 6.3%.
- Moore et al. has shown that TEM has a significantly better reliability of achieving negative margins and avoiding fragmentation when removing the specimen than the traditional transanal approach. Additionally, TEM offers several advantages over traditional transanal excision such as clearer visualization, better exposure, and access to higher lesions in the rectum.

COMPLICATIONS

- Air leakage is a frustrating complication that can occur during a TEM procedure because it leads to loss of pneumorectum and ultimately can inhibit view of the lesion. Some precautions that should be taken to avoid this problem include checking all equipment tubes and connections to make sure they are airtight and to make sure there are no cracks or pinholes in the rubber caps. When an air leak is encountered, a systematic review of the equipment is needed to troubleshoot the problem.
- During a TEM procedure, it is not uncommon to enter the peritoneal cavity while dissecting the specimen. Although this was previously thought to be detrimental for the patient's recovery, recent studies have found that entrance into the peritoneal cavity is not a contraindication for transanal resection of rectal lesions.
- Entrance into the peritoneal cavity occurs more commonly in anterior and lateral lesions due to the level of peritoneal reflection in these locations and it occurs less commonly in posterior lesions, which are invariably extraperitoneal. If the peritoneal cavity is entered during the procedure, it should be have a two-layer closure with a braided, absorbable, figure-of-eight suture (3-0 Vicryl), with a full-thickness closure on top of this.
- Early in the surgeon's experience, high anterior lesions should be avoided so as to ensure the peritoneal cavity is not breached.
- Postoperative complications for TEM patients are minimal (range from 6.7% to 9.8%) and include bleeding, perforation, and wound dehiscence.
- Other complications reported include fever, fistula formation, rectal stenosis, and urinary dysfunction.
- In our experience, wound separation is the most common complication with most of these (91%) healing without additional surgery.
- It is mandatory to always discuss with the patient the possible need for an abdominal operation, a stoma, additional surgery, and the possibility of fecal incontinence.

Chapter 42

Transanal Single Port Excision of Rectal Lesions

Avo Artinyan   Daniel Albo

DEFINITION

- The first description of transanal excision (TAE) of rectal lesions is often attributed to Parks and colleagues. The classic technique described by Parks[1] involves the excision of low rectal lesions under direct vision with the aid of transanal retractors and standard surgical instruments. Although relatively effective for low rectal lesions, TAE is extremely difficult for lesions in the midrectum and effectively impossible for lesions in the upper rectum.
- The advantages associated with TAE versus radical surgery include the following: lower morbidity, less pain, shorter operating times, shorter hospital stays, no wound complications, faster/more complete recovery, and avoidance of permanent colostomy.
- Transanal endoscopy microsurgery (TEM) generally refers to an approach for the local excision of lesions in the mid- to upper rectum first described by Buess et al.[2] in the early 1980s.
- Although several variations in technique and instrumentation have been described, common to all of these are the following: (1) endoscopic visualization of the rectum, (2) gas/CO_2 insufflation, and (3) the use of laparoscopic and/or other specialized instrumentation that allows for bimanual surgical dissection and suture repair.
- The procedure is notably distinct from endoscopic mucosal resection (EMR) and other techniques that rely on flexible gastrointestinal endoscopy with associated limited instrumentation introduced via the working channels of these scopes.
- Other terms such as transanal minimally invasive surgery (TAMIS) describe the same procedure with slight variations in instruments, especially with respect to the transanal access platform. In this chapter, we use the term transanal endoscopy microsurgery to include all of these procedures and variations.
- The procedure has recently seen an increase in popularity with the introduction of newer, less expensive instrument platforms as well as expanding interest in, and indications for, the local excision of rectal cancer.

DIFFERENTIAL DIAGNOSIS

- TEM can be used to treat a wide variety of both malignant and benign rectal conditions, including but not limited to large rectal adenomas, early rectal cancers, neuroendocrine tumors, endometriomas, and rectal strictures.
- These lesions encompass a wide variety of pathophysiologic entities with many common underlying complaints that alert the clinician to pathology within the distal large bowel and rectum.
- TEM can serve as both a diagnostic procedure as well as an effective therapeutic procedure in the appropriate setting.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with rectal lesions (usually rectal polyps and rectal cancers) generally present with occult or clinically evident rectal bleeding. Those with early or small lesions may be completely asymptomatic with rectal pathology discovered on screening colonoscopy.
- A thorough history and physical examination should be performed, important components of which include the following:
  - Presence of ***rectal pain and/or tenesmus***, which can often alert the surgeon to a more extensive lesion with sphincter/levator ani involvement
  - Presence of ***obstructive symptoms***
  - Description of ***anorectal function***, with any fecal incontinence or leakage documented preoperatively
  - ***Urinary and erectile function***, with dysfunction documented preoperatively
  - A ***detailed oncologic history*** including both personal and family history of colorectal cancer, other malignancies, and hereditary cancer/polyposis syndromes
- Physical examination should include the following:
  - ***Routine abdominal examination***, with particular attention to the presence of any surgical incisions, which may become pertinent should laparoscopy or laparotomy be necessary.
  - ***Digital rectal examination*** with gross assessment of sphincter function
  - ***Bilateral inguinal nodal examination*** for clinically evident nodal metastases
  - ***Rigid proctoscopy by the surgeon*** to define the anatomic parameters of the lesion
- Rigid proctoscopic examination is the most critical portion of the physical examination and is the key to proper selection of patients for TEM. Examination should be standardized and should document the following findings:
  - The distal and proximal extent of the lesion measured from the ***anal verge***
  - Position of the lesion within the circumference of the rectum (anterior, posterior, or lateral)
  - Total circumference of the rectal wall involved by the lesion

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A ***complete colonoscopy*** should be performed on all patients preoperatively. In the setting of possible colorectal neoplastic disease, the location of all polyps should be described, and all suspicious lesions should be endoscopically excised or biopsied if excision is not feasible. Lesions that are unresectable or are suspicious for invasive adenocarcinoma should be tattooed to facilitate resection if necessary in the future.

- For all suspicious rectal lesions (≤15 cm from anal verge on rigid proctoscopy), locoregional staging with ***endorectal ultrasound (EUS)*** **or** ***rectal magnetic resonance imaging (MRI)*** should be performed to define the depth of the lesion and the potential for nodal involvement.
- With all suspected or confirmed colorectal neoplastic disease, ***complete staging computed tomography (CT) of the chest, abdomen, and pelvis*** should be performed to rule out metastatic disease.
- ***Positron emission tomography (PET)/CT*** should be used selectively for patients with suspected metastatic disease or those that are poor candidates for intravenous (IV) contrast secondary to renal insufficiency or contrast allergy.
- ***Anal physiologic studies with manometry*** should be strongly considered for patients with preoperative symptoms and signs of fecal incontinence to document preoperative sphincter function.

SURGICAL MANAGEMENT

Indications for Transanal Endoscopy Microsurgery

- ***Large rectal polyps not amenable to colonoscopic resection*** (usually sessile adenomatous polyps)
- ***Rectal adenocarcinoma***—The indications for the local excision of rectal adenocarcinoma continue to evolve, particularly with the recent completion of multidisciplinary trials such as the American College of Surgeons Oncology Group (ACOSOG) Z6041 trial. Because TEM is used to excise local disease and does not adequately address nodal disease, the degree to which the procedure is appropriate and successful is directly proportional to the likelihood of nodal metastases. In the combined literature, the risk of nodal disease is best predicted by T stage and is on the order of 5% to 10% for T1 lesions, 15% to 25% for T2 disease, and 35% to 75% for T3 disease. Other pathologic factors are also useful in predicting risk of nodal disease and recurrence, and these are potentially applicable for patient selection (Table 1). ***The desire to perform/undergo a minimally invasive procedure*** **should not** ***supplant sound oncologic principles.***
  - ***Low-risk T1 disease***—Definitive therapy for rectal cancer should be reserved only for patients with low-risk T1 disease. This is also the current position of the National Comprehensive Cancer Network (NCCN).
  - ***High-risk T1 or any T2 disease with combination therapy***—Patients with high-risk T1 or any T2 disease who undergo TEM with curative intent should ideally be treated in a clinical trial setting with either preoperative or postoperative chemoradiation. Given that TEM is not the standard of care in this setting, the risks and benefits of TEM versus radical resection need to be carefully discussed with the patient and appropriate consent obtained and documented.
  - Lesions of any stage, technically amenable to TEM, in ***patients who refuse radical resection***, appropriate discussion and consent must be documented
  - Lesions of any stage, technically amenable to TEM, for ***palliative purposes***
- Other ***less common indications*** that have been reported include rectal carcinoids, endometriomas, angiodysplasia, rectal ulcers, rectal strictures, and other benign pathologies. Just as with rectal adenocarcinoma, the decision to perform TEM in these settings should be based on sound clinical judgment.

Lesion diameter >4 cm

Anatomic Considerations

- TEM is ideally suited for lesions whose *entire* extent falls within 5 to 15 cm from the anal verge.
  - The technical "sweet spot" for TEM is between 6 and 10 cm (midrectum), beyond which the surgeon has to contend with instrument limitations, diminished visualization and exposure, and the potential for peritoneal entry.
- TEM has been described for lesions proximal to 15 cm. However, peritoneal entry is much more likely with full-thickness excision in this setting, and extensive expertise is required to perform an adequate and safe suture repair.
  - The likelihood of peritoneal entry is dependent on the circumferential location of the lesion (Table 2). For example, the mean distance to the peritoneal reflection anteriorly in men is at 9.7 cm, compared to 15.5 cm posteriorly. Dissection in the posterior midline can also result in entry into the intraabdominal colonic mesentery, without frank intraperitoneal entry.[3]
- Lesions distal to 5 cm are usually covered in part or completely by the transanal access device. These lesions are more suited for conventional TAE.
- There is no absolute contraindication based on the total circumferential extent of the lesion, and complete circumferential excisions have been described. However, excision of lesions that occupy more than 40% of the circumference is technically much more challenging, may be associated with more advanced lesions, and can lead to compromised margins. Sound judgment and careful patient selection are required.

Preoperative Preparation

- The key to the technical success of the TEM operation is adequate visualization and exposure. As a result, preoperative

Table 2: Distance of Peritoneal Reflection from Anal Verge (Mean with Range, cm)

Location	Females	Males
Anterior	9 (5.5–13.5)	9.7 (7–16)
Lateral	12.2 (8.5–17)	12.8 (9–19)
Posterior	14.8 (11–19)	15.5 (12–20)

Adapted from Najarian MM, Belzer GE, Cogbill TH, et al. Determination of the peritoneal reflection using intraoperative proctoscopy. *Dis Colon Rectum.* 2004;47(12):2080–2085, with permission.

mechanical bowel preparation is invaluable. We ask our patients to have a normal lunch and take a clear liquid diet with adequate hydration thereafter and nothing by mouth after midnight. We prefer a mechanical bowel preparation with two bottles of magnesium citrate in the afternoon the day before surgery, with a Fleet enema the night before and the morning of the procedure.

- In addition, we administered one dose of IV cefoxitin antibiotic within 1 hour of initiation of surgery.
- Appropriate informed consent should be obtained. In addition to the possibility of the more common complications, the consent should also address the following:
  - The likelihood of technical success of the procedure
  - The potential need for reoperation based on pathologic findings (either repeat TEM or radical resection)
  - Oncologic outcomes in comparison to radical resection, particularly local recurrence
  - The likelihood of peritoneal entry for upper rectal lesions. For upper rectal lesions where peritoneal entry is a significant possibility, we routinely consent for possible laparoscopy and/or laparotomy with primary repair or radical resection.

Positioning

- Appropriate patient positioning is critical to the technical success of the procedure. Every effort should be made to position the patient such that the lesion is down at the 6 o'clock position.
- For posterior lesions, we prefer a high lithotomy position (**FIG 1A**).
- For anterior lesions, we prefer to place the patient in prone jackknife position on a split-leg table, with the surgeon positioned between the legs (**FIG 1B**).
- For lateral lesions, we place the patient in either one of the aforementioned positions and rotate the table to turn the lesion to 6 o'clock as much as possible. If the lesion cannot be placed completely down, then we have found that it is easier to perform the excision, as well as the repair, when the lesion is oriented toward the dominant hand of the surgeon. The "circumferential sweet spot" for a right-handed surgeon in our experience is presented in **FIG 1C**.

Equipment

- Multiple transanal access platforms have been used and are appropriate for TEM. The standard procedure described by Buess et al.[2] uses the operating transanal proctoscope by Wolf. Other transanal access platforms that have been used have incorporated equipment for single-incision laparoscopic surgery. These platforms have now gained U.S. Food and Drug Administration (FDA) approval for transanal access. Although we have used a number of these systems, our preferred transanal access platform is currently the GelPOINT Path system manufactured by Applied Medical.
- We routinely use both standard and articulating laparoscopic instruments designed for single-incision laparoscopic surgery. In a typical case, we often use a 5-mm scope operated by the assistant, a standard Maryland grasper in the left surgeon's hand for grasping and retraction, and an

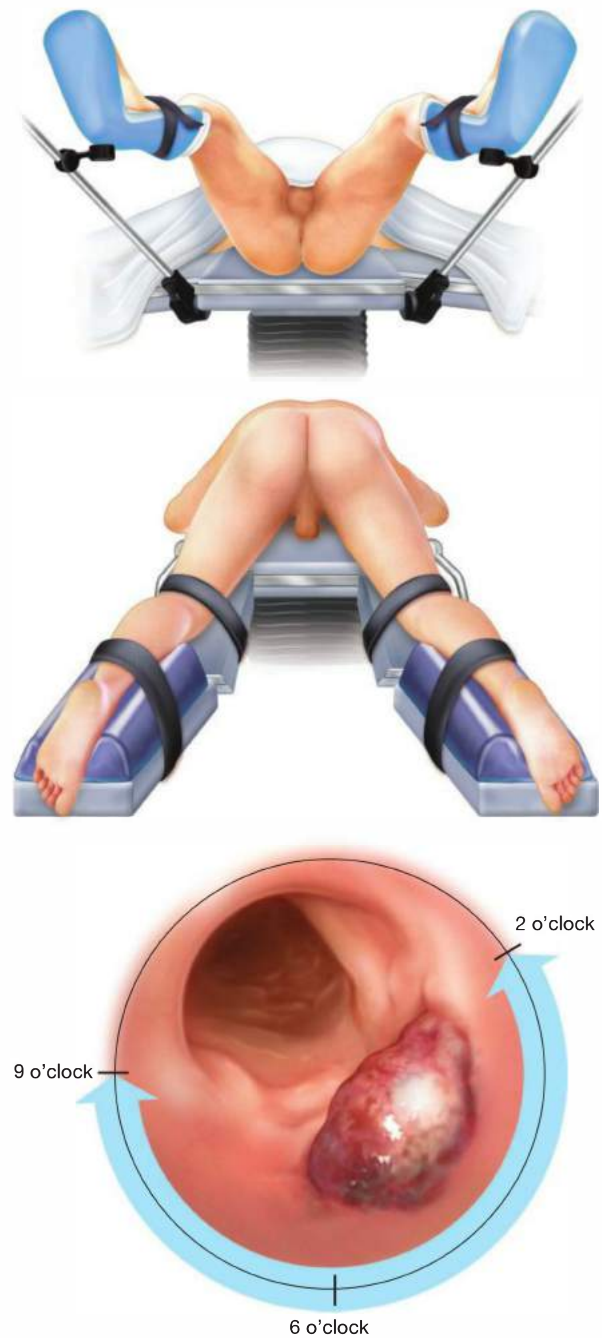

FIG 1 ● **A.** High lithotomy position, perineal view (for posterior lesions). **B.** Modified prone jackknife on a split-leg table, posterior view, ideal for anterior lesions. **C.** Circumferential sweet spot for operative dexterity for a right-handed surgeon. Lesion, excision, and repair should ideally fall within 2 o'clock to 9 o'clock positions.

articulating hook cautery or harmonic scalpel in the right surgeon's hand for excision. For repair, we use a standard laparoscopic needle driver.

- Our preferred energy sources are monopolar cautery and ultrasonic shears such as a harmonic scalpel.

FIG 2 ● The transanal port is folded in and grasped with ring clamps to facilitate insertion into anal canal.

- The patient is placed under general endotracheal anesthesia, a Foley catheter is routinely inserted, and the patient is appropriately positioned.
- A minimal sterile preparation of the perineum is performed, and the patient is draped in standard fashion.
- We perform an intersphincteric block with 1% lidocaine with epinephrine.
- The transanal access port is heavily lubricated, folded in and grasped from inside the port with a ring clamp (**FIG 2**), and then introduced gently into the rectum. Occasionally, gentle manual dilation of the sphincter is necessary to allow atraumatic placement of the port. We have found that the anal port naturally hugs the sphincters and stays in place and, therefore, do not routinely anchor the device with sutures.
- The instrument ports are first placed into the gel cap, and the gel cap is applied to the transanal port (**FIG 3**). Prior to applying the cap, we place a lightly lubricated Ray-Tec sponge into the rectum, which we later push into the proximal rectum in order to allow adequate insufflation of the distal rectum (**FIG 4**). The rectum is insufflated to 15 mmHg.
- Placing one or more proximal Ray-Tec sponges limits the amount of insufflation to the remainder of the colon and helps maintain a clean working space free of any remnant fecal material (**FIG 4**).

FIG 3 ● Transanal access device with cap and ports inserted into anal canal.

FIG 4 ● Lightly lubricated Ray-Tec is inserted proximally to minimize proximal insufflation and limit soiling of operative field.

- One of the difficulties we have found is periodic pneumorectum collapse. This can be limited by the following:
  - Inserting proximal Ray-Tecs as described earlier
  - Assuring an adequate prep, as we have noted that feculent material in the rectum and rectosigmoid will cause large bowel peristalsis
  - Avoiding excessive torque on the instruments to prevent loss of insufflation around the transanal access device
  - Higher insufflation pressures may be necessary to obtain adequate exposure.
- The excision technique is divided into the four critical steps:[4]
  - Delineation of the excision margins (1 cm grossly in most instances) (**FIG 5**)
  - Full-thickness incision of the rectal wall into perirectal tissue (**FIG 6**)
  - Circumferential dissection and specimen removal (**FIG 7**)
  - Suture repair (**FIG 8**)
- We routinely mark 1-cm margins using a hook cautery device. These cautery marks can become extremely helpful later during the excision, particularly if visualization becomes compromised (**FIG 5**).
- A full-thickness incision is made 1 cm ***distal*** to the lesion using hook cautery, with the left hand lifting up the rectal wall to supply countertraction (**FIG 6**). The perirectal tissue is usually easily recognized by the presence of perirectal fat. Anteriorly the perirectal space may consist only of loose areolar tissue. This

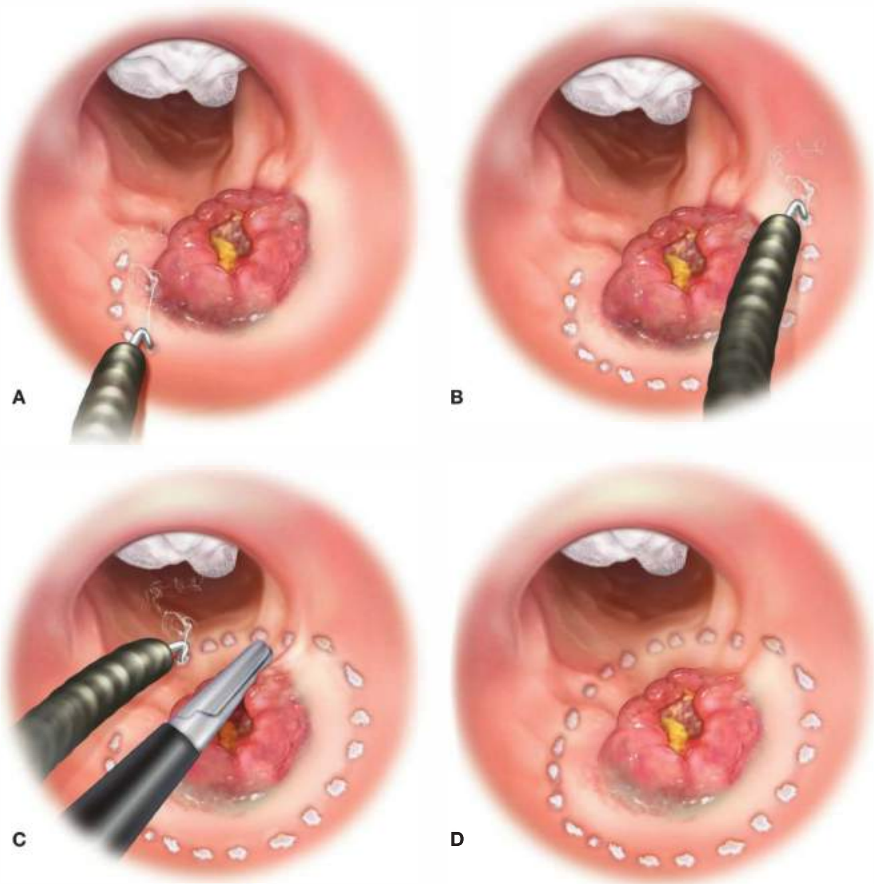

FIG 5 ● Delineation of margins of excision, 1 cm in the majority of cases. (**A–D** demonstrate progression of circumferential margin delineation)

initial step must be performed with extreme caution with anterior and lateral lesions in order to prevent injury to genitourinary and vascular structures adjacent to the rectum.

FIG 6 ● Full-thickness incision of the rectal wall into perirectal fat.

- Once the perirectal space is entered, the perirectal fat is pushed away from the rectal wall with a combination of blunt and cautery dissection, and the rectal wall above is progressively divided either with hook cautery, hot scissors, or harmonic scalpel along the cautery line marked earlier in the case (**FIG 7**).
- This dissection is continued until the specimen is entirely free. Of note, the perirectal plane is *relatively* avascular, with occasional small vessels to the rectum easily controlled with cautery. If the dissection does not proceed in a straightforward manner or is unusually bloody, the usual culprit is dissection within an incorrect plane, or the lesion is more advanced than initially recognized.
- Once the specimen is free, the lesion is grasped, taking care to maintain appropriate orientation; the cap is lifted off; and the specimen is removed. The specimen is then properly oriented on a piece of Telfa dressing and is walked over by the surgeon to the pathologists for gross examination. We perform frozen section

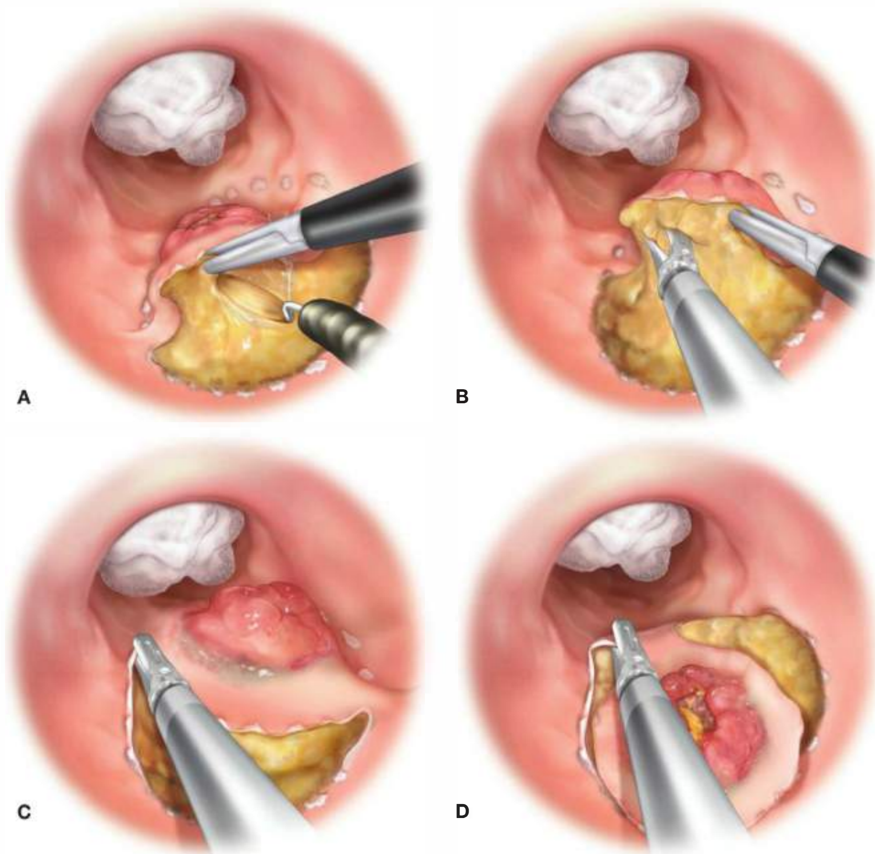

FIG 7 ● Circumferential dissection of the lesion with 1-cm margins. The deep fat is taken with either hook cautery or harmonic scalpel. The rectal wall is then taken also with either cautery or harmonic scalpel. (**A–D** demonstrate progression of circumferential dissection)

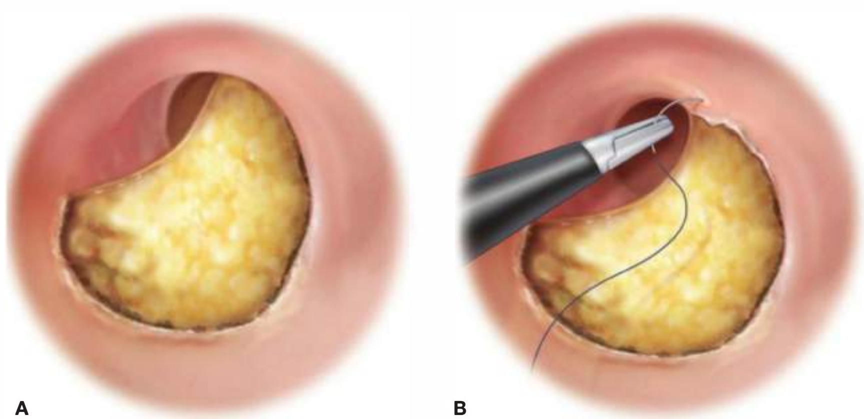

FIG 8 ● Suture repair is completed transversely from right to left (surgeon's dominant to non-dominant side). The sutures are secured on both ends with Lapra-Tys. A single running suture or two to three shorter running sutures may be used. (**A–D** demonstrate progression of suture repair) *(continued)*

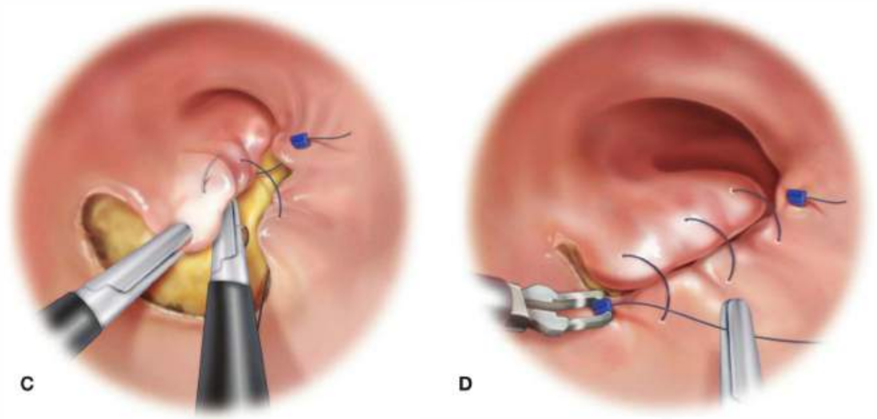

FIG 8 ● *(continued)*

examination selectively, only for suspicious margins on gross evaluation (FIG 9).

- Once the margins have been assessed and have been cleared, we proceed to perform a suture repair of the defect. The pneumorectum—which causes the size of the defect to appear more pronounced—can be decreased to facilitate closure. Even without this maneuver, very large defects can be reapproximated without significant difficulty.
- The defect can be repaired with a single running suture, or multiple interrupted sutures, transversely from right to left (FIG 8). Given that a single suture tends to be long and is somewhat tedious to handle in a small space, we prefer to place multiple shorter running sutures. We prefer a multifilament Vicryl suture, secured on one end with a Lapra-Ty. After running the suture for a number of throws, another Lapra-Ty is used to secure the remaining end, thus avoiding intracorporeal tying. Using this approach, we usually end up placing two to three running sutures to close a 180-degree defect.
- Once the repair is completed, the sponges are removed, the pneumorectum is released, and the transanal access device is gently pulled out. We place a rolled Gelfoam sponge soaked in lidocaine jelly into rectum. The sponge is removed and/or evacuated by the patient on postoperative day (POD) 1.

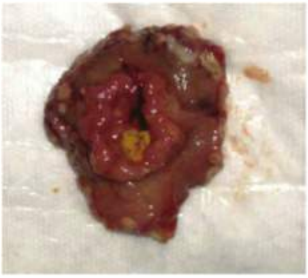

FIG 9 ● Excised specimen is placed on Telfa, appropriately oriented and taken to pathology for gross and/or frozen examination.

PEARLS AND PITFALLS

Indications/patient selection	■ Appropriate patient selection is critical both with respect to disease and size and location of lesion. ■ Appropriate lesions are those 5–15 cm from anal verge, with sweet spot 6–10 cm (midrectum). ■ Lesions >40% present a greater technical challenge, can lead to compromised margins, and may be associated with more advanced disease. ■ Risk of peritoneal entry varies by circumferential position (anterior lesions carry the highest risk of peritoneal entry).
Positioning	■ Always position the patient such that the lesion is down (6 o'clock). ■ If 6 o'clock position is not completely possible, err toward surgeon's dominant hand.
Preoperative preparation	■ Adequate mechanical bowel preparation is required to facilitate visualization. ■ With poor prep, fecal material has tendency to migrate into the field.

Exposure	▪ Ray-Tec sponge(s) placed proximally can limit insufflation of the colon and keep the operative field clean.
Excision	▪ Marking the margins with cautery and starting with a distal full-thickness incision facilitate the remainder of the dissection. ▪ Harmonic scalpel is extremely useful but can cause a blanching artifact of the mucosa that can obscure the margins during dissection.
Repair	▪ Defect is closed transversely from right to left using single running suture or two to three shorter running sutures. ▪ Use of Lapra-Tys or self-locking sutures obviates need for tying in a confined space.

POSTOPERATIVE CARE

- The patient is usually admitted overnight for observation. In the absence of significant pain, fevers, bleeding, or urinary retention, the patient is discharged home on POD 1. If low-grade fevers are noted, we have opted to use empiric antibiotics with observation until resolution.
- For the purposes of oncologic surveillance, given the concern for local recurrence, we survey the excision site with flexible sigmoidoscopy every 3 months for the first 6 months, then every 6 months for 2 years, followed by yearly and/or appropriate endoscopy and cancer screening, for a total of 5 years. In patients with invasive cancer, we perform CT scans of the abdomen and pelvis every 6 to 12 months for the first 3 years, then annually, for a total of 5 years, with the frequency determined by degree of suspicion.

OUTCOMES

Oncologic Outcomes

- The oncologic success of TEM for rectal adenocarcinoma is dependent both on the ***adequacy of technique*** and on ***appropriate patient selection.***
  - Local/locoregional recurrence is frequently the result of residual disease.
    - Luminal recurrences are likely related to residual disease at the excision site (suboptimal technique).
    - Nodal/regional recurrences are likely secondary to unrecognized nodal disease (suboptimal patient selection).
    - The risk of locoregional recurrence in low-risk T1 lesions excised with negative margins is comparable to radical resection (~5% *in most series*).
    - The risk of locoregional recurrence in unselected T1 and T2 patients is 10% or more and 30% or more, respectively, without additional therapy.[5]
    - Local recurrences are not always salvageable with radical surgery and may entail multivisceral resection. Therefore, although clinical trials with combined therapy are currently underway, TEM is currently *not* the standard of care in the United States for high-risk T1 and T2 lesions.
  - Overall survival with TEM is likely comparable to radical resection in appropriately selected patients.

Complications

- The TEM procedure, in large part, avoids the most severe complications of radical resection, including superficial and deep surgical site infections; anastomotic leaks; ventral hernia; postoperative bowel obstruction; and functional complications such as erectile dysfunction, urinary retention, and fecal incontinence.
- The risk of operative mortality is significantly lower than that of radical surgery and is less than 1% in major series.
- The risk of minor morbidity is less than 15% in most large series, with the risk of major morbidity of less than 5%.
- Specific perioperative complications are as follows:
  - ***Bleeding***—Postoperative bleeding is usually self-limited, with an infrequent need for transfusions. In a minority of cases, transanal ligation/cauterization may be necessary, with a very small likelihood of laparotomy and anterior resection.
  - ***Functional complications***—Urinary retention and anal incontinence occur relatively infrequently, and, in almost all cases, are transient. A brief period of anal leakage is often associated with traction injury from the transanal access device and usually resolves completely within a few months.
  - ***Suture dehiscence***—Dehiscence can occur in approximately 15% of patients, although most dehiscences of the extraperitoneal rectum are likely subclinical.
    - Suture dehiscences of the extraperitoneal rectum may present clinically with fevers. Although transanal repair of dehiscence can be performed, most instances can be managed nonoperatively with systemic antibiotics. These patients need to be observed, ideally as inpatients, for possible progression of pelvic sepsis. Signs of refractory and progressive pelvic sepsis should prompt consideration of abdominal exploration with fecal diversion and possibly radical resection.
  - ***Peritoneal entry***—Unintended peritoneal entry is more common with anterior and lateral lesions and more common with upper rectal lesions. In most instances, this is recognized intraoperatively and can be managed with transanal suture repair. With high upper rectal lesions, peritoneal entry may be planned and, in this setting, should not be considered a complication.

Significant expertise is required to perform an airtight repair, as suture dehiscence in this location will almost always lead to peritoneal soiling and peritonitis, necessitating abdominal exploration with repair or resection.

- ***Rectal stricture***—The risk of stricture long term is less than 5% for primary excisions.
- Relatively rare complications include intraoperative injury to genitourinary structures; rectovaginal, rectourethral, and rectovesical fistulae; complications related to positioning; and medical complications not related to the technical portion of the procedure, such as *Clostridium difficile infection* and anesthetic complications.

Chapter 43

Laparoscopic Diverting Colostomies: Formation and Reversal

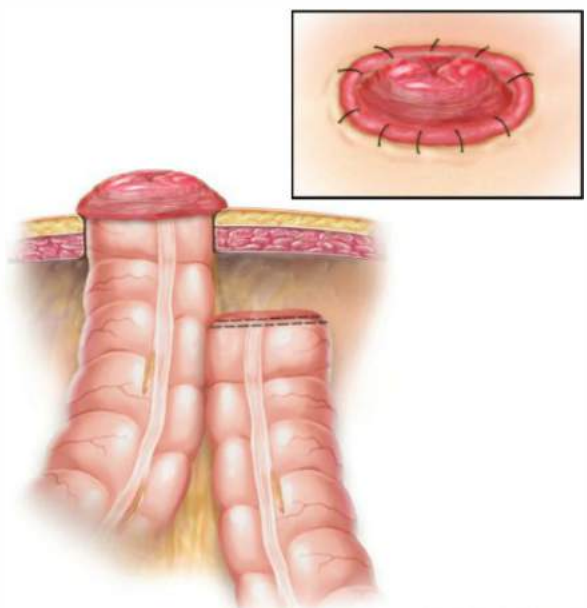
David Taylor   Andrew Stevenson

DEFINITION

- A colostomy is a surgically created communication through the body wall between the colon and the skin. There are several different kinds of colostomies, including the following:
  - End colostomy: a colostomy in which a divided end of colon passes through the stomal trephine to open externally with a circumferential colocutaneous anastomosis (**FIG 1A**). A stomal trephine is a surgically created defect through layers of abdominal wall through which the colon passes to the external opening.
  - Double-barreled colostomy: a colostomy in which two divided ends of colon pass through the stomal trephine to open externally, each via a circumferential anastomosis (**FIG 1B**).
  - Loop colostomy: a colostomy in which a loop of colon passes through the stomal trephine to open externally via a colocutaneous anastomosis. A variable portion (usually 50% to 75% of the circumference) of the antimesenteric colonic wall is used for colocutaneous anastomosis. A variable portion (usually 25% to 50% of the circumference including the mesenteric border) of the colonic wall remains in continuity (**FIG 1C**).
  - Tube colostomy: a colostomy in which a prosthetic tube passes from the colonic lumen through the abdominal wall to open externally.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Diverting colostomies may be temporary or permanent. The possibility and likelihood of a stoma reversal must be taken into consideration prior to its formation.
- Diverting colostomies may be indicated by any combination of distally located pathology (i.e., malignancy, obstruction, sepsis, fistula, inflammatory bowel disease [IBD]), functional disorders (i.e., pelvic floor or anal sphincter dysfunction), or recent or concurrent surgical procedure.
- Patient factors such as age, gender, body habitus, current medical comorbidities, and previous medical and surgical conditions along with psychological, social, and cultural issues must be elicited and taken into consideration.
- Prior to embarking on reversal of colostomies, detailed knowledge is needed of the stoma creation and other operative procedures. Details such as type of stoma, resection of colon, peritoneal contamination, mobilization of splenic flexure, and marking of distal colon or rectum, if present, with a nonabsorbable suture are helpful in the operative planning process. In addition, up-to-date knowledge of the original pathology or indication necessitating formation of the stoma in the first instance is essential.
- Physical examination primarily focused on the patient's body habitus, abdominal contour, and presence of abdominal scars is important in the consideration of the type and site of the stoma to be formed.



A

FIG 1 ● **A.** End colostomy. *(continued)*

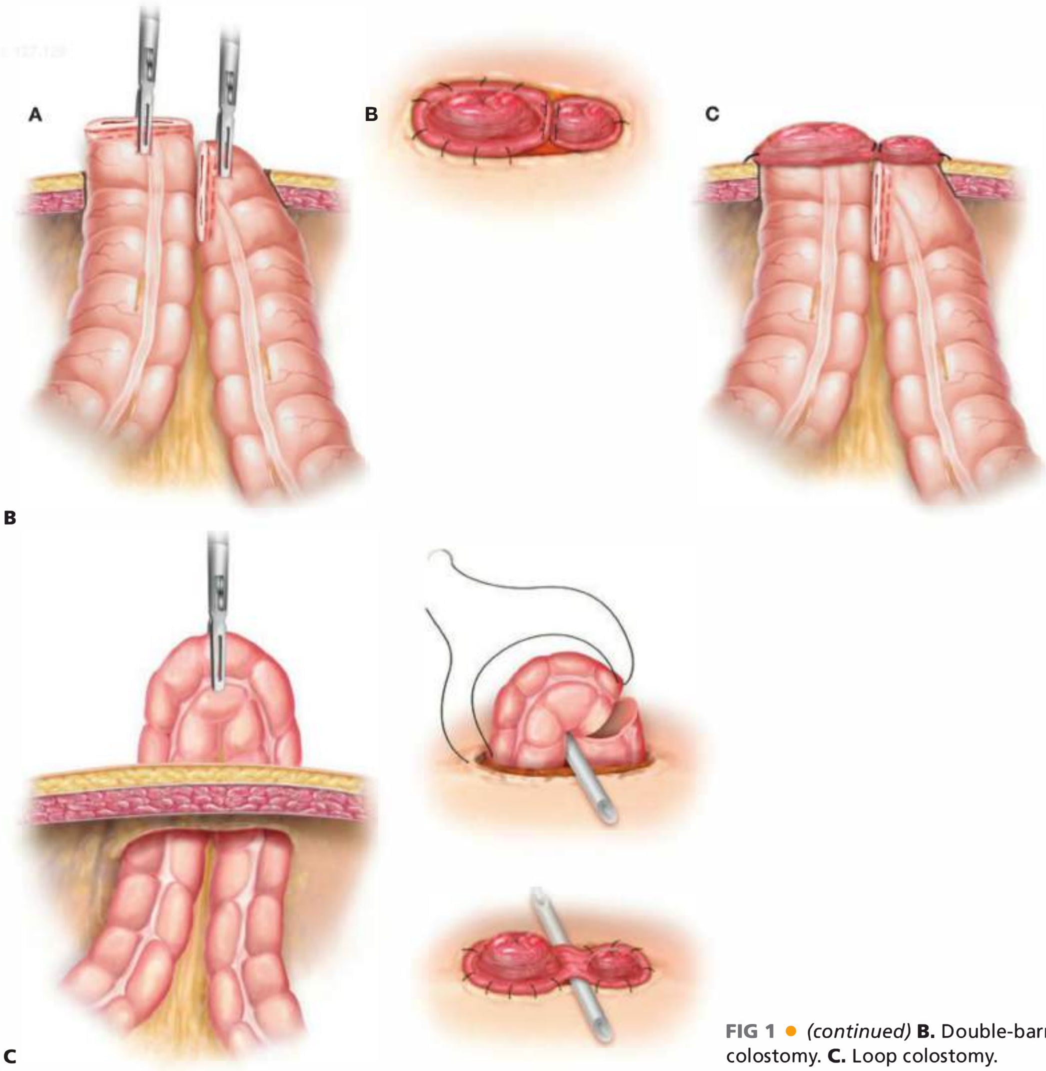


FIG 1 ● *(continued)* **B.** Double-barreled colostomy. **C.** Loop colostomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative investigation will be directed toward the underlying condition necessitating fecal diversion to exclude pathology proximal and/or distal to the intended colostomy site.
- Unrecognized Crohn's colitis, ileocolonic IBD strictures, synchronous tumors or other pathology may result in stomal complications or failure.
- Colonoscopy, computed tomography (CT) scan and/or colonic transit studies may help plan the type and site of stoma formation.

SURGICAL MANAGEMENT

Preoperative Planning

- It is critical to determine preoperatively which section of colon is to be used and if an end, double-barreled, or loop colostomy is to be formed.
- In the setting of proximal diversion for distal pathology, we prefer to use the sigmoid colon. Should this not be possible, we often opt for a diverting loop ileostomy. Alternatively, a transverse colostomy is an adequate option.
- The decision-making process regarding formation of an end, double-barreled, or loop colostomy is more complex and is illustrated in Table 1.
- Preoperative assessment and education, as well as preoperative stoma marking by an experienced stomal practitioner in conjunction with the surgeon, is highly recommended.
- Identifying the optimal stomal site should involve assessment of the patient standing, sitting, and supine. Factors involved in stomal site assessment are also listed in Table 1.

Perioperative Care

- Deep vein thrombosis (DVT) prophylaxis is recommended in the form of antithromboembolic compression stockings,

Table 1: Decision Making Regarding Stoma Site and Type

Stoma position	Preferable: readily visible, accessible, and transrectus Avoid: skin creases, belt lines, scars/incisions, hernia, and bony prominences; lateral ostomies may interfere with arm motion while walking.
Sigmoid colostomy	Ideal site: LLQ, transrectus at a point one-third the distance between the umbilicus and the ASIS
Transverse colostomy	Ideal site: RUQ, transrectus at a point one-third from the distance between the umbilicus and the junction of the costal margin and midclavicular line.
Stoma type	End colostomy: preferable for permanent stomas. Technically easier to construct and associated with a reduced complication rate. Advantageous in the difficult-to-construct stoma (e.g., the obese abdomen). Double-barreled colostomy: usually reserved for stomas constructed during an operation in which a segment of colon has been resected and an anastomosis was not undertaken, but subsequent reversal is likely. Loop colostomy: preferable for temporary stomas and/or when there is distal obstruction
Obese patients	Consider an end colostomy. Division of the colon and part of the mesentery will give more length and allow easier passage of the stoma through the ST. Consider siting the stoma in the upper abdomen where there is thinner abdominal wall. (The lower abdomen adiposity is most pendulous.) Visualization and therefore appliance manipulation is compromised if the stoma is situated on the underside of an adipose roll or pendulous abdomen.

ASIS, anterosuperior iliac spine.

sequential compression devices, and/or prophylactic heparin or low-molecular-weight heparin (LMWH).
- A single 2-g dose of Cefoxitin is administered prior to incision unless contraindicated.

Patient Positioning

- For creation of sigmoid colostomy and reversal of end colostomy, the patient is positioned in a modified Lloyd-Davies position (**FIG 2A**) on a nonslip pressure area care mat (Jelly Mat). The right upper limb is secured in the neutral position by the patient's side padded with jelly cushions to protect potential pressure points. These patients are prepped with an aseptic solution and draped with legging drapes and an under-buttock drape followed by square draping to expose the entire anterior and lateral abdominal wall.
- For creation of a transverse colostomy, and for the reversal of loop or double-barreled sigmoid colostomies, the patient is positioned supine, with the arms secured in the neutral position by the patient's side padded with jelly cushions to protect potential pressure points (**FIG 2B**). For patients in the supine position, standard square draping is adequate.
- Bladder decompression with a urinary catheter is not necessary except for closure of end sigmoid colostomy.
- Gastric decompression with an orogastric tube, which is to be removed prior to completion of the general anesthetic, is used.
- The laparoscopic equipment is assembled with all cords and tubes exiting/entering the sterile field over the right side of the patient's chest.

Laparoscopic Equipment

- All ports used are 5-mm balloon-tipped clear ports, with the exception of a 12-mm balloon-tipped port used through the stomal site.
- We use a 5-mm 0-degree camera for insufflation-assisted optical entry into the peritoneal cavity and a 5-mm 30-degree camera at all other times.
- Monopolar diathermy attached to laparoscopic scissors is adequate in almost all laparoscopic techniques described in this chapter. Advanced energy devices are reserved for difficult dissections and for the closure of end colostomies. For intracorporeal stapling and dividing, we use 60-mm reticulating linear endostaplers with 1.8-mm cartridge for division of colon and 1.2-mm cartridge for division of mesentery.
- For extracorporeal stapling and dividing, we use 75–80 mm linear staplers with 1.8-mm closed staple height for colonic division, 1.5-mm closed staple height for the longitudinal staple line of double-stapled side-to-side anastomosis, and 1.8-mm closed staple height for the transverse staple line of double-stapled side-to-side anastomosis.

Surgical Team Positioning

- Five surgical team configurations are described in this chapter (**FIG 3**).

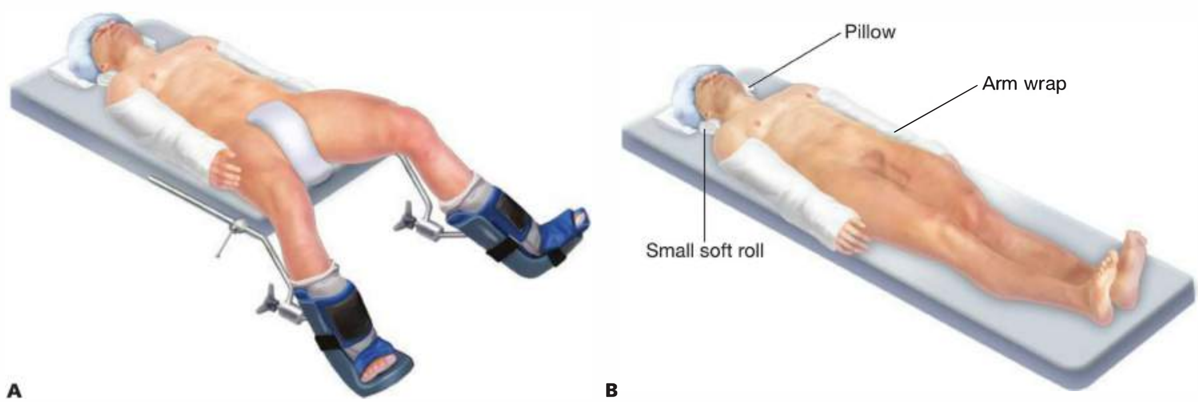

FIG 2 ● **A.** Patient positioning: laparoscopic formation of sigmoid colostomy and laparoscopic reversal of end sigmoid colostomy. The patient is placed on a modified Lloyd-Davies position, with the legs on stirrups and the arms tucked to the side. All pressure points are padded to prevent neurovascular injuries. **B.** Patient positioning (lap formation of transverse colostomy).

- Configuration 1. The operating surgeon stands to the patient's left side, with the surgical assistant to the patient's right side and the instrument nurse adjacent to the patient's right knee.
- Configuration 2. The operating surgeon stands adjacent to the patient's right side with his or her right hand dissecting with the energy device via the right lower quadrant (RLQ) or suprapubic (SP) port and with his or her left hand using a bowel grasper via right upper quadrant (RUQ) port. The assistant stands to the surgeon's left side, with the camera in his or her right hand via the midline (ML) port and the bowel grasper via the stomal trephine (ST) or left lateral (LL) port site. The instrument nurse is adjacent to the patient's right knee. The monitor is placed adjacent to patient's left hip.
- Configuration 3. The operating surgeon stands to the patient's right side, with the dissecting energy device in his or her right hand via the ST or LL port and a bowel grasper in his or her left hand via the RUQ port. The assistant stands to the surgeon's left side, with the camera in his or her right hand via ML port site. The instrument nurse or a second assistant stands between the patient's lower limbs with a bowel grasper on his right or left hand via the RLQ port site. The monitor is placed adjacent to left side of the patient's chest.
- Configuration 4. The operating surgeon stands to the patient's right side with the assistant to the patient's left side and the instrument nurse adjacent to the patient's right knee.
- Configuration 5. The operating surgeon stands to the patient's left side, with the dissecting energy device in his or her right hand via the LUQ port and the bowel grasper in his or her left hand via ST port (three-port transverse colostomy formation technique) or via the left lower quadrant (LLQ) port (four-port transverse colostomy formation technique). The assistant stands to the surgeon's left side with the camera in his right hand via the ML port, and bowel grasper in his left hand via the ST port. The instrument nurse stands adjacent to the patient's right knee. The monitor is placed adjacent to the right side of the patient's chest.

Port Placement

- Port placement planning and marking is important. The key to port placement is the RLQ port. The RLQ, RUQ, and ML ports should be placed a hand's breadth distance from each other.
- The RLQ port (5 mm) is inserted medial to, and at or just cranial to the level of the anterior superior iliac spine, just lateral to the path of the inferior epigastric vessels.
- The RUQ port (5 mm) is inserted a hand's breadth cranially along a craniocaudal line from the RLQ port.
- The ML port (5 mm) is placed via a small incision in the umbilicus or supraumbilically in obese patients with pendulous abdomens.
- The LL port (5 mm) is placed as laterally as possible at the level of the ML port. This port is optional, especially when the ST is created as the first step.
- The ST port (5- or 12-mm) is placed at the preoperatively marked stoma site. If an endoscopic linear stapler is to be used, a 12-mm port is mandatory.

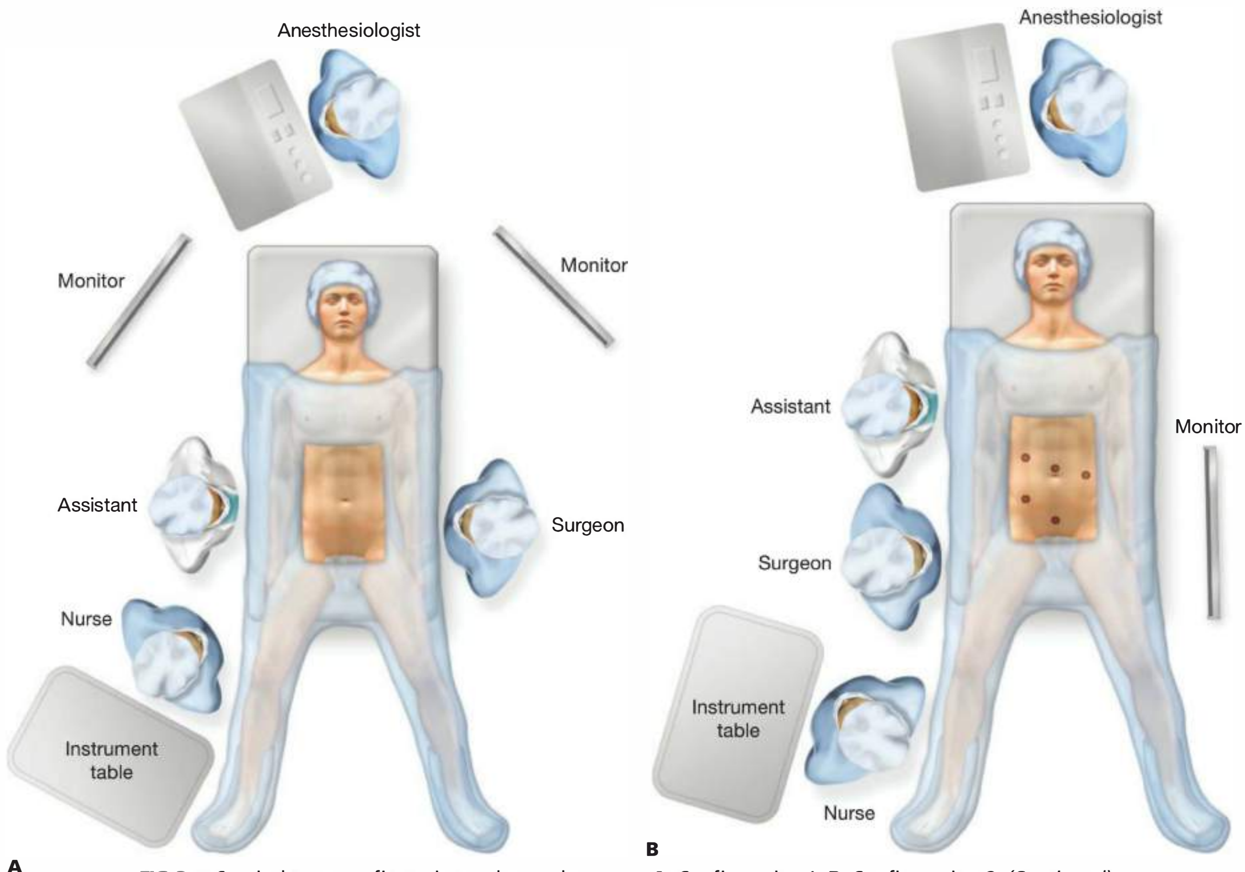

FIG 3 ● Surgical team configuration and port placement. **A.** Configuration 1. **B.** Configuration 2. *(Continued)*

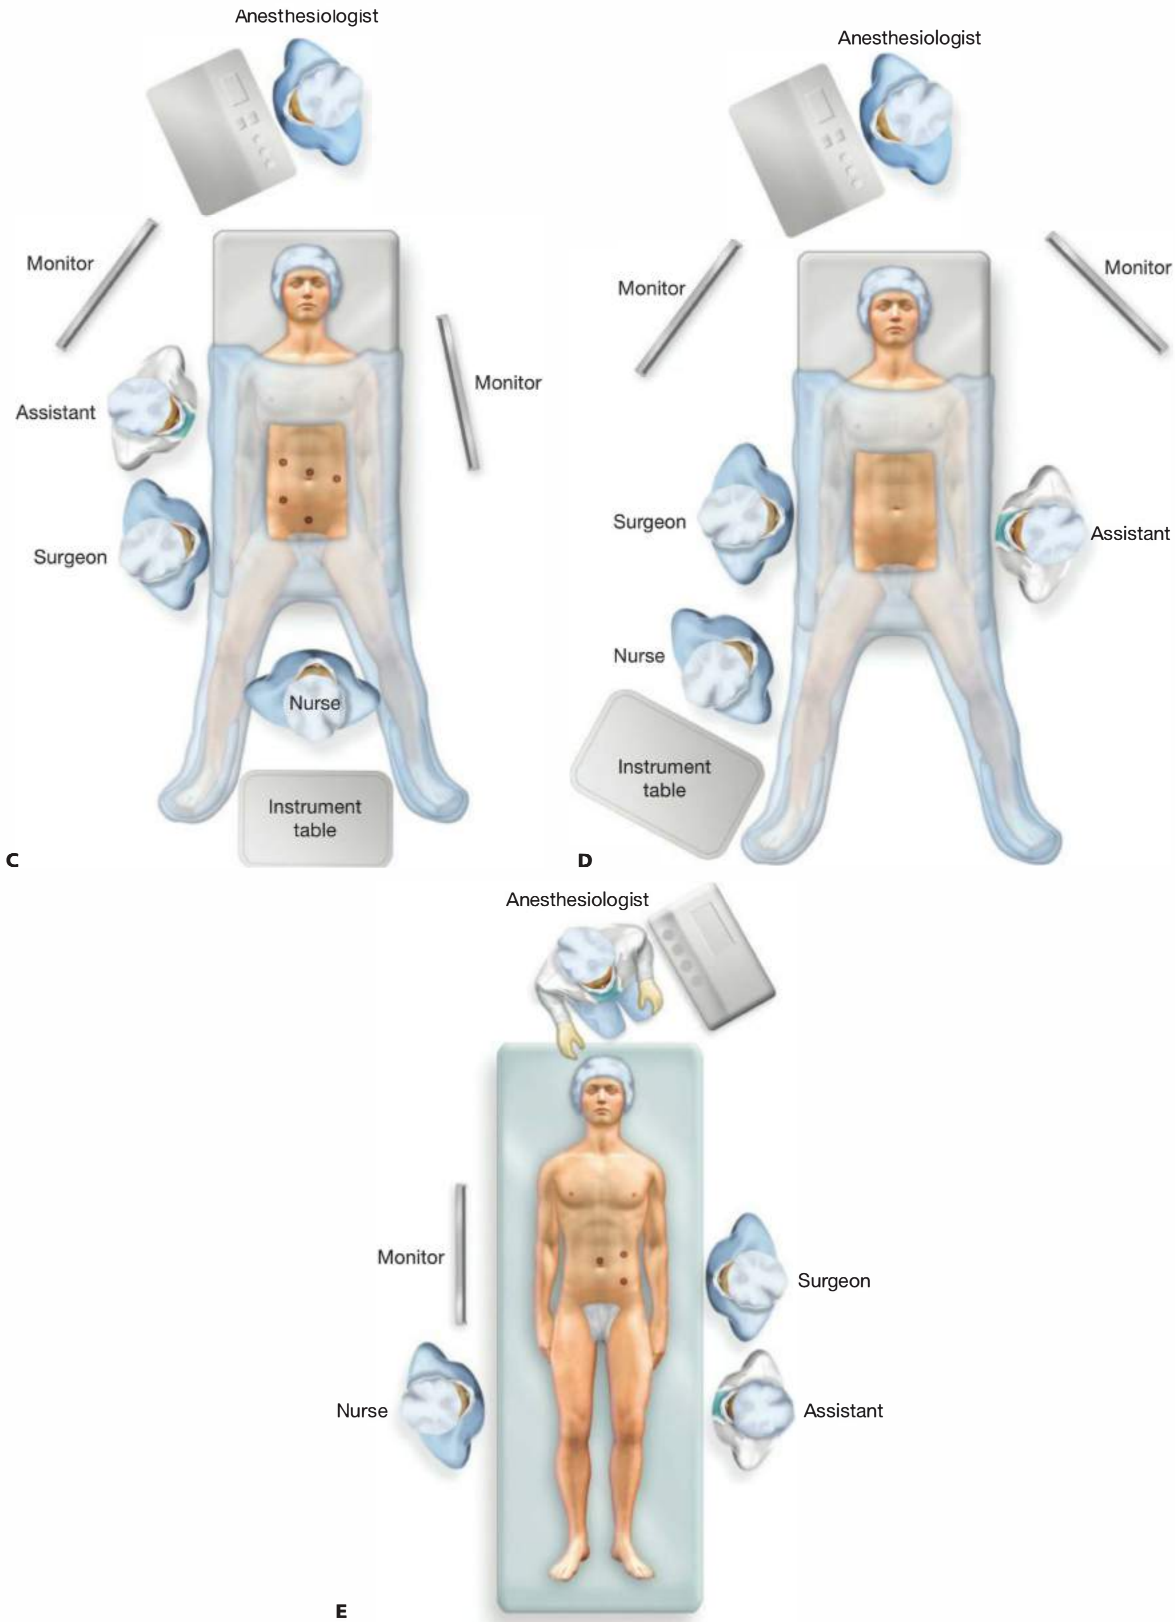

FIG 3 • *(Continued)* **C.** Configuration 3. **D.** Configuration 4. **E.** Configuration 5.

LAPAROSCOPIC FORMATION OF SIGMOID COLOSTOMY

Creation of the Stomal Trephine

- When sure about the need of a colostomy, we prefer to create the ST as the first step before the contour and layers of the abdominal wall have been altered by a pneumoperitoneum or surgical incisions.
- Using surgical team configuration 1 as previously described, a disc of skin at the preoperatively marked site is excised. Dissection through the subcutaneous adipose tissue proceeds to the anterior rectus sheath.
- The anterior rectus sheath is incised longitudinally enough to safely allow subsequent passage of the sigmoid colon but not excessive such that the patient is subjected to an unacceptably high risk of development of a parastomal hernia. The rectus muscle fibers are separated longitudinally.
- A small (<1 cm) incision is made in the posterior rectus sheath. The peritoneum is grasped and incised. A 5-mm or 12-mm balloon port is inserted via the peritoneal defect. A 12-mmHg pneumoperitoneum is insufflated.
- A 5-mm 30-degree high-definition laparoscope is inserted.
- If unsure about the need of a colostomy, we delay formation of the ST until a later stage of the procedure. In these cases, we insufflate the pneumoperitoneum using a 5-mm insufflation-assisted optical entry port via the RUQ.

Lateral to Medial Colon Mobilization

- Configuration 2 is used. The operating table is placed in a Trendelenburg position rotated with the right side down.
- The bowel grasper in the surgeon's left hand retracts the rectosigmoid junction medially and cranially. The assistant's left hand grasper may retract the proximal sigmoid colon or provide countertraction to the lateral wall of the pelvic brim.
- Energy device dissection begins at the pelvic brim. The sigmoid is mobilized from lateral attachments (**FIG 4A**). The dissection proceeds in a lateral to medial direction toward the apex of the sigmoid mesentery.
- At this stage, the left ureter and gonadal vessels should be identified and preserved intact in the retroperitoneum (**FIG 4B**). As the mobilization of the sigmoid and descending colon mesentery continues proximally, anterior to the ureter and gonadal vessels, it is often advantageous to use configuration 3. The grasper held by the instrument nurse/second assistant retracts the colon distal to that retracted surgeon's left hand grasper. The sigmoid and descending mesentery should be mobilized to the midline.
- A technical tip for the medial colonic retraction is that the colon is initially lifted anteriorly and then retracted medially. This ensures the colon acts as a "blanket" under which the small bowel is trapped, keeping it off the operative field.
- It is not usually necessary to mobilize the splenic flexure from its attachments. Although the extent of descending colon mobilization is variable, we recommend "overmobilization" to avoid undue tension. Inadequate mobilization at this stage will result in subsequent difficulty and frustration during passage of the colon through the ST and stomal maturation, resulting in an imperfect and often retracted stoma.

Sigmoid Colon Delivery through Stomal Trephine

- Configuration 2 is used. The sigmoid colon is assessed to select the optimal segment for stomal formation (most often it is the sigmoid apex). Maximum mobility from proximal and distal colon and the mesentery and proximity to the intended stomal site are the most significant factors in this selection.
- The intended segment is grasped with a locking bowel grasper via the ST port. Correct orientation is confirmed and the assistant is instructed to ensure orientation is

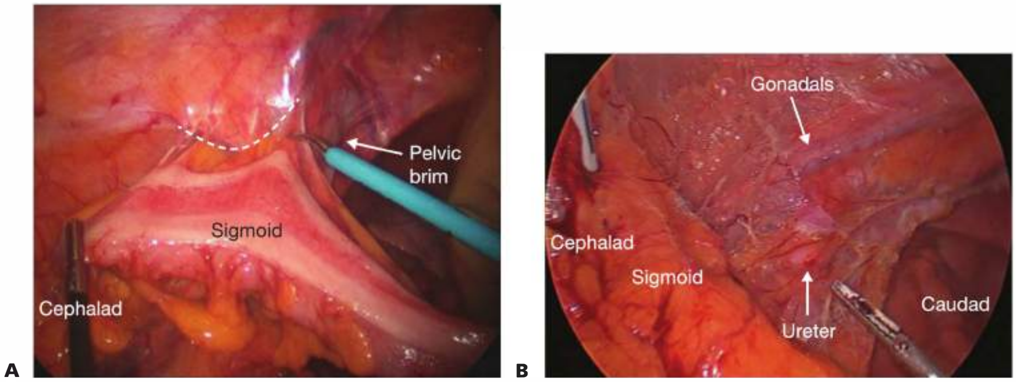

FIG 4 ● Laparoscopic sigmoid colostomy: medial to lateral mobilization of the sigmoid colon. **A.** The sigmoid is mobilized by transecting the lateral peritoneal attachments *(dotted line)*, starting at the level of the pelvic brim. **B.** After transecting the lateral peritoneal attachments and mobilizing the sigmoid to the ML, the left ureter and gonadal vessels can be identified in the retroperitoneum as they cross the common iliac artery.

maintained by holding the shaft of the bowel grasper. An additional bowel grasper may be placed and locked to the colon distal to the intended site if there are any concerns regarding loss of correct orientation.

- With the assistant holding the ST grasper, the surgeon moves to the left side of the patient to use configuration 1. The camera is withdrawn. The surgeon places two handheld retractors along the ST, retracting the rectus muscle fibers medially and laterally. The medial retractor is transferred to the assistant's right hand with the surgeon's right hand maintaining the lateral retractor. The surgeon's left hand takes control of the ST grasper and subsequently the assistant's left hand takes control of the lateral retractor.
- The pneumoperitoneum is released. The surgeon's right hand extends the posterior sheath and peritoneal vertical incision to an adequate length. The balloon of the port is deflated. The port is externalized along the shaft of the grasper. The colonic loop is then carefully externalized through the ST by extracting the ST grasper aided if required by nontraumatic bowel grasping (Rampley) forceps (**FIG 5**).

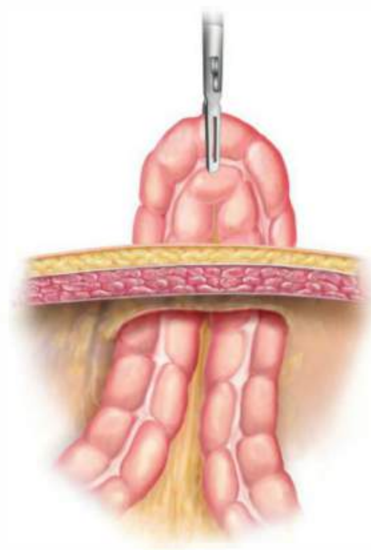

FIG 5 ● Laparoscopic sigmoid colostomy: extraction of the sigmoid loop with a laparoscopic grasper inserted through the ST port site (the port has been removed).

COLOSTOMY CREATION

Loop Colostomy Creation

- A supporting "rod" (optional) may be passed through a 5-mm defect in the mesentery adjacent to the apex of the externalized loop and sutured to the skin edge of the ST in the 3 o'clock and 9 o'clock positions (**FIG 6A**). Confirmation of correct colonic loop orientation is possible laparoscopically if deemed necessary.
- The ports are removed and port site incisions are closed with a 4-0 absorbable suture and occlusive dressings are applied.
- The apex of the colonic loop is opened by means of a transverse antimesenteric colotomy extending for 50% to 75% of the colonic circumference. The resulting proximal and distal limbs of the stoma are subsequently matured using between 8 and 12 seromuscular to subcuticular interrupted 3-0 absorbable sutures (**FIG 6B**). The stomal appliance is applied.

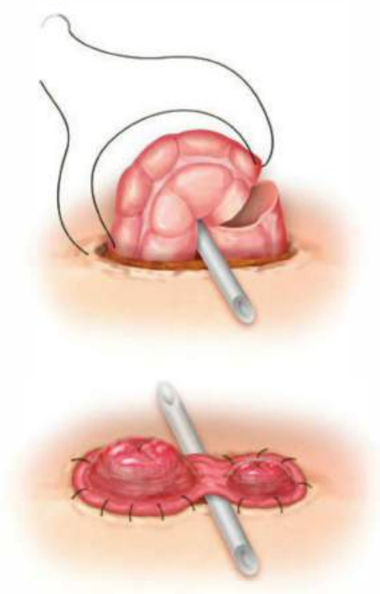

FIG 6 ● Creation of a loop sigmoid colostomy. The apex of the colonic loop is opened transversely for 50% to 75% of the colonic circumference. The resulting proximal and distal limbs of the stoma are subsequently matured flush to the skin with interrupted absorbable sutures.

Double-Barreled Colostomy Creation

- With an adequate length of sigmoid colonic loop externalized, a defect is created in the mesentry adjacent to the apex of the loop. The colon is then divided at this level with a linear stapler; the ends of the colon are grasped with nontraumatic bowel (Rampley) forceps (**FIG 1B**).
- The port site incisions are closed with 4-0 absorbable sutures and occlusive dressings are applied.
- The staple line of the proximal limb is excised. Three seromuscular–subcuticular interrupted 3-0 absorbable sutures are placed (but not tied) in the 3, 9, and 12 o'clock positions of the skin edge of the ST and the cut edges of the opened proximal colon.
- A 10-mm length of one end of the staple line of the distal colonic limb is excised. Three seromuscular–subcuticular interrupted 3-0 absorbable sutures are placed (and tied)

in the 5, 6, and 7 o'clock positions of the ST and the small opening of the distal limb.

- The proximal sutures are tied. Additional seromuscular to subcuticular interrupted 3-0 absorbable sutures are placed at intervals between already placed sutures as necessary. A stomal appliance is applied.

End Colostomy Creation

- For an end colostomy formation, instead of delivering the intact loop of sigmoid colon through the ST, the mobilized colon is transected intracorporeally.
- After identifying the optimal site for colonic division, a defect is created in the adjacent colonic mesentry with the energy device. The colon is then transected intracorporeally at this level with a 60-mm endoscopic linear stapler (**FIG 7**) inserted via the ST 12-mm port. Depending on the thickness of the adjacent mesentry and abdominal wall, a variable distance (between 30% and 50%) of mesentery is divided radially using an energy device, a linear cutting stapler with a vascular cartridge, or between ligation clips.
- The proximal colonic end is grasped with a locking bowel grasper via the ST port. Correct orientation is confirmed and the assistant is instructed to ensure orientation is maintained by holding the shaft of the bowel grasper.
- The proximal colonic end is brought out through the ST port site as discussed previously.
- The port site incisions are closed with 4-0 absorbable sutures and occlusive dressings are applied.
- The stoma is then matured with 8 to 12 seromuscular to subcuticular interrupted 3-0 absorbable sutures. A stomal appliance is applied.

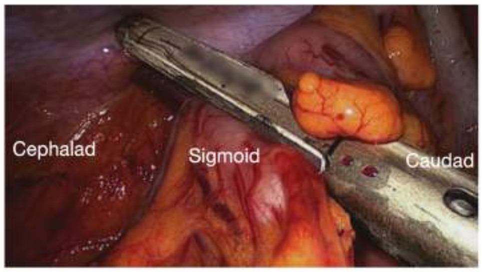

FIG 7 ● Laparoscopic end sigmoid colostomy. The distal sigmoid colon is transected intracorporeally.

LAPAROSCOPIC FORMATION OF END TRANSVERSE COLOSTOMY

Creation of the Stomal Trephine and Port Placement

- Using surgical team configuration 4, the ST is created at the preoperatively marked site (if sure about the need of the colostomy). A 12-mm or 5-mm balloon port is inserted and the pneumoperitoneum is insufflated.
- If unsure about the need of a colostomy, we delay formation of the ST until a later stage of the procedure. In these cases, we insufflate the pneumoperitoneum using a 5-mm insufflation-assisted optical entry port via the left upper quadrant.
- We use 5-mm ports in the LUQ and periumbilical locations and a 12-mm ST port (three-port technique) as described in the "Port Placement" section. An accessory LLQ port (four-port technique) is required in difficult omental mobilization cases.

Mobilization and Formation of Stoma

- Configuration 5 is used.
- The omentum is separated from proximal transverse colon with an energy device (**FIG 8**).
- After identifying the optimal site for colonic division, a defect is created in the adjacent colonic mesentry with the energy device.
- The transverse colon is then transected at this level with an Endo GIA 60-mm linear cutting stapler inserted via the ST 12-mm port.
- Depending on the thickness of the adjacent mesentry and abdominal wall, a variable distance (between 30% and 50%) of mesentry can be divided radially. This may be performed using an energy device, a linear cutting stapler, or between ligation clips (**FIG 8**).
- The proximal colonic end is grasped with a locking bowel grasper via the ST port. Correct orientation is confirmed and the assistant is instructed to ensure orientation is maintained by holding the shaft of the bowel grasper.
- The process of extracting the proximal colonic end or loop of transverse colon through the ST is identical to that described earlier.
- The port site incisions are closed with 4-0 absorbable suture and occlusive dressings applied.
- The stoma is then matured with 8 to 12 seromuscular–subcuticular interrupted 3-0 absorbable sutures. A stomal appliance is applied.

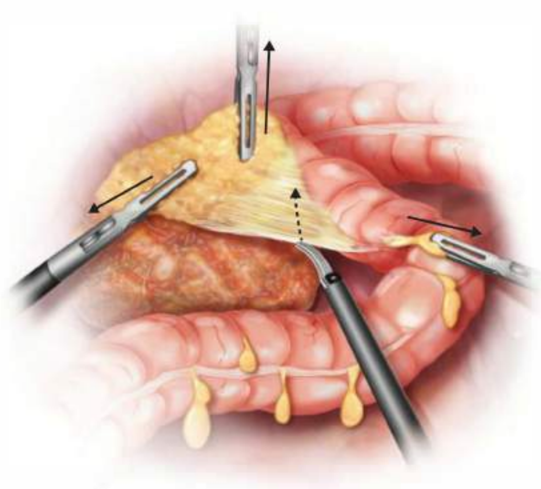

FIG 8 ● Laparoscopic transverse colostomy. The omentum is separated from the transverse colon with an energy device.

CLOSURE OF A LOOP OR DOUBLE-BARRELED COLOSTOMY

Mobilization and Closure of Stoma

- In patients with a thin abdominal wall, we incise the mucocutaneous border circumferentially. In a patient with a thicker abdominal wall due to obesity or muscle bulk, we use an elliptical skin incision inclusive of the stoma with the long axis of the ellipse oriented transversely.
- The stoma is mobilized to the peritoneal cavity by means of sharp dissection. The colonic loop or ends should be adequately mobile to comfortably externalize beyond the skin.
- Closure of the colonic loop defect or anastomosis of the colonic ends can be achieved using either a hand-sewn single-layer seromuscular technique with 3-0 absorbable suture or a side-to-side double-stapled anastomotic technique with a linear stapling device (**FIG 9A,B**).
- The reanastomosed colon is internalized within the peritoneal cavity. The fascial defect is closed craniocaudally with interrupted 0 absorbable sutures.
- The wound is lavaged with saline. Long-acting local anesthetic is infiltrated into the fascia and subcutaneous tissues.
- If a circumferential incision was used initially, the skin defect is reduced to 5- to 10-mm diameter defect by means of a subcuticular purse-string 3-0 absorbable suture. An absorbent occlusive dressing is applied.
- If an elliptical incision was initially used, the skin is closed with interrupted 3-0 absorbable subcuticular sutures. An occlusive dressing is applied.

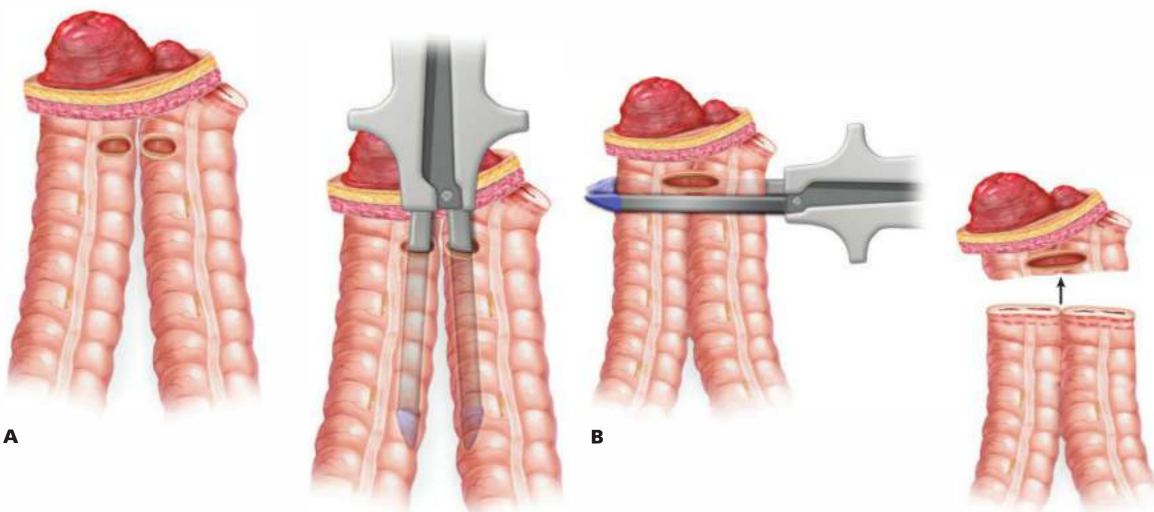

FIG 9 ● Reversal of loop colostomy. **A.** The colostomy is resected with a linear stapler. **B.** A side-to-side stapled colocolonic anastomosis is performed with a linear stapler.

LAPAROSCOPIC CLOSURE OF END SIGMOID COLOSTOMY

Team Setup and Port Placement

- Surgical team configuration 2 is used.
- The peritoneum is insufflated to 12 mm of pressure using a 5-mm insufflation-assisted optical entry port via the RUQ.
- The 5-mm ports are inserted in the RLQ and RUQ ports and ML and LL locations. The LL port is useful during mobilization of the descending colon and splenic flexure. It may not be necessary when a splenic flexure mobilization is not necessary.
- A 12-mm ST port may be inserted after the stoma site after the stoma has been mobilized into the abdominal cavity. A 12-mm SP (optional) is inserted if the rectum and/or the inferior mesenteric artery (IMA) require transection using an endoscopic linear stapler and it is not ergonomically feasible to do so via the 12-mm ST port.
- The peritoneum is insufflated to 12 mm of pressure using a 5-mm insufflation-assisted optical entry port via the RUQ.

Mobilization (+/− Resection)

- With adequate Trendelenburg and right side rotated down positioning, further adhesiolysis proceeds as required to mobilize small bowel and omentum from the pelvis and remainder of the operative field.
- With no Trendelenburg but ongoing right side down positioning (using configurations 2 and then 3), the descending colon and splenic flexure (**FIG 10**) are mobilized toward the ML as required to ensure adequate colonic length for a tension-free anastomosis, ensuring protection of the left ureter and gonadal vessels.

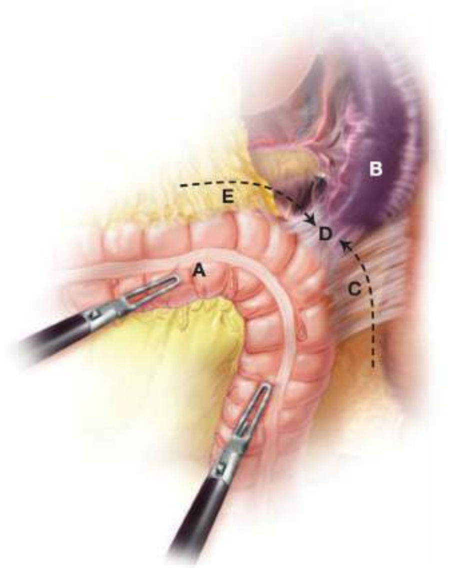

FIG 10 ● Mobilization of the splenic flexure. The surgeon retracts the splenic flexure of the colon *(A)* downward and medially, exposing the attachments of the splenic flexure to the spleen *(B)*. The phrenocolic *(C)* and splenocolic *(D)* ligaments are transected in an inferior to superior and lateral to medial direction. The gastrocolic ligament *(E)* is then transected in a medial to lateral direction until both planes of dissection meet and the splenic flexure is fully mobilized.

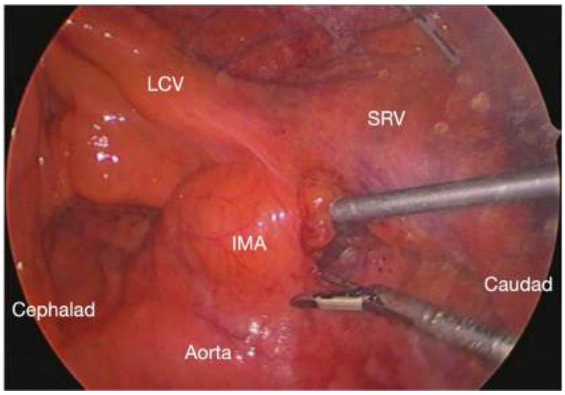

FIG 11 ● IMA dissection. With the assistant retracting the rectosigmoid junction anteriorly and cranially, the peritoneum is incised deep to the arch of the superior rectal vessels (SRV). At this point, the IMA, taking off the aorta, can be seen with its terminal branches, the SRV and the LCV.

- At this point, there are two basic scenarios that the surgeon may encounter: (1) There is a distal sigmoid stump, with an intact IMA and (2) there is a distal rectal stump; the IMA may be intact or transected.
  - When there is a distal sigmoid with an intact IMA from the previous surgery
    - Using configuration 2, the distal sigmoid stump is identified and mobilized from adhesions along with its mesentry along the lateral border ("lateral mobilization") toward the ML, ensuring protection of the left ureter and gonadal vessels (**FIG 4B**). This dissection continues distally to mobilize the left aspect of the upper mesorectum.
    - With the assistant retracting the rectosigmoid junction anteriorly and cranially, the peritoneum is incised deep to the arch of the IMA/superior rectal vessels (SRV) (**FIG 11**).
    - Dissection of the avascular window deep to the IMA/SRV arch continues from medial to lateral until it becomes confluent with the previously performed LL mesocolon mobilization.
    - The camera is rotated 90 degrees clockwise to allow better visualization through the created window to the left pelvic sidewall and brim. The ureter should be visualized through this window (**FIG 12**).
    - The second assistant or scrub nurse helps expose the retroperitoneal structures in this window by retracting the rectosigmoid junction and mesentry toward the anterior abdominal wall using the passing the suction/irrigator via the SP port under the IMA/SRV (**FIG 12**). The assistant's left hand grasper can then be repositioned proximally on the sigmoid stump to facilitate superior exposure for further dissection. Dissection continues cranially to identify and isolate the origin of the IMA off the aorta.
    - If a "high" IMA division, proximal to the origin of the left colic vessels (LCV), is mandated for the purposes of a tension-free anastomosis, the IMA can be divided with an endoscopic linear stapler or between Hem-o-lok® clips (**FIG 13**), ensuring preservation of the left ureter and gonadal vessels.
    - If adequate mobility and colonic length will permit subsequent colorectal anastomosis without high division of the IMA, the IMA is divided distal to the origin of the left colic artery (LCA) (termed a "low" IMA division; **FIG 13**).

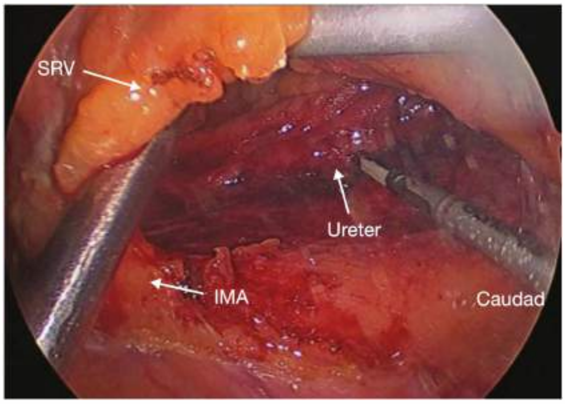

FIG 12 ● Identification of the left ureter. After dissection of the IMA/SRV off the retroperitoneum, the left ureter is visualized and preserved intact prior to IMA transection.

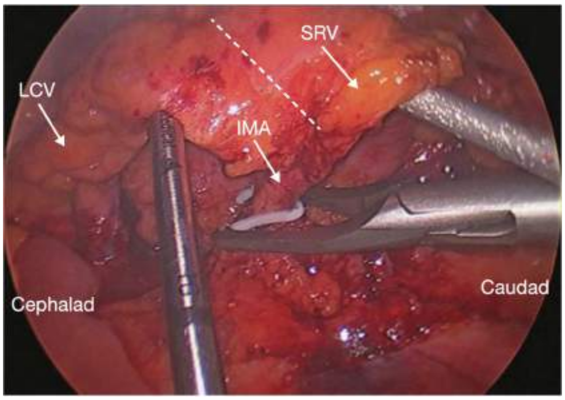

FIG 13 ● IMA transection. The IMA is transected between endovascular clips at its origin off the aorta ("high" IMA ligation). If a high IMA ligation is not needed to achieve a tension-free anastomosis, a "low" transection can be performed across the LCV *(dotted line)*, preserving the IMA/SRV intact.

- The rectosigmoid junction and mesentery are further mobilized. The upper mesorectum is divided with the energy device and the upper rectum is divided with an endoscopic linear stapler via the 12-mm SP port. The specimen is placed in endoscopic pouch and can subsequently be removed via the ST at a later stage.

- When there is a rectal stump from the previous surgery
  - If the IMA and upper rectum were divided at the time of the initial procedure, the rectal stump is identified and its end is mobilized. Rectal stump mobilization can be aided by per anal insertion of lubricated rectal "sizers" (by a second assistant or the scrub nurse).
  - If the proximal colonic end has adequate length to ensure a tension-free anastomosis, no further proximal mobilization is required.
  - If necessary, additional mobilization of the descending colon, splenic flexure, and high division of the IMA (if not previously transected) using surgical team configuration 3 may be required.
  - It is better to "overmobilize" rather than "undermobilize" the colon to achieve a tension-free anastomosis.

Colorectal Anastomosis

- Using surgical team configuration 1, the stoma is mobilized. In patients with a thin abdominal wall, we incise the mucocutaneous border circumferentially. In obese patients with a thicker abdominal wall, we use an elliptical skin incision inclusive of the stoma with the long axis of the ellipse oriented transversely.
- The stoma is mobilized to the peritoneal cavity by means of sharp dissection. A short segment of the colonic end is resected to ensure the subsequent anastomosis is formed using a healthy, scar-free, colonic end.
- A purse-string applicator clamp is placed across the colon at the resection site. The colon is cut distal to but flush with the purse-string clamp. The short colonic segment is discarded. The clamp is released and the cut edges are gently grasped with two Babcock forceps. The anvil of a 28 or 29F end-to-end anastomosis circular stapling device is inserted into the colonic end and the purse string ligated to ensure closure of the colonic end around the stem of the anvil. The colonic end and anvil are internalized into the peritoneal cavity.
- If a resection of distal sigmoid/rectal stump has occurred, the specimen can be removed in a bag via the ST defect after insertion of an appropriate wound protection device.
- The ST fascial defect is closed craniocaudally with interrupted 0 absorbable sutures.
- Using surgical team configuration 2 with Trendelenburg positioning and after re-instigation of the pneumoperitoneum, an end-to-end the stapler colorectal anastomosis is fashioned (**FIG 14**).

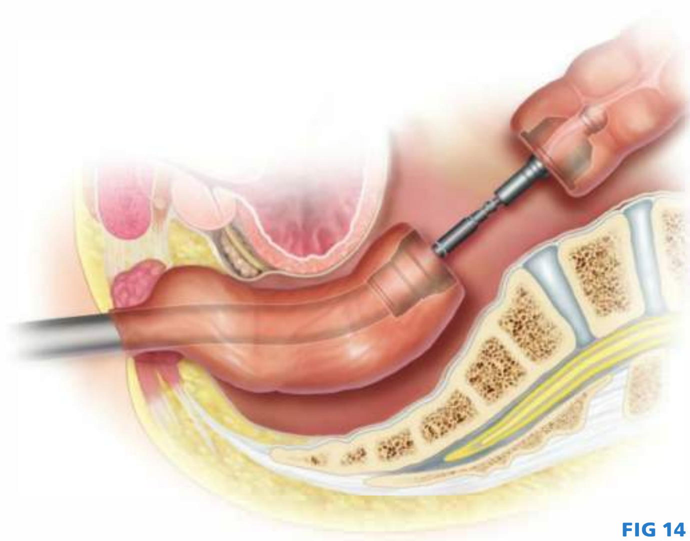

FIG 14 ● Stapled end-to-end colorectal anastomosis.

- The stapler is inserted per anally, either by the surgeon or an experienced assistant, to the proximal limit of the rectal stump under laparoscopic visualization.
- The stylet of the stapler is advanced through the proximal end of rectal wall. The anvil and colonic end are grasped and the shaft of the anvil is "docked" onto the stylet. Colonic and mesenteric orientation is checked. The stylet, with anvil attached, is retracted into the head of the stapling device until appropriate tissue compression is achieved, ensuring no adjacent structures (e.g., vagina) are incorporated.
- The stapling device is deployed. The stapling device is partially opened and removed per anally. Proximal and distal "donuts" are assessed for completeness.
- The colonic mesentery is inspected to ensure no small bowel is herniated deep to it.
- The integrity of the anastomosis is tested by air insufflation under water. The presence of air bubbles would indicate an anastomotic leak, necessitating a revision of the anastomosis. A pelvic drain is not used unless the anastomosis is extraperitoneal.
- Ports are removed. The fascial defect of any 12-mm ports are closed with a 0 absorbable suture and the port site skin incisions are closed with 4-0 absorbable suture.
- The ST wound is lavaged with saline. Long-acting local anaesthetic is infiltrated into the fascia and subcutaneous tissues.
- If a circumferential incision was initially used, the skin defect is reduced down to a 5- to 10-mm diameter defect by means of a subcuticular purse-string 3-0 absorbable suture. An absorbent occlusive dressing is applied.
- If an elliptical incision was initially used, the skin is closed with interrupted 3-0 absorbable subcuticular sutures. An occlusive dressing is applied.

PEARLS AND PITFALLS

Important principles	■ Adequate preoperative preparation and planning ■ Adequate mobilization ■ Good blood supply ■ Appropriate aperture diameter
Permanent stomas	■ End colostomies are preferable over loop or double-barreled colostomies. ■ Consider prophylactic mesh placement, especially in patients at risk of parastomal hernias. We use the laparoscopic "buttonhole" or Sugarbaker techniques.
Transverse colostomies	■ Avoid compromise to the left branch of the middle colic vessels, especially in situations in which the IMA may have been divided or compromised.
Tips in the obese patient	■ Aggressive preoperative weight loss is advisable: It reduces the thickness of the abdominal wall and the mesenteric bulk. ■ More extensive mobilization is required due to thicker abdominal wall. ■ Site the stoma further cranially than the standard position: The abdominal wall adipose tissue will be displaced caudally when the patient sits or stands. Also, the abdominal wall is thinner in the upper abdomen. ■ End colostomies are easier to construct and associated with fewer complications. The length available is superior, the mesenteric bulk is less, and the trephine aperture required is less. ■ A small Alexis™ wound protector/retractor placed through the ST often aids passage of the stoma. Cutting the inner ring aids removal of the device.

POSTOPERATIVE CARE

- Routine postoperative DVT prophylaxis is standard. An enhanced recovery style progression is routine with early mobilization and return to full diet.
- If a stoma has been created, stomal education should commence as early as possible (on the first postoperative day), as competency of stomal care is often the determining factor delaying patient discharge.
- When a colorectal anastomosis has been performed, our practice is to leave a rectal catheter in situ for 3 to 5 days. The rectal catheter is flushed with 20 mL of saline three times per day and remains in situ until the patient is passing flatus via or past the rectal catheter.

COMPLICATIONS

- Bleeding
- Anastomotic leak
- Wound infection
- Parastomal abscess
- Fistula
- Stomal retraction/stenosis
- Skin irritation/ulceration
- Stomal prolapse
- Parastomal or incisional hernia

Chapter 44

Surgical Management of Hemorrhoids

Bidhan Das

DEFINITION

- Hemorrhoids are a normal constituent of normal anorectal anatomy. The terms "hemorrhoid" or "hemorrhoidal disease" effectively refer to conditions related to the vascular cushions of the anal canal. The goal of any hemorrhoid treatment plan is the control of symptoms, rather the removal of these vascular cushions as a rule.
- Hemorrhoids by their definition classically by Thomson in 1975 are specialized structures that act as vascular cushions contained within the submucosal space of the anal canal. It is thought that they serve to maintain closure of the anal canal and contribute to fecal continence.
- Hemorrhoidal tissue is not necessarily limited to the three cardinal "quadrants," and commonly, additional hemorrhoids in between these quadrants are found. Interestingly, hemorrhoidal tissue is neither artery nor vein, noting that histologically, they have no muscular wall and are, in fact, sinusoids.
- Hemorrhoid pathology is classified as either internal or external (**FIG 1**), relative to its position at the dentate line, and internal hemorrhoids are graded according to severity of symptoms. It is exceedingly important to understand this functional anatomy before choosing the type of operative therapy.
- Operative hemorrhoidectomy classically describes the removal of both internal (proximal to the dentate line) and external hemorrhoidal tissue (distal to the dentate line). However, new advances and procedures such as Doppler-guided hemorrhoidal ligation or transanal hemorrhoidal dearterialization (THD) can be performed with less pain and enhanced recovery times, as there is no cutting of the anoderm, and the operative field is proximal to the dentate line.
- Excisional hemorrhoidectomy remains the gold standard operation to which all treatments are compared, as its safety as well as durability has withstood the test of time. However, it remains a painful operation, and other measures may be weighed against a possibly higher recurrence rate with substantially reduced postoperative pain.
- Furthermore, with the rising population of patients on full anticoagulation because of the growing ability to treat severe cardiovascular diseases as chronic illnesses, older techniques such as sclerosant therapy become handy operative tools for the acutely bleeding patient, in whom further suturing runs the risk of further bleeding.

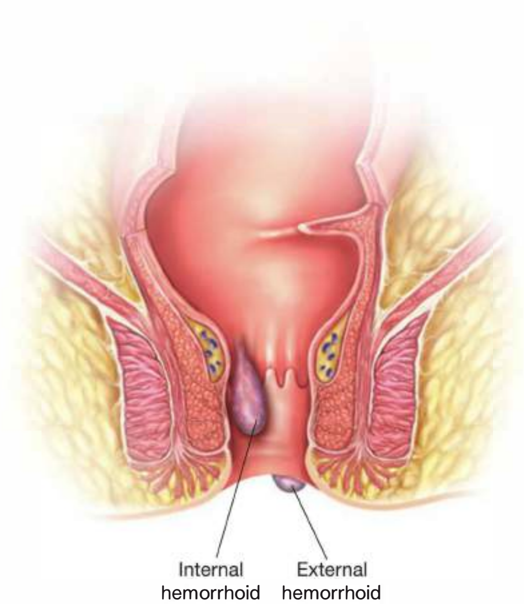

FIG 1 ● Internal versus external hemorrhoids. Position of the hemorrhoids relative to the dentate line *(dotted arrow)* classifies them as internal (proximal to the dentate line) or external (distal to the dentate line).

DIFFERENTIAL DIAGNOSIS

- Anal cancer, particularly melanoma
- Rectal prolapse (**FIG 2A,B**)
- Anorectal varices
- Perianal cyst disease
- Anal condyloma
- Pedunculated polyps
- Protruding anal papillae
- Anal skin tags, particularly sentinel tags associated with anal fissures
- Crohn's disease

PATIENT HISTORY AND PHYSICAL FINDINGS

- In order to treat hemorrhoids effectively, the other items in the differential diagnosis must be ruled out. Additionally, when considering surgical options, the pain of a traditional hemorrhoidectomy may be avoided by other methods that treat internal hemorrhoidal disease. Accurate diagnosis and determination of internal versus external hemorrhoidal disease must be ascertained to decide on the best operation for the patient.
- A thorough history and physical should be performed prior to treatment, including a detailed past medical history, present medications and allergies, and particularly conditions such as cirrhosis or previous treatment with radiation.
- Toileting behaviors, alteration in bowel function, and dietary changes must also be noted.
- Conditions that impair venous drainage, push vascular cushions outward, behavioral/toileting abnormalities, and changes in sphincter function are all commonly believed to contribute toward worsening hemorrhoidal symptoms. Ultimately, venous congestion with subsequent hypertrophy of internal hemorrhoidal cushions leads to symptomatic hemorrhoids.

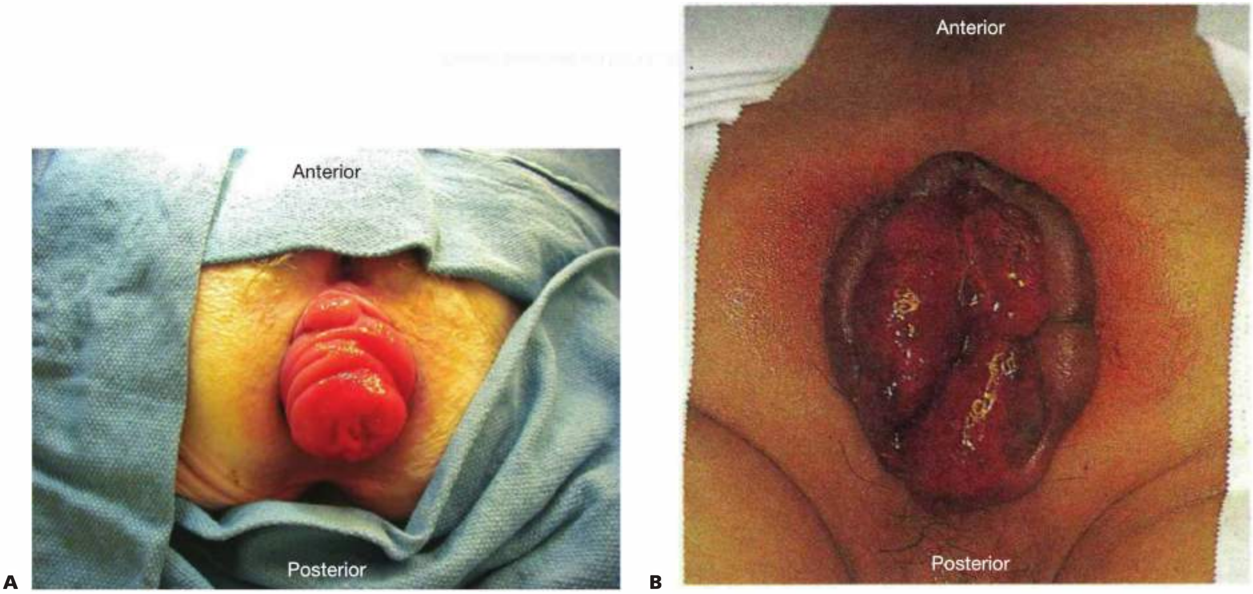

FIG 2 ● Rectal prolapse. It is important to differentiate **(A)** rectal prolapse from **(B)** prolapsing internal hemorrhoids.

- Prolonged straining increases abdominal pressure, which then impairs venous return, thus making the hemorrhoidal cushions unable to decompress transient congestion. Supportive tissues of the cushions then become gradually more and more attenuated, leading to prolapse of the cushion. Further prolapse then increases the possibility of trapping blood in the cushions with less abdominal pressure, thus causing progressive enlarging. Continued prolonged straining is an important preoperative history point because the behavior will need to be modified in the postoperative period to reduce pain and can worsen the efficacy of suture ligation operations.
- Dietary factors and toileting behavior are also critical issues because they not only impair postoperative recovery, but they can also promote postsurgical anal fissures, compounding a difficult postoperative recovery.
- Cirrhotic patients are at high risk for having anorectal varices, which are often mistaken for hemorrhoidal cushions. Elective hemorrhoidectomy for anorectal varices is fraught with excessive bleeding even to the point of hemodynamic instability in the stable patient once dissection for a misdiagnosis has started.
- A complete rectal examination, which includes not just a digital rectal examination (DRE) but anoscopy and proctoscopy, is essential to the diagnosis. It is important to distinguish between rectal prolapse versus mucohemorrhoidal protrusion. Proctoscopy aids in the diagnosis of inflammatory bowel disease while allowing control of bleeding and biopsy. The number, location, grade designation, and relative size of hemorrhoids should be noted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Given a thorough physical examination, imaging or other diagnostic modalities are rarely indicated.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients do not require bowel preparation for hemorrhoidectomy of any kind. Often, a simple enema before operation is sufficient for evacuation of the rectum. A rigid proctoscopy in the operating room before starting the procedure not only completes the preparation but also reviews the rectal mucosa for any signs of inflammation that may alter the surgical therapy or alert the surgeon to a heretofore unknown cause of straining.
- The operation can be performed using a number of anesthetic choices and options, including: general anesthesia, local anesthesia with intravenous sedation, or even regional anesthesia.
- Sequential compression devices (SCDs) are placed on the patient prior to the induction of general anesthesia.
- When performing a THD procedure, a patient should be examined for the presence of external hemorrhoidal disease. The operating surgeon may feel that there is more benefit in performing a traditional hemorrhoidectomy when there is a substantial external component that could be worsened by an internal ligation procedure, which could cause subsequent levator spasm and tenesmus postoperatively.
- When performing rubber band ligation of internal hemorrhoids, an office setting is most often well tolerated.

Positioning

- Multiple positions are excellent for hemorrhoidectomy operations, including lateral Sims position (**FIG 3**), prone jackknife (**FIG 4**), or high lithotomy (**FIG 5**) using C-type "candy cane" footholders. Anesthesia concerns and surgical needs often are satisfied with the use of high lithotomy position. It is important to note that for prone jackknife, the folding mechanism of

FIG 3 ● Sims position.

the operating table should be at the patient's hip for maximal exposure, whereas in lithotomy the sacrum should be at the very edge of the bed. In smaller patients, a flattened and folded blanket or bedroll can be placed under the sacrum to provide some elevation of the perineum and forward projection.

- Lithotomy patients using the C-type footholders often benefit from 45-degree angling of the footholder base toward the patient's head, whereas the "C" should be orthogonal to the patient's body. SCD/Venodyne boot cords can be tucked behind the adjustment flanges of the footholders. Such a position pushes the patient's knees cephalad and feet medially.
- For lithotomy patients undergoing either traditional hemorrhoidectomy or THD, an under-the-buttocks drape with a plastic drain pocket can be used to store the Doppler device or to clip instruments while suture ligating or sewing for ready access.

FIG 4 ● Prone jackknife position.

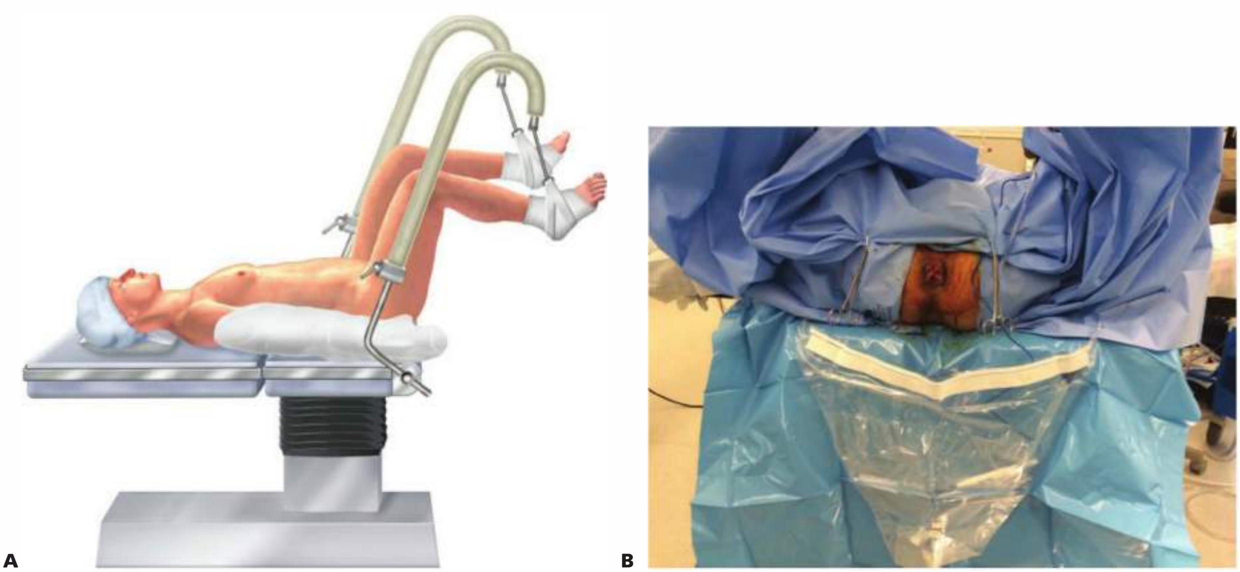

FIG 5 ● **A.** Lithotomy position with C-type (candy canes) footholders. **B.** Final Setup for High Lithotomy with Under-the-Buttocks drape with plastic pouch; white band can be used to hold instruments.

TRADITIONAL EXCISIONAL HEMORRHOIDECTOMY (CLOSED FERGUSON TECHNIQUE)

Delineation of Hemorrhoidal Cushions and Skin Incisions

- After performing a proper anoscopy using serial dilation of graded Hill-Ferguson retractors, a hemorrhoidal bundle can be readily exposed. Using a forceps or hemostatic clamp, the hemorrhoidal cushions can be gathered to facilitate the skin incision, which should spare the anoderm but include the hemorrhoidal bundle. This incision can be minimized by undermining directly underneath the hemorrhoidal bundle at the distal aspect and cutting inward directly into the anal canal to start the dissection (**FIG 6**).

Dissection of the Hemorrhoidal Vascular Tissue from the Internal Sphincter

- After cutting directly under the hemorrhoid bundle distally and through the dermis, a Metzenbaum scissor

FIG 6 ● Delineation of hemorrhoidal cushions and skin incision. Elevation of the anoderm with a clamp distal to the hemorrhoidal cushion allows for a precise incision.

carefully and sharply separates the vascular submucosal tissues from the adherent, often fibrous internal sphincter and intersphincteric groove (**FIG 7**).

- A rule of thumb: Dissect the sphincter from the hemorrhoid rather than hemorrhoidal tissue from the sphincter.

Continued Skin Excision and Pedicle Isolation

- As the surgeon dissects the sphincter off the hemorrhoid, a substantial "tunnel" is created; to save anoderm, the edges of the "tunnel" are simply cut directly toward the proximal aspect of the hemorrhoid, which can help make the operation progress by better easily delineating the hemorrhoidal bundle.
- As the incision reaches a point proximally, the hemorrhoid bundle is delineated completely and isolated cephalad, and in such a manner the vascular pedicle of the hemorrhoid is effectively isolated.

Pedicle Clamp, Specimen Removal, and Suture Ligation

- With the hemorrhoidal tissue narrowed down to a pedicle, this vascular structure can be clamped with a hemostat, the specimen cut and removed, and a suture ligature of absorbable suture can be applied, leaving the tail long (**FIG 8**).

Closure

- Using the same suture and the pedicle suture ligation as an elevated anchor, continuous (**FIG 9**) or running, locking bites can be taken to close the incision, grabbing small fibers of the internal sphincter as one works distally to anchor the cut edges and promote hemostasis.
- Upon leaving the limits of the anal sphincter and thus the mucosa, no further deeper tissue anchoring is used. One variant of the closure is to tie the suture to itself, every two bites, which can effectively act as a mucosal proctopexy until the end of the mucosal opening is reached. The suture is tied to itself at the distal aspect of the anoderm.
- The same process is repeated in the other two quadrants and can be modified for areas that are not in the traditional quadrants.

A 
B

FIG 7 ● **A.** Dissection of the hemorrhoidal vascular tissue from the internal sphincter. Using scissors, dissect the sphincter from the hemorrhoid rather than hemorrhoidal tissue from the sphincter. **B.** The pedicle is isolated.

A

FIG 8 ● **A.** Suture ligation of hemorrhoidal vascular pedicle. After the hemorrhoidal pedicle has been transected at its origin and the hemorrhoidal tissue has been removed, the pedicle is suture ligated for hemostasis. **B.** Suture is kept long, as an anchoring stitch.

Hemostasis Assessment and Packing

- After completion of hemorrhoidectomy, a repeat examination using Hill-Ferguson retractors is performed to ensure continued hemostasis. After verification of hemostasis, a Surgicel is tucked into the anal canal, which can be removed at any time or with first flatus or defecation. Should bleeding be encountered, an interrupted suture or figure-of-eight suture can be applied liberally.

FIG 9 ● Closure. Using the same suture and the pedicle suture ligation as an elevated anchor, continuous or running, locking bites can be taken to close the incision, grabbing small fibers of the internal sphincter as one works distally to anchor the cut edges and promote hemostasis.

RUBBER BAND LIGATION OF HEMORRHOIDS

Isolation of the Hemorrhoidal Cushion

- Anoscopy is performed using serial dilation of either graded Hill-Ferguson retractors or office anoscopy (Buie, Hirschman, lighted Welch Allyn) to demonstrate that there is an internal hemorrhoid of grade II or III classification.
- Pressure can then be placed against the anoscope, which will make the already protruding hemorrhoid even more prominent (**FIG 10**).

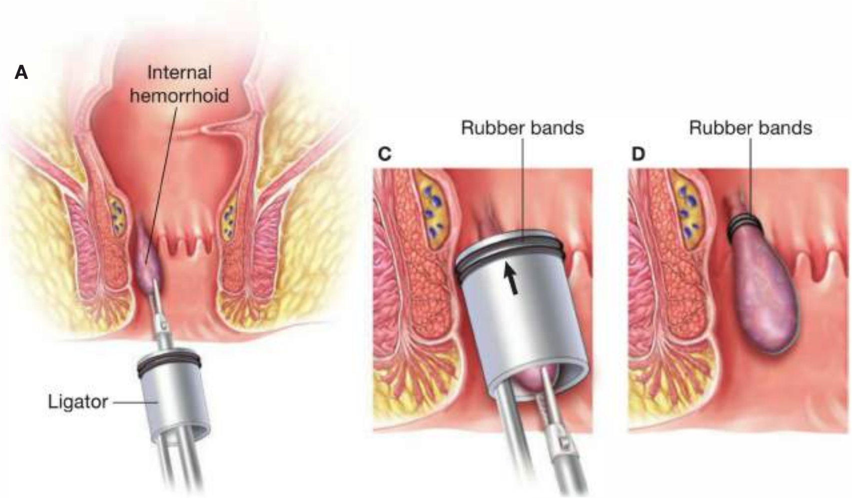
FIG 10 ● Hemorrhoidal banding: isolation of the hemorrhoidal pedicle with an anoscope.

Rubber Band Application

- With the anoscope pressure being maintained, a Barron ligator is used to ligate the hemorrhoid (**FIG 11**) by first passing the hemorrhoid-seizing forceps through the window of the ligator after the ligator has been loaded.
- The forceps then grab the protruding internal hemorrhoid as broadly as possible (**FIG 11A,B**) and the ligator is pushed directly down onto the hemorrhoid until the base of the hemorrhoid is reached while seizing forceps has the hemorrhoid still elevated.
- The ligator fires the rubber band around the base of the hemorrhoid (**FIG 11C**). It is of the *utmost* importance that the ligation is performed definitively proximally to the dentate line (**FIG 11D**).

Maintenance of Band Ligation

- To complete the procedure, a fine gauge short needle (25 gauge) is used to instill 2 to 3 mL of local anesthetic submucosally on the "cap" of the ligated hemorrhoid to create a large "mushroom" that will prevent slippage of the rubber band.



B

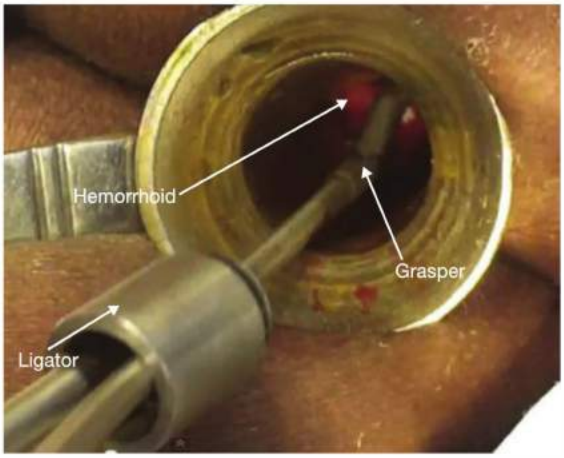


FIG 11 ● Rubber band application. **A,B.** The forceps grab the protruding internal hemorrhoid as broadly as possible. **C.** The ligator is pushed directly down onto the hemorrhoid until the base of the hemorrhoid is reached. **D.** The ligator fires the rubber band around the base of the hemorrhoid. It is of the *utmost* importance that the ligation is performed definitively proximally to the dentate line *(dotted arrow)*.

SUTURE LIGATION OF INTERNAL HEMORRHOIDS

Suture Ligation

- After anoscopy demonstrates the internal hemorrhoid, a figure-of-eight suture of absorbable suture material is placed to completely encompass the hemorrhoidal bundle without passing the needle through the cryptoglandular interface and thus reducing the chance of abscess.
- The suture is tied in such a way that the knot lies toward the most cephalad portion of the internal hemorrhoid. Such a placement can sometimes gather and fixate the internal hemorrhoid proximally in addition to the vascular ligation.

DOPPLER-GUIDED LIGATION OF THE HEMORRHOIDAL TERMINAL ARTERY BRANCHES AND MUCOSAL PROCTOPEXY USING TRANSANAL HEMORRHOIDAL DEARTERIALIZATION DEVICE

Isolation of Distal Branches of the Hemorrhoidal Arteries

- The THD device is a specifically designed anoscope/proctoscope equipped with a Doppler probe that faces outward and a light source attached to a pivot cage for a specifically designed suture and needle driver set (**FIG 12A**). Continuous Doppler audio waveform is provided with a double crystal that is made to focus and capture the larger diameter arteries located in the superficial layers of the rectal wall.
- Following lubrication and a thorough anoscopy using serial dilation with graded Hill-Ferguson retractors, the proctoscope is inserted through the anal canal reaching the distal rectum (roughly 6 to 7 cm from the anal verge).
- By moving the proctoscope with the Doppler ultrasound activated, one can hear the waveforms generated and isolate the six strongest waveforms that correlate to six equidistant positions around the anal canal (**FIG 12B**).

Transfixion with Suture Ligature

- Once a hemorrhoidal artery is located, the rectal mucosa and submucosal wall are transfixed with a figure-of-eight/"Z-stitch" to ligate the artery (**FIG 12C**). This transfixion suture is performed with the provided 2-0 absorbable polyglycolic acid with a $^{5}/_{8}$-in needle at the prefabricated notch, inserting the needle driver tip into the provided pivot cage (**FIG 12D**), which is in the center of the proctoscope's lumen. The pivot cage is used twice to perform an appropriate figure-of-eight/Z-stitch to ligate the artery.
- The suture is then tied after the Doppler probe is removed. This removal allows the operating surgeon's finger to slide deep into the anal canal to set the knot. The tail is left long, as this suture will act as an anchor for the upcoming mucosal proctopexy.

Mucosal Proctopexy

- Holding the THD proctoscope as a continued retractor and holding the long anchor tail against the scope, mucosal and submucosal bites can be taken to eliminate the prolapse of the hemorrhoid or mucosa. These bites are taken distal to the transfixion site at a step size of half a centimeter and can be tied back to the anchor stitch to create the "mucopexy" (**FIG 13**).
- Note that this mucopexy terminates at least 5 mm proximally to the dentate line and is tied to the first anchor stitch for a substantial mucosal proctopexy and to avoid potential abscess formation.
- This procedure is repeated five more times for a completed procedure.
- At the conclusion an anoscopic examination of each suture site is performed to verify no undue bleeding which can be treated with suture ligation. A Surgicel light packing is placed in the anal canal and can be removed any time or by first flatus or defecation.

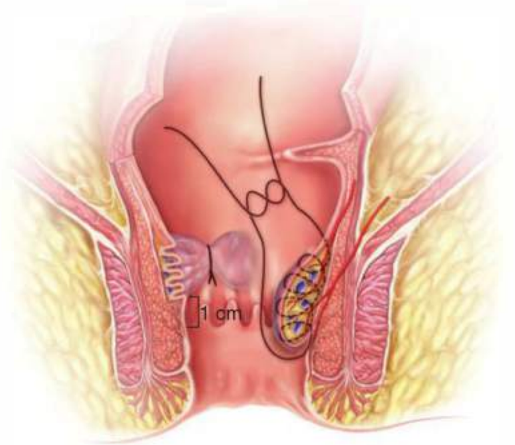

FIG 13 ● Mucosal proctopexy. Holding the THD proctoscope as a continued retractor and holding the long anchor tail against the scope, mucosal and submucosal bites can be taken to eliminate the prolapse of the hemorrhoid or mucosa. These bites are taken distal to the transfixion site at a step size of half a centimeter and can be tied back to the anchor stitch to create the mucopexy. This mucopexy terminates at least 5 mm proximally to the dentate line and is tied to the first anchor stitch for a substantial mucosal proctopexy and to avoid potential abscess formation.

TECHNIQUES

SCLEROSANT INJECTION OF HEMORRHOIDS

Delineation of Hemorrhoidal Cushions and Verification of Anatomy

- After performing a proper anoscopy using serial dilation of graded Hill-Ferguson retractors, a hemorrhoidal bundle can be readily exposed using a Hill-Ferguson retractor with countertraction provided by the opposite hand holding a gauze. At this point, it is essential to note that there should be no external component and that the internal hemorrhoids to be targeted are grades I and II.
- Using an angled spinal needle (18- to 22-gauge with a bend of 30 degrees an inch from the tip), the proximal aspect of the hemorrhoidal bundle is found and a submucosal injection of a sclerosant solution of the surgeon's choice, usually between 3 and 5 mL in volume, is performed (**FIG 14**).
- Accurate injection reveals swelling of the mucosa without blanching of the mucosa, with a "striation sign" indicative of bridging hemorrhoidal veins.

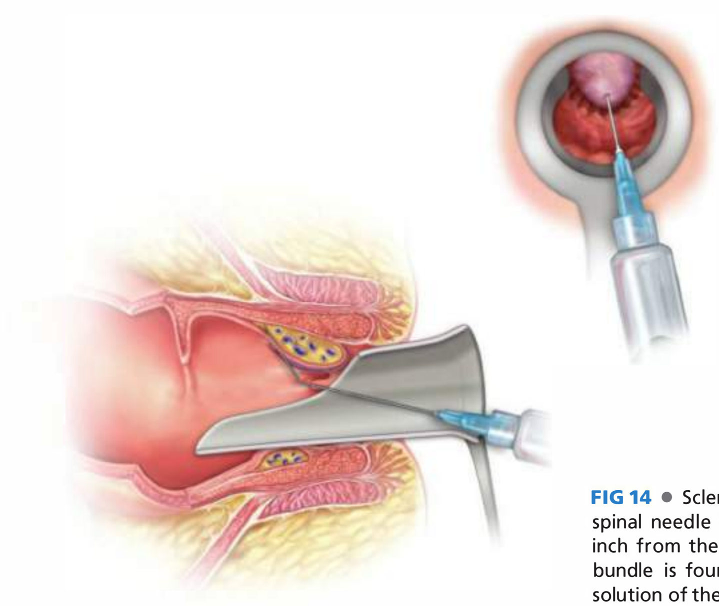

FIG 14 ● Sclerosant injection of hemorrhoids. Using an angled spinal needle (18- to 22-gauge with a bend of 30 degrees an inch from the tip), the proximal aspect of the hemorrhoidal bundle is found and a submucosal injection of a sclerosant solution of the surgeon's choice, usually between 3 and 5 mL in volume, is performed.

PEARLS AND PITFALLS

Indications	■ A thorough evaluation of the anorectum with classification of the hemorrhoidal cushions is essential in picking the optimal procedure. ■ Ruling out inflammation or prior radiation can help prevent wound complications. ■ Operative hemorrhoidal treatment requires a failure of conservative therapy. ■ Sclerotherapy has limited indications but is invaluable in the anticoagulated patients, as it creates no bleeding. ■ Doppler-guided techniques are for those with internal hemorrhoidal disease without external components.
Incisions	■ Sparing the anoderm reduces postoperative pain and anal stenosis. ■ In traditional hemorrhoidectomy, isolation of the hemorrhoidal pedicle can be done as soon as the hemorrhoidal bundle narrows. Never "chase the hemorrhoid" proximally into the rectum—it can be very difficult to ligate a lost "bleeder" appropriately if it retracts and such a proximal dissection will not improve the patient's symptoms of bleeding, irritation, or prolapse.

Dissection and suturing	■ Including fibers of the underlying sphincter during running closure of the mucosal gap may prevent a dissection-based hematoma. ■ When performing a mucosal proctopexy or a suture ligation, it is important that the stitch remains proximal to the dentate line to prevent cryptoglandular interface abscess formation. ■ Using a long initial anchor stitch for the hemorrhoidal pedicles can always provide a mucosal proctopexy by gathering the mucosa and tying back to the anchor while closing. ■ In order to reduce the risk of anal stenosis, minimize the amount of normal tissue resected/incorporated between hemorrhoidectomy sites. A small anodermal incision with submucosal dissection of the vascular tissue may also help.
Hemostasis	■ Surgical hemostasis is paramount. ■ Up to 5 to 8 postoperative days, the hemorrhoidal pedicle can slough or suffer from infection and cause pronounced bleeding. ■ Most postoperative bleeding occurs as a result of poor ligation and requires urgent suture ligation.
Proctopexy	■ Although the anchor stitch is often well affixed, the mobility of mucohemorrhoidal prolapse makes for an insufficient proctopexy if the knot that is made between the anchor and the running suture is not set proximally by the operating surgeon. The proctopexy is meant to gather the mucosal tissues and slide them cephalad; as such, the knot must lie near the anchoring suture, not toward the anal verge.
Rubber band ligation	■ It is imperative that the band is placed 1 to 2 cm proximal to the dentate line to minimize postbanding pain. ■ Many surgeons only band one hemorrhoid at each visit to minimize discomfort; multiple ligations are associated with greater pain, vasovagal syncope, and urinary retention. ■ Should vasovagal symptoms or substantial discomfort occur, injection of a local anesthetic with epinephrine can be performed to help alleviate symptoms; perhaps, the best treatment is to remove the band. ■ Although banding seems trivial, there are several reported cases of necrotizing pelvic infections leading to sepsis and even death after elective band ligation. It is also advised that the surgeon be mindful of treating the immunocompromised patient.
Sclerotherapy	■ Some surgeons are concerned about intravenous injection of sclerosant, so withdrawal with the injecting needle is helpful before injecting. ■ Intramucosal injection (induces mucosal blanching) must be avoided because it can lead sloughing and ulcerations. ■ No mucosal swelling, however, may mean the injection is too deep and can result in prostatic abscess, pyelophlebitis, and small soft tissue/rectal ulceration.

POSTOPERATIVE CARE

- These operations can all be safely performed in the outpatient setting.
- A bare minimum of intravenous fluids should be administered to reduce the risk of postoperative urinary retention. We limit our intraoperative fluid use to less than 200 mL.
- Routine use of diluted liposomal bupivacaine (Exparel) has dramatically reduced postoperative pain, shortened recovery, and reduced postoperative narcotic use.
- Postoperatively, warm water tub soaks are used to relax the levators, reduce levator spasm, and alleviate urinary retention.
- Postoperatively, we prescribe a low-dose narcotic (hydrocodone-acetaminophen), an oral nonsteroidal antiinflammatory drug (NSAID) (ketorolac 10 mg three times a day for 5 days), and a low-dose muscle relaxant (diazepam 2 mg orally three times a day to assist with pelvic floor spasm). Prescription narcotic medications are unnecessary after in-office rubber band ligation.
- The patient is given instructions to consume a high-fiber diet (25 g per day), slowly increase water intake to match fiber intake, refrain from straining, and consume a daily or twice-daily dose of a stool softener such as polyethylene glycol.
- Signs and symptoms of vasovagal episodes or pelvic sepsis are explained to the patient.

OUTCOMES

- Operative excisional hemorrhoidectomy has, by far, the lowest recurrence rate but results in increased patient pain postoperatively. Recurrence rates are quoted at 1.4%.
- Doppler-guided ligation is a newer modality of treating hemorrhoids that still has yet to attain long-term follow-up data to accurately assess recurrence rates. In a study of 170 patients with a majority having grade III disease (82.7%), control of bleeding was obtained in 159 patients (93.5%) and control of prolapse in 152 (89.5%), with mean follow-up 11.5 ± 12 (range, 1 to 41) months.
- Eighty percent of patients with grade I or II hemorrhoids will note improvement in symptoms after rubber band ligation and up to 70% will remain completely symptom free. The recurrence rate, though, is higher with banding than with surgical excision.
- The results of sclerotherapy in resolving internal hemorrhoids have been evaluated in small trials and retrospective reviews. Many researchers have found the benefits of

injection therapy to be short-lived and somewhat comparable to diet control. However, in the actively bleeding/oozing anticoagulated patient, a modality that does not promote further bleeding may be invaluable. Khoury et al. prospectively randomized 120 patients with grades I and II disease to single versus multiple injections, with nearly 90% reporting resolution or improvement in symptoms 1 year after injection and no difference with regard to the number of treatment sessions required.

COMPLICATIONS

- Bleeding with severe hemorrhage (occurring less than 5% of all cases)
- Urinary retention
- Infection of closed hemorrhoidectomy sites
- Fecal impaction
- Anal stenosis
- Skin necrosis
- Intramucosal or suture abscess from ligation techniques
- Cryptoglandular abscess
- Tenesmus
- Persistent or excessive levator spasm
- Pelvic sepsis, necrotizing soft tissue infections, anorectal necrosis
- Systemic absorption of sclerosant solution leading to acute respiratory distress syndrome (ARDS)

Chapter 45 Surgical Management of Anal Fissures

Daniel Albo

DEFINITION

- An anal fissure is an acute longitudinal tear or a chronic ovoid ulcer in the squamous epithelium of the anal canal.
- They are also often referred to as fissure in ano.
- The exact etiology of anal fissures is debated. Risk factors that increase the likelihood of developing an anal fissure include the following:
  - Increased sphincter tone
  - Chronic constipation
  - Straining to have a bowel movement, especially if the stool is large, hard, and/or dry
  - Sedentary lifestyle
  - Sexual practices: anal intercourse, insertion of anal/rectal foreign bodies
  - Overly tight or spastic anal sphincter muscles: failure of relaxation of the anal sphincter during bowel movements
  - Decreased blood flow to the perianal skin
  - Scarring in the anorectal area
  - Inflammatory bowel disease, such as Crohn's disease and ulcerative colitis
  - Anal cancer, especially after radiation therapy
  - Tuberculosis
  - Sexually transmitted diseases (such as syphilis, gonorrhea, chlamydia, chancroid, HIV)
  - Leukemic infiltrates
  - Decreased blood flow to the anorectal area
  - Anal fissures are also common in women after childbirth and in young infants.
  - Women are more commonly affected than men (58% vs. 42%).

DIFFERENTIAL DIAGNOSIS

- Hemorrhoids (specially thrombosed hemorrhoids)
- Anal canal cancer
- Anal trauma

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with intense anal pain during and especially after defecation. The pain can last for several minutes to a few hours after having a bowel movement.
- Although patients are often asymptomatic between bowel movements, they often develop a "fear of defecation" and may try to avoid defecation secondary to the pain.
- Chronic constipation is common.
- Some bright red anal bleeding, especially on the toilet paper, is common.
- On physical exam, the anus appears tight and spastic. The pain is usually severe enough that the patient will not tolerate a digital rectal exam in the office.
- On anoscopy, which oftentimes is done under conscious sedation due to severe anal pain, the fissure is usually linear, although ovoid-shaped fissures are oftentimes seen as well.
- Anal fissures are almost universally present along the posterior midline in men and they are often associated with a sentinel skin tag at the squamous-columnar epithelial junction (anal verge). In women, they can also be seen on an anterior location (**FIG 1**).
- Anal fissures seen in Crohn's disease and tuberculosis are frequently painless.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnosis is made by visual inspection. Unless findings suggest a specific cause or the appearance and/or location is unusual, further studies are not required.
- In selected cases, flexible sigmoidoscopy or colonoscopy may be indicated.

SURGICAL MANAGEMENT

- The majority of anal fissures will resolve with medical management and will not require surgery.
- Medical management includes the following:
  - Aggressive prevention of constipation
    - Increase fiber and decrease fat in the diet
    - Fiber supplementation
  - Increase water intake

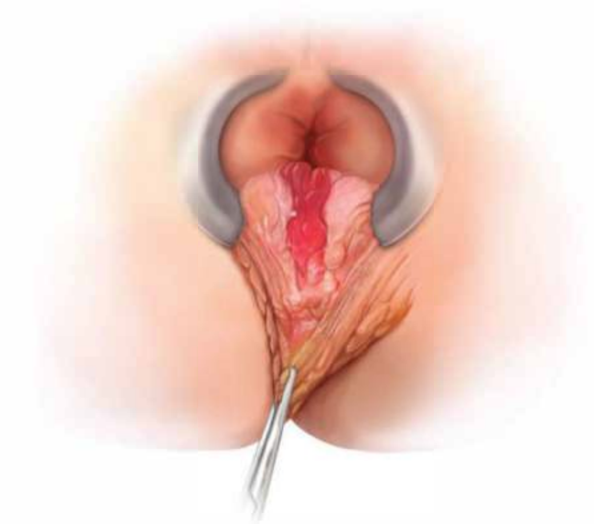

FIG 1 • Anal fissure. With an anoscope inserted in the anal canal, an anal fissure can be seen in the posterior midline of the squamous epithelium of the anal canal. A sentinel skin tag can be seen on the distal end of the fissure on the anal verge.

- Use of moist pads (flushable baby wipes) for wiping and anal hygiene
- Avoiding straining or prolonged sitting on the toilet
- Soaking in a warm bath (also called a sitz bath), 10 to 20 minutes several times a day, to promote the relaxation of the anal muscles

- These conservative measures lead to healing of the anal fissure in a few weeks to a few months in 80% to 90% of patients. However, when these conservative measures alone are not successful, pharmacologic intervention can also be instituted. This includes the following:
  - Topical nitrates ointment: Examples include nitroglycerin ointment 0.4% (Rectiv) and glyceryl trinitrate ointment (Rectogesic). Although effective, they are dose dependent. Disabling headaches are common at higher doses, making patient compliance with the treatment unreliable.
  - Topical calcium channel blockers, including nifedipine or diltiazem ointment, are as effective as nitrate ointments but with significantly less side effects. Examples include topical nifedipine 0.3% with lidocaine 1.5% ointment and diltiazem 2% ointment.
- Combination of medical therapies may offer up to 98% cure rates.
- A combined surgical and pharmacologic treatment, administered by colorectal surgeons, is periodic direct injection of botulinum toxin (Botox) into the anal sphincter to relax it. Oftentimes, these injections prove less and less potent with each application. With patients spending thousands of dollars and not achieving a permanent cure, they oftentimes elect to have surgery.
- When conservative medical therapy fails, surgery is considered.

Preoperative Planning

- Mechanical bowel preparation is not necessary.
- Fleet enemas are prescribed for the night before and the morning of surgery to clear the rectal vault.
- Intravenous cefoxitin is administered within 1 hour of skin incision.
- A preoperative time-out and briefing is conducted with the entire surgical team in attendance.
- An anal block with bupivacaine extended-release liposome injection is associated with both pain relief for 72 hours and a 45% reduction in total opioid consumption at 72 hours.

Positioning

- The patient is placed supine on a modified lithotomy position with the legs on padded stirrups to prevent neurovascular injuries to the calves (**FIG 2**).
- Alternatively, the patient can be placed in a prone jackknife position on a split-leg table, with the surgeon positioned between the legs (**FIG 3**). The buttocks are spread apart with tape.
- The author prefers to perform these procedures under general anesthesia.
- Using headlights is critical for good visualization.

FIG 2 ● Modified lithotomy position. The legs are placed on stirrups with padding to help prevent neurovascular injuries.

FIG 3 ● Prone jackknife position. The lower extremities are placed on a split-leg table position to allow the surgeon to operate from in between the patient's legs.

CLOSED LATERAL INTERNAL SPHINCTEROTOMY (TRANSCUTANEOUS)

- Using lubrication, perform a gentle anal dilation with two fingers.
- An anoscope is used to confirm the presence of the anal fissure.
- With the patient on a modified lithotomy position and palpating with the tip of your right index finger, identify the anal intersphincteric groove (**FIG 4**). The intersphincteric groove is a distinct groove in the anal canal, forming the lower border of the pecten analis, marking the change between the subcutaneous part of the external anal sphincter and the border of the internal anal sphincter.
- For the closed internal lateral sphincterotomy, the author prefers to use a cataract scalpel due to the vertical plane of the cutting edge of the blade (**FIG 5**), as opposed to the oblique plane of the cutting edge of a no. 11 blade. This makes it easier to cut the internal sphincter more evenly as the scalpel is withdrawn from the intersphincteric groove.
- Place your left index finger in the anal canal. In cases of HIV or hepatitis B/C infection, insert an anal speculum instead of inserting your own finger as a precaution to avoid potential transmission of communicable disease in case of inadvertent injury to your index finger during the sphincterotomy.
- Using a no. 11 blade scalpel on your right hand, create a small opening on the skin overlying the intersphincteric groove on the patient's left lateral side. Performing the closed lateral internal sphincterotomy on the anal canal's left lateral side is easier for a right-handed surgeon to perform (scalpel in your dominant hand).

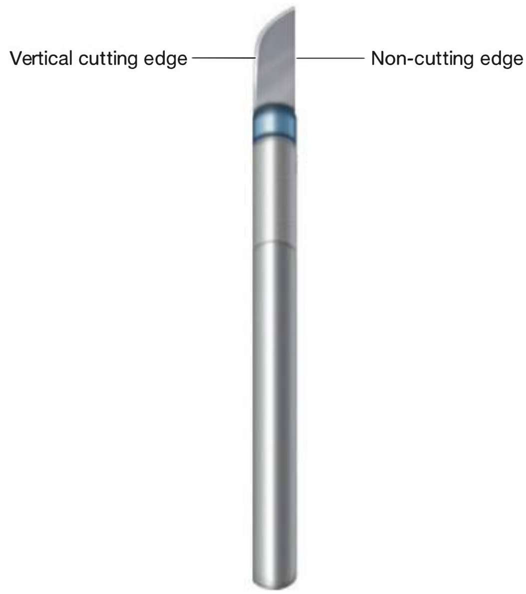

FIG 5 ● A cataract scalpel. This scalpel's blade has a vertical cutting edge and a blunt edge on the opposite side, making its shape and size ideal to insert in the intersphincteric groove.

- Introduce a cataract blade scalpel through this skin opening and into the intersphincteric groove, with the blade of the knife in between the internal and external anal sphincter muscles and until the tip of the blade is located just distal to the level of the dentate line (**FIG 6**). The blade should be inserted parallel to the sphincter

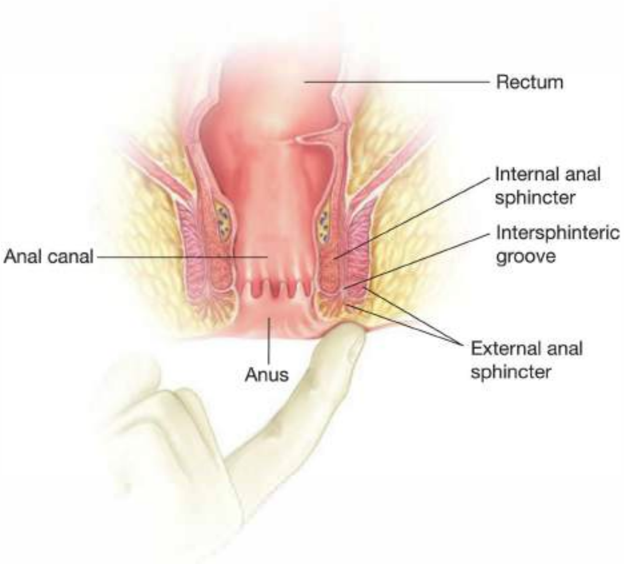

FIG 4 ● The intersphincteric groove. The intersphincteric groove can be easily palpated by the surgeon's right index finger between the external and internal anal sphincters.

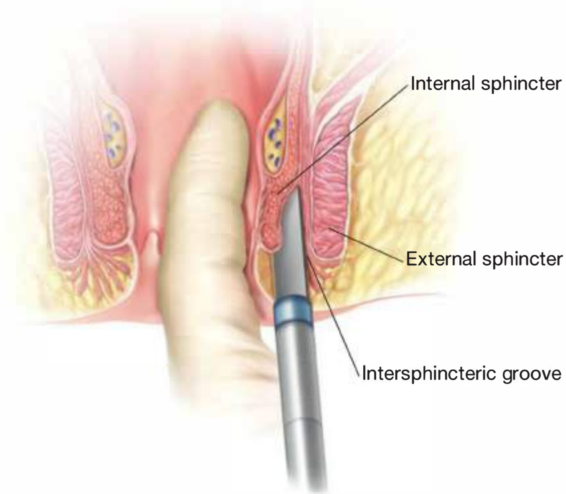

FIG 6 ● Closed internal lateral sphincterotomy: insertion of the cataract scalpel into the intersphincteric groove. The blade of the cataract scalpel is inserted into the groove, parallel to the plane of the sphincters, in order to avoid inadvertent injury to the external sphincter upon insertion.

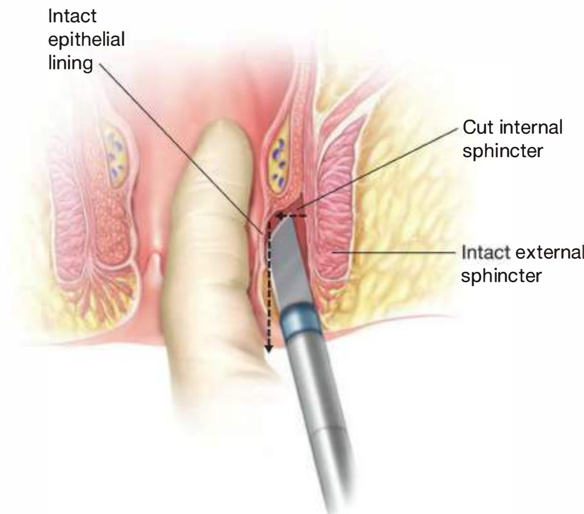

FIG 7 ● Closed internal lateral sphincterotomy. The cataract scalpel blade is first pushed internally toward the anal canal and is then withdrawn *(dotted arrows)*, cutting the internal sphincter in the process. The index finger inside the anal canal allows the surgeon to gauge the proper depth of transection through the sphincter without violating the epithelial lining of the anal canal.

muscles, so that it is oriented on an anterior/posterior direction, therefore preventing accidental cutting of the external sphincter on the way in.

- Alternatively, you can use a no. 11 blade scalpel if a cataract scalpel is not available.
- Now, turn the blade of the cataract scalpel 90 degrees so that the left lateral cutting edge is facing inward, toward the internal anal sphincter.
- Press the cutting edge of the blade toward your index finger (placed in the anal canal), cutting the internal sphincter in the process (**FIG 7**). As you withdraw the scalpel outward, finish cutting the internal sphincter evenly in one sweeping motion. Repeat this maneuver if necessary.
- If you transected the internal sphincter appropriately, you should feel the anus relax immediately.
- Avoid cutting the mucosa of the anal canal because this could lead to troublesome anal fistulae postoperatively. In the event that the anal canal mucosa is cut, reapproximate it with running fast-absorbable 3-0 suture. The presence of your index finger in the anal canal allows you to feel the blade as it cuts through the internal sphincter and helps prevent cutting the mucosa of the anal canal.
- Minor bleeding from the skin opening at the end of the procedure is not uncommon; holding pressure from inside and outside the anal canal is usually all that it is necessary to achieve hemostasis. If more troublesome bleeding occurs from the transected internal sphincter muscle bed, you can inject thrombin glue into the area and hold pressure. In the rare cases where the bleeding does not stop, you may have to open the overlaying mucosa of the anal canal to expose the bleeder and control it surgically.
- Place a tampon in the anal canal at the completion of the procedure for hemostasis; the patient can remove it postoperatively.
- In patients with large left lateral hemorrhoids, the closed lateral internal sphincterotomy can be performed on the patient's right lateral side, in between the right anterior and right posterior hemorrhoidal pedicles. This helps reduce the risk of bleeding from a transected hemorrhoidal pedicle. The technique used is the same as the one described here, but using your right index finger in the anal canal and cutting with the scalpel in your left hand.

OPEN LATERAL INTERNAL SPHINCTEROTOMY

- Using lubrication, perform a gentle anal dilation with two fingers.
- An anal speculum is inserted to confirm the presence of the anal fissure and to expose the anal canal.
- With the patient on a modified lithotomy position and palpating with the tip of your right index finger, identify the anal intersphincteric groove (**FIG 4**). The intersphincteric groove is a distinct groove in the anal canal, forming the lower border of the pecten analis, marking the change between the subcutaneous part of the external anal sphincter and the border of the internal anal sphincter.
- Make a radial incision with a no. 15 blade scalpel over the intersphincteric groove on the patient's left lateral side and extend it toward the anal canal for a distance of 1 to 1.5 cm (**FIG 8A**).
- Performing the open lateral internal sphincterotomy on the anal canal's left lateral side is easier for a right-handed surgeon to perform. In patients with large left lateral hemorrhoids, the closed lateral internal sphincterotomy can be performed on the patient's right lateral side, in between the right anterior and right posterior hemorrhoidal pedicles. This helps reduce the risk of bleeding from a transected hemorrhoidal pedicle.
- Using Metzenbaum scissors to develop a submucosal plane, separate the anal mucosa from the underlying internal sphincter (**FIG 8B**).
- The distal aspect of the internal anal sphincter and the medial aspect of the external anal sphincter are exposed.
- The intersphincteric groove is dissected gently with Metzenbaum scissors, completely separating the internal sphincter from the external sphincter.
- The internal sphincter is then transected full thickness (**FIG 8C**) under direct visualization with Metzenbaum

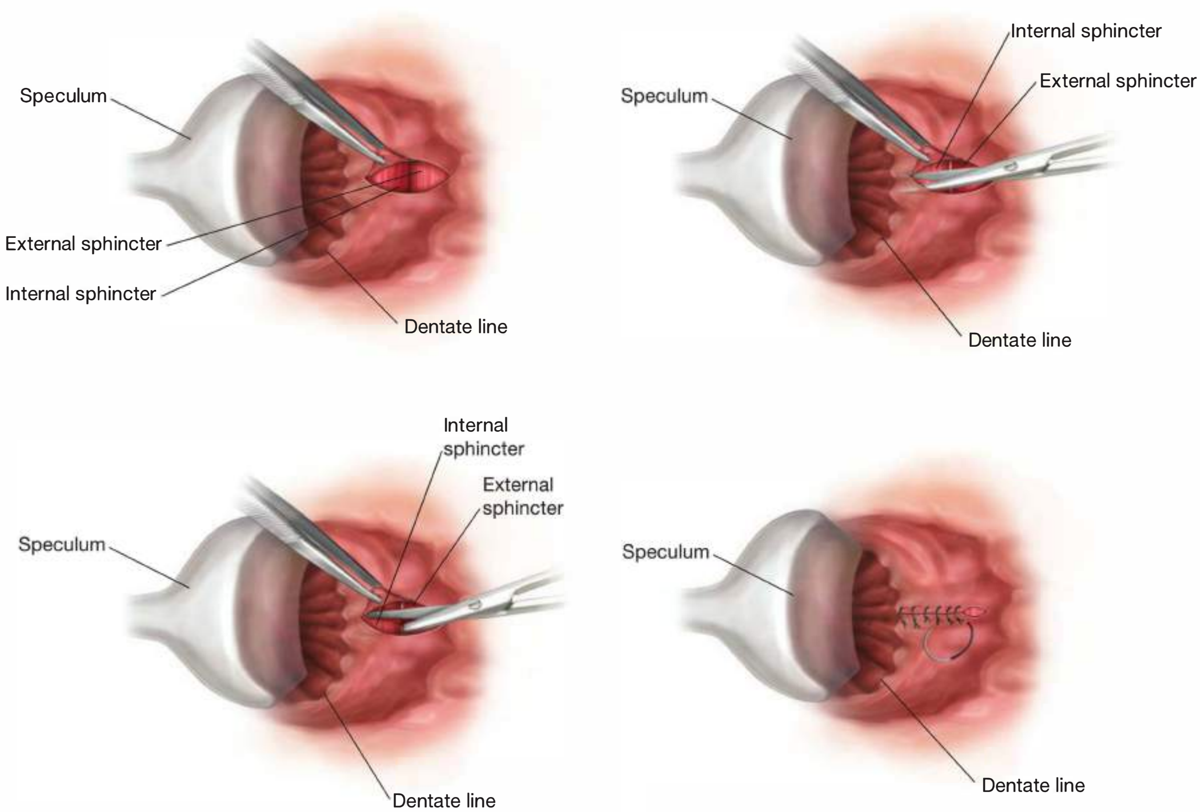

FIG 8 ● Open internal lateral sphincterotomy. **A.** A radial skin incision is made. **B.** A submucosal dissection is performed exposing the internal and external anal sphincters. **C.** The internal sphincter is cut to the level of the dentate line. **D.** The skin incision is closed with running absorbable suture.

scissors to the level of the dentate line (typically about 2 cm in length).

- If you transected the internal sphincter appropriately, you should feel the anus relax immediately.
- Hemostasis is carefully achieved with electrocautery.
- The incision is closed with a running, rapidly absorbable 3-0 suture (**FIG 8D**).
- Place a tampon in the anal canal at the completion of the procedure for hemostasis.

Other Procedures

- The Lord procedure: Dilation of the anus is performed initially with two fingers and then slowly stretching the anal canal (over 2 to 3 minutes) until it accommodates four fingers. The dilation, performed by moving the two fingers around in a circular fashion, accomplishes what was originally described as a "controlled" disruption of the internal sphincter. The problem is that there is really no way of controlling the disruption of the sphincter in this way and it is easy to disrupt the external sphincter as well. This procedure has largely been abandoned due to an unacceptably high incidence of anal incontinence associated with it.
- Excision of the fissure with posterior open sphincterotomy: This procedure has also been largely abandoned due to the deformity that it produces in the anal canal and unacceptably high incidence of anal incontinence associated with it.

PEARLS AND PITFALLS

Patient positioning	■ The author prefers the modified lithotomy position with the legs elevated.
Visualization	■ Using headlights is critical for good visualization.
Intersphincteric groove	■ It is critically important to properly identify the intersphincteric groove. ■ Gentle palpation with the tip of the right index finger allows for easier localization of this groove.
Closed internal lateral sphincterotomy	■ A left lateral internal sphincterotomy is easier to perform for a right-handed surgeon. ■ A right lateral internal sphincterotomy may be preferred in patients with large left lateral hemorrhoids. ■ Using a cataract blade greatly facilitates a more uniform transection of the internal sphincter. ■ Cut the internal sphincter as you withdraw the blade out. ■ Having your left index finger inside the anal canal helps prevent accidentally cutting the anal mucosa.
Open internal lateral sphincterotomy	■ Separate the internal and external sphincters. ■ Cut the internal sphincter to the level of the dentate line. ■ This results in higher incidence of anal sphincter dysfunction postoperatively when compared to the closed technique.
Postoperative care	■ Aggressive prevention of constipation with a bowel regimen is mandatory.

POSTOPERATIVE CARE

- This procedure is typically performed on an outpatient basis.
- The patient removes the anal tampon the day after surgery or during the first bowel movement.
- Aggressive prevention of constipation with a bowel regimen is mandatory.
- The patient is placed on a high-fiber, low-fat diet.
- The author recommends over-the-counter fiber supplementation (totaling 25 to 35 g of fiber per day). Stool softeners and increasing water intake are also necessary to promote soft bowel movements and to aid in the healing process.
- Judicious use of laxatives.
- Nonsteroidal antiinflammatory agents are prescribed. Narcotic use is used sparingly due to their tendency to induce constipation.
- Warm sitz baths for comfort purposes are used.
- Wiping after bowel movements is only allowed with flushable baby wipes (no toilet paper) to prevent irritation.
- Use of zinc oxide ointments may help accelerate the healing of deep anal fissures.

OUTCOMES AND POSTOPERATIVE COMPLICATIONS

- Garcia-Aguilar and colleagues have published perhaps the most comprehensive analysis of outcomes after open internal sphincterotomy (OIS) and closed internal sphincterotomy (CIS).
- Overall, both techniques accomplish excellent results in terms of resolution of pain and healing of the fissure.
- Differences in persistence of symptoms (3.4% OIS vs. 5.3% CIS), recurrence of the fissure (10.9% vs. 11.7% CIS), and need for reoperation (3.4% OIS vs. 4% CIS) were statistically not significant.

- However, statistically significant differences were seen in the percentage of patients with permanent postoperative difficulty controlling gas (30.3% vs. 23.6%; $P < .062$), soiling underclothing (26.7% vs. 16.1%; $P < .001$), and accidental bowel movements (11.8% vs. 3.1%; $P < .001$) between those who underwent OIS and those who had CIS.
- Although 90% of patients reported general overall satisfaction, more patients undergoing CIS (64.4%) than OIS (49.7%) were very satisfied with the results of the procedure.
- The author concluded that lateral internal sphincterotomy is highly effective in treatment of chronic anal fissure but is associated with significant permanent alterations in continence. CIS is preferable to OIS because it effects a similar rate of cure with less impairment of control.

Chapter 46

Operative Treatment of Rectal Prolapse: Perineal Approach (Altemeier and Modified Delorme Procedures)

Valerie Bauer

DEFINITION

- Rectal prolapse is a "falling down" of the rectum caused by weakness in surrounding supportive tissues. Straining during constipation secondary to functional disorders of elimination (anismus) and anatomic causes of outlet obstruction such as middle and anterior pelvic organ prolapse (enterocele, sigmoidocele, rectocele, hysterocele, and cystocele) are major risks factors. Other risk factors include low anterior cul-de-sac, multiparity, anal sphincter muscle weakness, levator diastasis, redundant rectosigmoid, and neurologic disease.[1] Recognition of the type of prolapse determines operative approach. Internal intussusception includes all layers of the rectum and rectosigmoid through the rectum and into the anal canal but not beyond. Partial thickness prolapse involves protrusion of the redundant **mucosal** layer of the rectum for a distance of 1 to 3 cm from the anal margin (**FIG 1A**). True prolapse consists of a full-thickness protrusion of all layers of the rectum through a sliding hernia of the cul-de-sac so that the rectum is out of the body (**FIG 1B**).[2]

FIG 1 ● Presentation of full-thickness rectal prolapse. **A.** Mucosal prolapse showing concentric circles of mucosal folds in association with hysterocele. **B.** Large prolapse in recurrent disease after a failed Altemeier procedure showing engorged mucosa and loss of concentric folds.

DIFFERENTIAL DIAGNOSIS

- Prolapsed and incarcerated internal hemorrhoids may appear similar to rectal prolapse. The appearance of concentric folds differentiate rectal prolapse from hemorrhoidal prolapse, which appears as radial invaginations relative to anatomic location of the internal hemorrhoidal cushions.
- Enterocele and sigmoidocele is the combined prolapse of posterior vaginal wall and herniation of the respective segments of bowel through the anterior cul-de-sac, which may cause anterior rectal prolapse and bleeding.
- Hysterocele and cystocele involve vaginal prolapse, which can also contribute to the "pulling down" of the fascial support of the rectum.
- Rectal cancer or polyps may act as a lead point from which colorectal prolapse occurs, hence underscoring the importance of diagnostic colonoscopy to rule out proximal mucosal pathology as a cause of intussusception.
- Inflammatory colitides should be considered for findings of isolated rectal ulceration, seen in the anterior rectum at the point of retroperitoneal fixation, where repeated internal prolapse forms. A discrete anterior solitary rectal ulcer is approximately 4 to 10 cm from the anal verge.

PATIENT HISTORY AND PHYSICAL FINDINGS

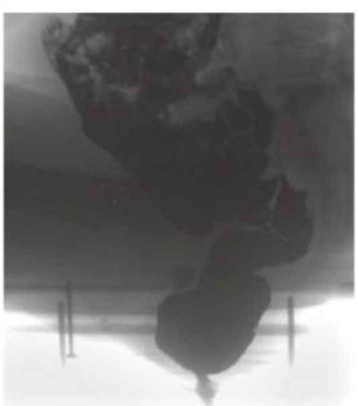
- Successful perineal proctosigmoidectomy for full-thickness prolapse (Altemeier) and mucosectomy for partial mucosal prolapse (modified Delorme) depends on proper determination of type of prolapse. Therefore, accurate history and recognition of physical examination findings is of paramount importance.
- Surgery for isolated internal prolapse is currently not performed in lieu of conservative management to include dietary and behavioral modifications, such as pelvic muscle rehabilitation for treatment of functional elimination disorders. However, future understanding of the relationship between posterior internal pelvic organ prolapse and middle/anterior pelvic organ prolapse may redefine guidelines for surgical indication using a multidisciplinary approach to multiorgan repair to include colorectal, urogynecology, and urology subspecialists.
- A thorough history must identify causes of constipation (and excessive straining) such as dietary and social behaviors (inadequate fiber intake, sedentary lifestyle), medications, and medical conditions (hypothyroidism, electrolyte disturbances, interstitial cystitis, pelvic organ prolapse, anxiety, or psychiatric disturbances).
- Past surgical history of multiple prior pelvic operations (hysterectomy, sacrocolpopexy, coloproctostomy) increases operative risk for complication. Prior abdominal repair of rectal prolapse with rectosigmoid resection is a contraindication to

perineal proctectomy due to altered mesenteric blood flow and risk for distal ischemia.

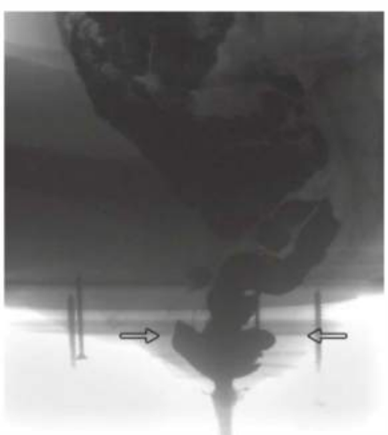
- Risk factors for colorectal cancer and polyps is determined through family history and personal history of changes in bowel habits, bleeding, and results of most recent colonoscopy.
- Obstetric and urogynecologic history aims to determine risk factors for anal muscle weakness and pelvic organ prolapse, such as number of intrauterine pregnancies, term vaginal deliveries, large-birth-weight baby, prolonged labor, use of forceps, high-grade vaginal tear, absence of controlled episiotomy, and urinary incontinence. Additionally, nulliparity has been associated with higher incidence of rectal prolapse as well.[3,4]
- Initial presentation is commonly described as "something falling out that has to be pushed back in." Other possible initial complaints include a feeling of fullness in the pelvis, severe pain (levator muscle spasm), bleeding, incomplete evacuation with splinting or positional maneuvers to eliminate, excessive straining, mucus or fecal staining, perineal discomfort and burning (due to chronic moisture), improved pain on lying down, and fecal urgency with "nothing there."
- Initial anorectal examination is done in prone jackknife or lateral Sims position. It begins with inspection of the perianal skin. In the absence of grossly visible prolapse at the anal margin, a patulous anus, fecal smearing, and thickening (lichenification) of anoderm due to chronic perineal moisture suggests rectal or mucosal prolapse. The appearance of the anus may be flat due to loss of compliance and function of the pelvic floor musculature (perineal descent syndrome). Visible scars due to episiotomy or prior anorectal surgery should be noted.
- Vaginal examination may reveal anterior vaginal prolapse (cystocele) or posterior vaginal wall prolapse (rectocele, enterocele).
- Digital rectal examination determines anal sphincter tone and function. Patients with full-thickness prolapse often have little to no resting or squeeze tone due to levator muscle separation and pudendal nerve damage. Patients are asked to squeeze to give some indication of sphincter strength (diagnostic of fecal incontinence). Digital palpation of the perineal body may also reveal anterior thinning and sphincteric defect due to prior obstetric injury or other mechanisms of levator separation.
- Digital compression in the anterior rectum may reveal rectocele. The patient should be asked to strain during digital palpation to evaluate for paradoxical contraction or lack of anal sphincter relaxation (indicative of functional elimination disorder, anismus). Similarly, exaggerated strain may reproduce internal prolapse and/or rectocele, which is appreciated by luminal protrusion into the posterior wall of the vagina.
- Anorectal examination uses a side-viewing anoscope (Hirschman) to evaluate the anal canal. Internal hemorrhoids may or may not prolapse with rectal prolapse. However, they may be inflamed, bleeding, or thrombosed due to excessive straining from outlet obstruction caused by the prolapse. Patients with rectal prolapse complain more of hemorrhoidal disease due to a lack of awareness of rectal prolapse. Rigid proctosigmoidoscopy allows for evaluation of the rectum and sigmoid up to 25 cm from the anal verge for evidence of prolapse or other mucosal disease. Anterior solitary rectal ulcer is classically seen between the first and second valve of Houston and represents the point of recurrent internal prolapse. Release of air insufflation and having the patient bear down as the scope is withdrawn will prolapse redundant tissue into the aperture of the proctosigmoidoscope, which is diagnostic of rectal prolapse in the office.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Having the patient squat or strain, especially after administration of fleet enema, will help protrude the prolapsed rectum. This test is performed in the clinic and is diagnostic of rectal prolapse (toilet test).
- Defecography uses fluoroscopic imaging to evaluate the structure and function of posterior, middle, and anterior pelvic floor during the three phases of elimination—rest, squeeze, and strain. It may be used to diagnose rectal prolapse if it is not clinically evident. Pelvic floor structures are visualized using thick barium paste instilled into the rectum, a barium-impregnated tampon in the vagina, oral contrast for small bowel, and intravenous contrast for visualization of the bladder. Internal rectal prolapse is demonstrated during strain in image (**FIG 2A,B**).
- Pelvic floor physiology testing determines preoperative functional baseline of the anal sphincter, especially when there is associated fecal incontinence. These tests include anal manometry, rectal sensation, and anal electromyography (EMG).
- Pudendal nerve terminal motor latency (PNTML) determines neurogenic impediment to anal sphincter muscle function.



A



B

FIG 2 • **A.** Cine defacography during the initial strain phase of elimination shows foreshortening of rectum with early internal intussusception. **B.** The prolapse progresses with strain, but not beyond the anal canal, illustrating internal recto-rectal intussusception (*arrows*) without mucosal or full thickness prolaspe.

Although pudendal neuropathy is not a contraindication for repair of rectal prolapse, its presence may predict poor outcome in improvement of fecal incontinence associated with rectal prolapse after surgery and should be discussed with the patient preoperatively.[5]

SURGICAL MANAGEMENT

Preoperative Planning

- Perineal repair of rectal prolapse is favored for patients with high-risk surgical comorbidites. Therefore, medical and cardiac risk stratification should be obtained prior to surgery and discussed with every patient, including the possibility of complication due to comorbid condition.
- Surgery is done under general anesthesia; however, in the high-risk population, the procedure can be performed under spinal or even local anesthesia.
- Patients undergo preoperative bowel preparation and fleet enemas before the procedure.
- Previous intraabdominal resection for repair of rectal prolapse increases ischemic complications from subsequent perineal resections, and it is considered a relative contraindication to perineal repair.

Positioning

- The patient may be placed in lithotomy position using candy cane or Allen stirrups or in prone jackknife position.

TECHNIQUES

PERINEAL PROCTECTOMY (ALTEMEIER PROCEDURE)

Preparation after Anesthesia Induction

- Rigid proctosigmoidoscopy is performed to ensure there is clean preparation. Residual stool may be suctioned and the rectum irrigated with saline or diluted Betadine solution until clean.
- A full perineal and vaginal preparation is performed using Betadine solution.
- A Foley catheter is inserted.
- Local anesthesia, using a total of 30 mL 0.25% Marcaine with 1:200,000 epinephrine, is infiltrated through a 22-gauge spinal needle in the intersphincteric groove circumferentially.
- A Lone Star retractor system (CooperSurgical Inc, Trumbull, CT) is positioned using small hooked retractors placed at the dentate line circumferentially (**FIG 3**).

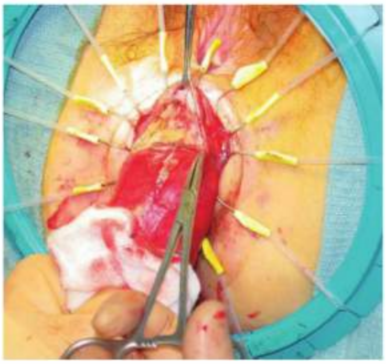


FIG 4 ● A full-thickness incision is placed 1 to 1.5 cm from the anal verge using electrocautery around the rectum.

Incision

- The prolapsed segment is grasped with Babcock clamps.
- Electrocautery is used to score a circumferential incision 1 to 1 ½ cm proximal to the dentate line. This is deepened through all the layers of rectal wall circumferentially (**FIG 4**).
- Clamps are applied to the distal edge of the rectum.

FIG 3 ● Placement of the Lone Star retractor using hooked elastic bands attached to the dentate line in a circumferential fashion.

Anterior Dissection of the Hernia Sac

- A deep pouch of Douglas is often encountered and dissected free from the anterior segment of the rectum (**FIG 5**).
- The hernia sac is resected, allowing access to the intraabdominal cavity and delivery of excess redundant bowel.
- The peritoneal edges are reapproximated using absorbable suture, thus excluding the abdominal cavity.

Posterior Dissection

- An energy device, such as Enseal (Ethicon Endo-Surgery Inc, Cincinnati, OH), may be used to seal and divide the mesorectum (**FIG 6**).
- Redundant bowel is freely delivered (**FIG 7A**). The extent of delivery may vary according to the degree of prolapse and extent of surgical dissection (**FIG 7B**).

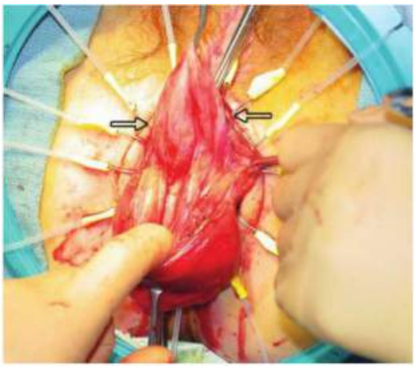

FIG 5 ● Sharp dissection frees the anterior hernia sac (as noted by the *arrows*) from the prolapsed rectal tissue.

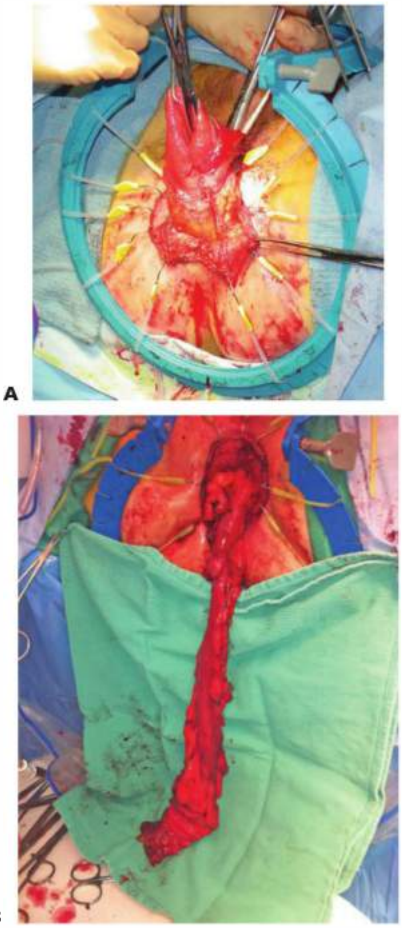
Posterior Levatorplasty

- A modification of the Altemeier's operation involves the addition of a levatorplasty, which is the plication of either the anterior or the posterior levator ani muscles with long-term absorbable sutures such as polydioxanone (PDS). Placation of either the anterior or posterior levator muscles decreases pelvic outlet aperture and decreases recurrence while improving continence.[6] Anterior levatorplasty is associated with a higher incidence of dyspareunia than posterior levatorplasty.
- The levator ani muscle is grasped on each side with a Babcock clamp and reapproximated using two to three interrupted sutures (**FIG 8**). Care should be taken to ensure that two fingerbreadths pass through the remaining aperture to avoid excessive compression of the rectum and subsequent constipation.

FIG 6 ● An energy device that enables sealing of mesorectal vasculature may be used to safely and rapidly divide the mesorectum in the process of mobilizing the redundant rectal prolapse.

A



B

FIG 7 ● **A,B.** Variable degrees of redundant prolapse may be observed in the mobilization and delivery of bowel.

- If the peritoneal cavity is entered, the peritoneum is closed with absorbable sutures. The bowel is fastened to the peritoneum and anterior tissue using interrupted absorbable sutures.

Resection of Redundant Rectosigmoid

- The level of transection is determined by the viability of the bowel and approximation to the proximal free edge of the distal resected cuff. Division begins anteriorly. In order to prevent retraction of the rectum into the pelvis, four corner sutures are placed and left tagged prior to completely transecting the rectum.
- Absorbable 2-0 Vicryl sutures are placed full thickness in interrupted fashion, reapproximating the bowel.
- Upon completion, rigid proctoscopy is performed to ensure the viability of the bowel proximal to the anastomosis and also to assess the integrity of the bowel, ruling out a possible perforation that might have been incurred during the dissection.
- The Lone Star retractor is removed and the anastomosis is interiorized.

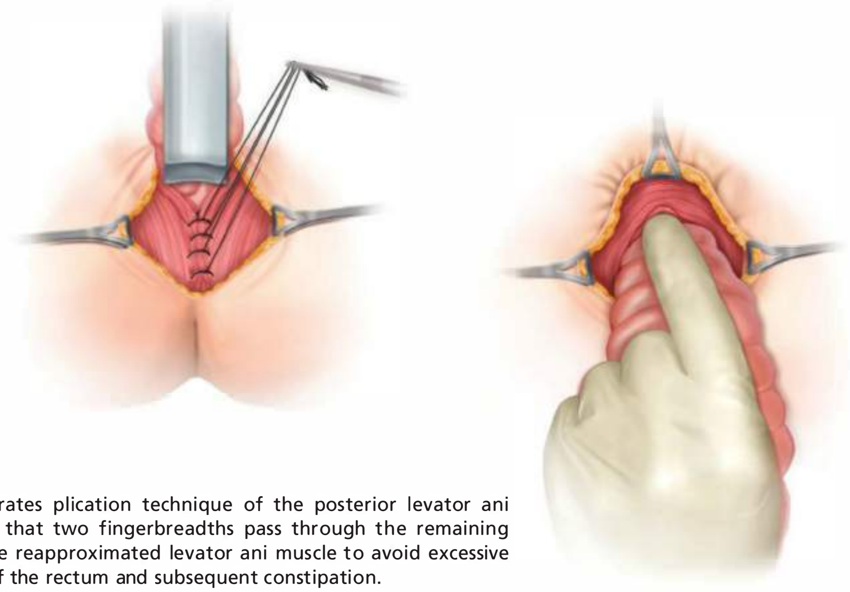


FIG 8 ● Illustrates plication technique of the posterior levator ani muscles. Note that two fingerbreadths pass through the remaining aperture in the reapproximated levator ani muscle to avoid excessive compression of the rectum and subsequent constipation.

DELORME PROCEDURE

- This procedure was described by Delorme in 1900, for repair of mucosal prolapse, and involves stripping of the mucosa from the prolapsed bowel, placating the denuded muscular wall, and reanastomosing the mucosal rings.[7]

Preparation after Anesthesia Induction

- The patient is positioned and prepared in similar fashion than that of an Altemeier procedure.
- The submucosa is infiltrated using a local anesthetic such as 0.25% bupivacaine with 1:200,000 epinephrine in order to reduce bleeding and facilitate the plane of dissection.

Incision

- A circular incision is made through the mucosa approximately 1 cm proximal to the dentate line (**FIG 9A**).
- A sleeve of mucosa and submucosa is sharply dissected from the underlying muscle to the apex of protruding bowel and the point at which there is some tension (**FIG 9B**).

Plication of muscularis propria

- The denuded muscle (muscularis propria) is prepared for longitudinal plication by placing serial Allis clamps in each quadrant. Vicryl sutures are placed in all four quadrants,

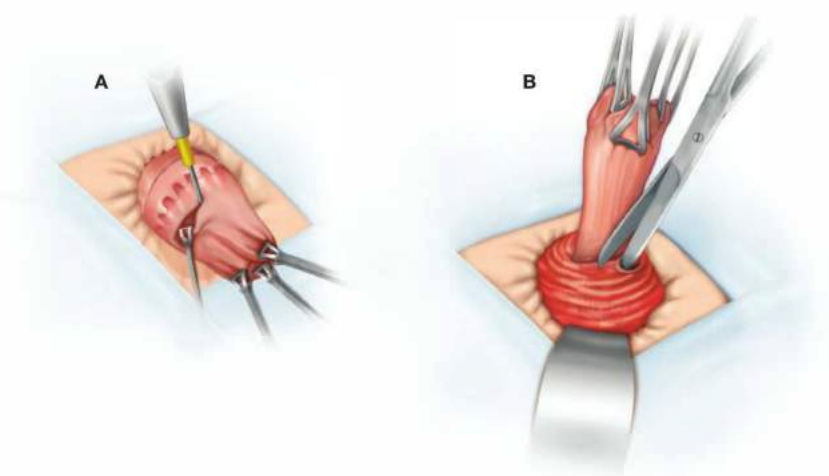

FIG 9 ● **A.** The mucosa is dissected 1.0 to 1.5 cm proximal to the dentate line, and **(B)** it is then stripped off of the muscularis propria.

beginning from proximal to the incised mucosa and ending at the level to where the mucosa is dissected (**FIG 10**).

- The placating sutures are tied after confirmation of absolute hemostasis.

Resection and anastomosis

- The stripped mucosa is then excised and anastomosed to the distal mucosa with interrupted absorbable sutures.

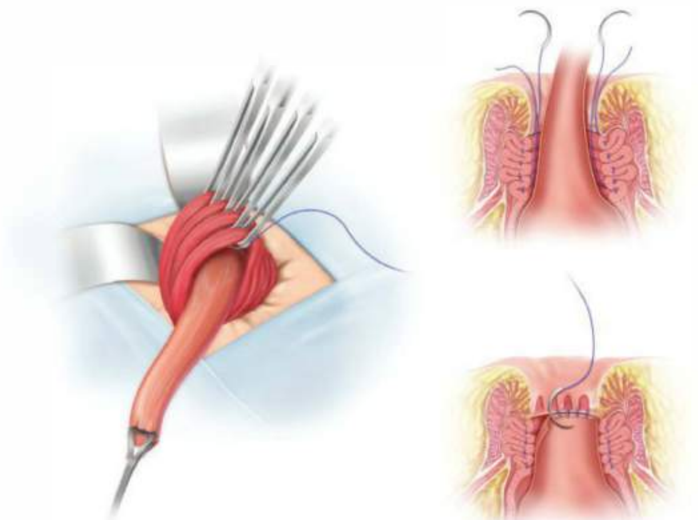

FIG 10 ● The muscularis propria is plicated in all four quadrants.

PEARLS AND PITFALLS

Indications	■ A thorough history and physical examination should be obtained, including in-office administration of enema to reproduce and confirm full-thickness or partial rectal prolapse. ■ Clinical suspicion for internal prolapse may be diagnosed with symptoms of incomplete defecation and defecogram showing rectorectal intussusception with or without obstruction. ■ Prior history of rectal prolapse repair increases risk for ischemia on subsequent perineal repair if the initial procedure involved division of mesenteric blood flow. ■ Complete colonoscopic evaluation should be performed to rule out proximal cause of obstructed defecation or prolapse.
Dissection	■ Identification, resection, and closure of the anterior hernia are important for obliterating the hernia sac contributing to the anterior prolapse. ■ Care should be taken to prevent division of the mesentery proximal to the bowel edge in order to minimize anastomotic ischemia and tension.
Levatorplasty	■ Placation of either the anterior or posterior levator muscles decreases pelvic outlet aperture and decreases recurrence while improving continence. ■ Anterior levatorplasty is associated with higher incidence of dyspareunia. ■ Posterior levatorplasty should allow two fingerbreadths between the bowel and muscle approximation to minimize constipation postoperatively.
Rigid proctosigmoidoscopy	■ Evaluates for potential unrecognized rectal perforation that may have been undetected during the dissection

POSTOPERATIVE CARE

- Regular diet is usually resumed on postoperative day 1.
- The Foley catheter is removed the day after surgery. The patient can be discharged on postoperative day 1.
- A bowel regimen should be implemented to minimize constipation and excessive straining postoperatively. The patient should be educated to take adequate fiber intake and gentle cathartics, such as milk of magnesia, each day for 2 weeks until the anastomosis has healed. Avoidance of excess straining should be stressed, along with orders for nothing per rectum.

OUTCOMES

- Perineal proctosigmoidectomy has variable reported recurrence rates ranging from 10% to 25% in large clinical studies. The addition of posterior levatorplasty improves recurrence rates down to 7.7% and also increases time to recurrence from 13.3 months to 45.5 months.[6]
- The Delorme procedure has similarly high recurrence rates but has been favored to perineal proctosigmoidectomy in cases of extreme comorbid conditions or failed surgery for prolapse.[8]

COMPLICATIONS

- Anastomotic dehiscence (intrapelvic leakage is uncommon) is usually due to tension and/or poor blood supply. Therefore, extreme care must be taken to mobilize the bowel adequately and to avoid transecting the mesentery too far proximally.
- Bleeding occurs in 5% of patients, with resulting pelvic hematoma.
- Anastomotic stricture: Most patients will develop some degree of stricture, but it rarely requires dilatation.

Chapter 47

Operative Treatment of Rectal Prolapse: Transabdominal Approach

Karin M. Hardiman

DEFINITION

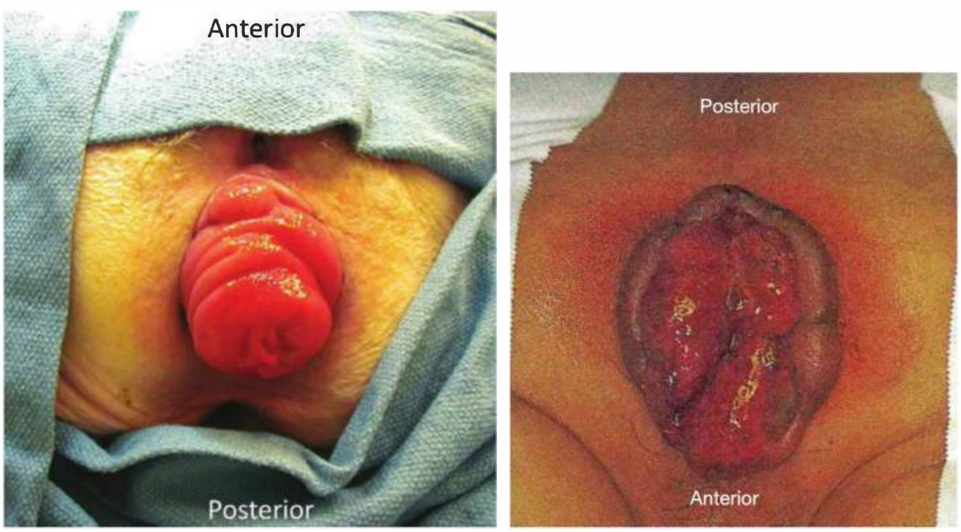
- Rectal prolapse is the full-thickness protrusion of the rectum through the anus. The rectum intussuscepts and then progresses onward to come out of the anus.

DIFFERENTIAL DIAGNOSIS

- It is important to differentiate rectal prolapse from prolapsing hemorrhoids (**FIG 1**), as the treatment paradigms are completely different.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Rectal prolapse is most common in multiparous elderly women with long-standing constipation. A small percentage is also seen in young male patients. Scleroderma and psychiatric disorders are also more common in patients with rectal prolapse.
- Patients describe having tissue extrude from their anus that usually retracts on its own or with manual pressure. Prolapse is most often associated with episodes of straining but it can occur even with ambulation, especially in elderly female patients. It is important to elicit how much they are prolapsing, how often, and how much it is bothering them in order to decide whether to operate. Prolapse is often associated with mild bleeding and mucus.
- It is important to elicit any bowel habits dysfunction that has to be addressed. Recurrence rates of prolapse are higher after surgery when severe constipation or obstructed defecation due to pelvic floor dysfunction are not addressed.
- The patient should be asked about their continence as the surgeries for prolapse described here do not immediately improve continence. After prolapse surgery, about half of patients have some improvement in continence over time, but if their incontinence is severe and they cannot squeeze on exam, they may be better served with an ostomy. Intense counseling is critical.
- Associated gynecologic and/or urologic pelvic floor dysfunction issues (including difficulty with urination and uterine prolapse) commonly seen in rectal prolapse patients should be addressed in a multidisciplinary fashion together with a urogynecologist.
- Patients often come with digital photographs of their prolapse that allow for confirmation of the diagnosis. Otherwise, it is important to elicit the prolapse in the clinic to be able to differentiate it from prolapsing hemorrhoids.
- The best way to confirm the rectal prolapse is to give the patient 5 minutes on the toilet to elicit the prolapse and then examine them. Rectal prolapse looks like a single long tube sticking out with concentric ring; prolapsing hemorrhoids look like multiple individual quadrants of tissue (**FIG 1**).
- Physical exam should include digital rectal exam to assess for masses. Having the patient push during the exam allows the examiner to feel for enterocele, rectocele, and cystocele. In addition, the patient should be asked to squeeze to assess the sphincter muscles.



A B

FIG 1 ● It is important to differentiate **(A)** rectal prolapse from **(B)** prolapsing internal hemorrhoids. Rectal prolapse is prolapsing tissue that has full concentric rings (patient is in supine position, in candy canes). Prolapsing internal hemorrhoids is a mucosal prolapse in three separate bundles (patient is in a prone jackknife position).

- Patients with an incarcerated rectal prolapse may on occasion present to the emergency room. In these cases, the treatment depends on the appearance of the bowel. If viable, gentle reduction with sedation, reassurance, and education are usually all that is needed and the patient can follow up electively; if not viable, a perineal proctectomy is needed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Any patient being evaluated for rectal prolapse should have a colonoscopy to rule out either a malignancy acting as the lead point of the prolapse or a synchronous tumor.
- In patients that are unable to elicit prolapse or bring you a picture, a defecography can be very helpful. During this procedure, the patient's small bowel, rectum, and vagina are all filled with contrast and the patient is asked to have a barium bowel movement while the radiologist takes a video. This often demonstrates the prolapse along with other types of pelvic floor dysfunction. The prolapse may not be seen on defecography, as evacuation of barium requires less straining than evacuation of hard stool in constipated patients.

SURGICAL MANAGEMENT

Operative Planning and Strategy

- The choice of operation is dependent on many factors including patient health, prior surgeries, the operating surgeon's comfort with laparoscopy, and whether the patient has a history of constipation.
- If the patient is healthy enough, then an abdominal rather than a perineal approach should be offered due to the lower risk of recurrence. Otherwise, they may be better served with a lower risk perineal operation or no operation at all.
- Rectal prolapse is not dangerous unless incarcerated, so not all patients are offered operation.
- Abdominal surgery for rectal prolapse should include dissection posterior to the mesorectum with fixation of the mobilized rectum just below the sacral promontory, as this fixation decreases the risk of recurrence. The fixation can be performed with sutures or with mesh.
- In constipated patients, resection of the sigmoid colon is recommended. In these cases, although not proven beneficial by Cochrane review of available evidence, either a full bowel preparation or just enemas can be performed preoperatively at the surgeon's discretion.
- The surgery can be performed open or laparoscopically. Laparoscopic surgery is associated with significant short-term advantages over open surgery.
- Preoperative antibiotics are given within 1 hour of incision to decrease the risk of postoperative wound infection and are stopped within 24 hours of surgery.
- Heparin prophylaxis is given perioperatively to lower the risk of deep vein thrombosis.

Positioning

- Any rectal prolapse should be reduced manually prior to starting the operation.
- For laparoscopic operations, the patient is placed on a lithotomy position with the legs on Yellofin stirrups and with the thighs parallel to the ground to avoid conflict with the surgeon's arms (**FIG 2**). Avoid pressure on the calves and lateral peroneal nerves.
- Both arms are tucked and padded to avoid nerve injuries (for open cases, the arms are placed on arm boards laterally). All lines and cords are kept out of the tucking.
- Tape the patient across the chest over a towel to secure him/her to the operating room (OR) table.

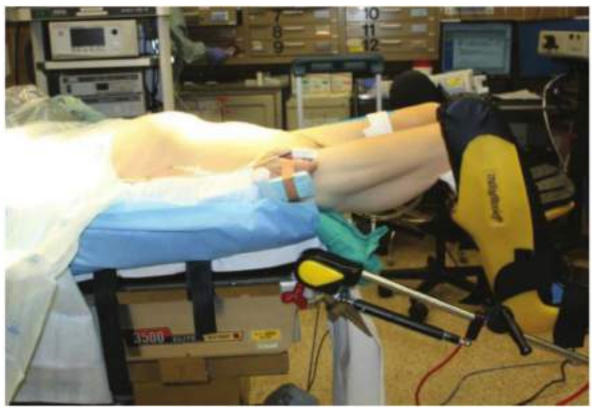


FIG 2 • Patient positioning for laparoscopic rectal prolapse repair. The patient is placed in a lithotomy position with the thighs parallel to the ground to avoid conflict with the surgeon's arms. The patient is placed on a beanbag with both arms tucked and taped to the table over a towel.

TECHNIQUES

LAPAROSCOPIC SUTURE RECTOPEXY

Insufflation, Port, and Team Setup

- The abdomen is accessed with either a Veress needle or a Hassan port at the inferior portion of the umbilicus and carbon dioxide (CO_2) pneumoperitoneum is established.
- Port placement (**FIG 3**): A 5-mm infraumbilical camera port is inserted for the 30-degree camera. Three 5-mm working ports are inserted in the right lower quadrant, the right upper quadrant, and the left lower quadrant.
- The surgeon stands on the patient's right side, with the scrub nurse next to him/her. The assistant stands on the left side of the table (**FIG 4**).

Posterior Dissection

- The patient is placed in a steep Trendelenburg position with the left side up. The bowel is placed in the upper abdomen. The sigmoid colon and rectum are often very redundant and can be hard to manipulate. At times, this may require additional port placement.
- The rectosigmoid is pulled toward the abdominal wall, tenting upward the base of its mesentery at the sacral promontory (**FIG 5**). The peritoneum is incised along the root of the mesocolon with cautery across the promontory and toward the right and left posterolateral aspect of the cul-de-sac.

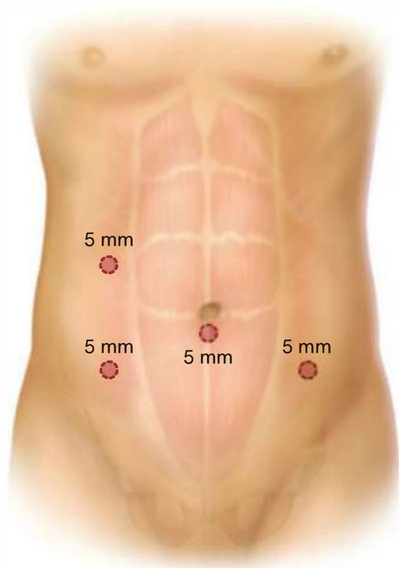

FIG 3 ● Laparoscopic rectopexy port placement. A 5-mm infraumbilical camera port is inserted for the 30-degree camera. Three 5-mm working ports are inserted in the right lower quadrant, the right upper quadrant, and the left lower quadrant.

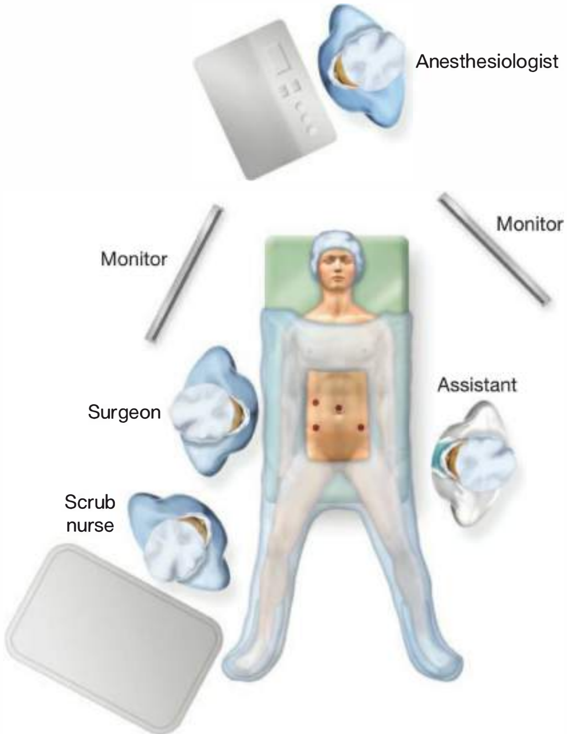

FIG 4 ● OR team setup. The surgeon stands on the patient's right side with the scrub nurse next to him/her. The assistant stands on the left side of the table.

- The rectum is then lifted anteriorly toward the abdominal wall in order to reveal the alveolar plane in the presacral space located between the mesorectum and the presacral fascia (**FIG 6**). Dissect the presacral space distally with an energy device until reaching just above the anal canal. Digital rectal examination may be needed to confirm the distal extent of dissection is appropriate (**FIG 7**).
- Avoid penetration into the endopelvic fascia along the lateral pelvic wall, because this can lead to serious bleeding from the hypogastric vein and its branches. Also, dissecting into the presacral fascia could result in catastrophic bleeding from the presacral venous plexus.
- The sympathetic nerves should be identified and preserved intact in the retroperitoneum.
- Minimize unnecessary dissection of the lateral rectal stalks.

Rectopexy

- Completely reduce the prolapse by retracting the rectosigmoid junction in a cephalad direction.

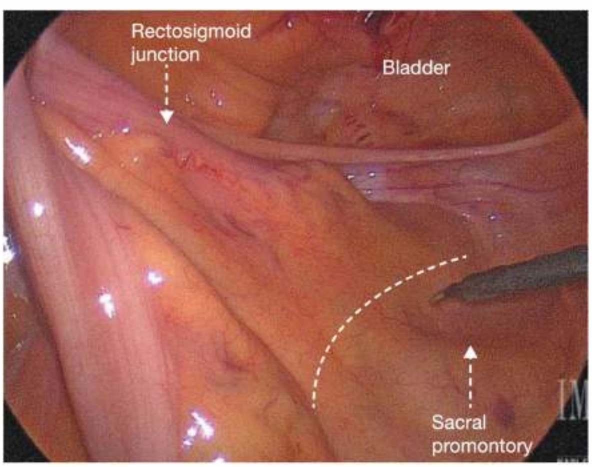

FIG 5 ● The rectosigmoid is pulled toward the abdominal wall, tenting out the base of its mesentery peritoneum at the sacral promontory. The peritoneum is incised along the root of the mesocolon *(dotted line)* across the promontory toward the right posterolateral cul-de-sac.

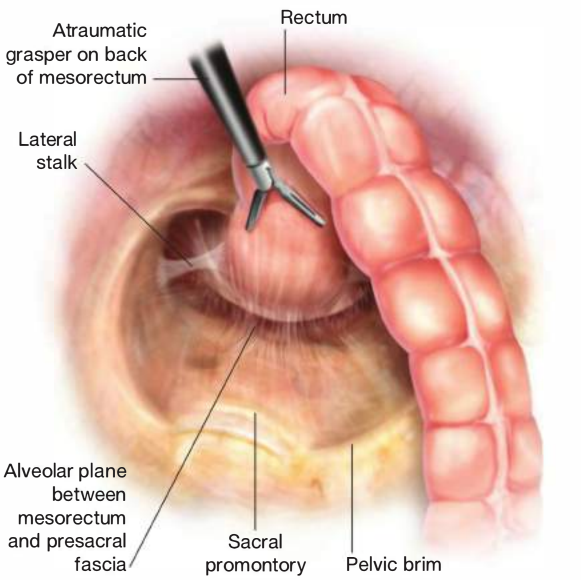

FIG 6 ● The rectum is lifted anteriorly toward the abdominal wall in order to reveal the alveolar plane between the mesorectum and the presacral fascia.

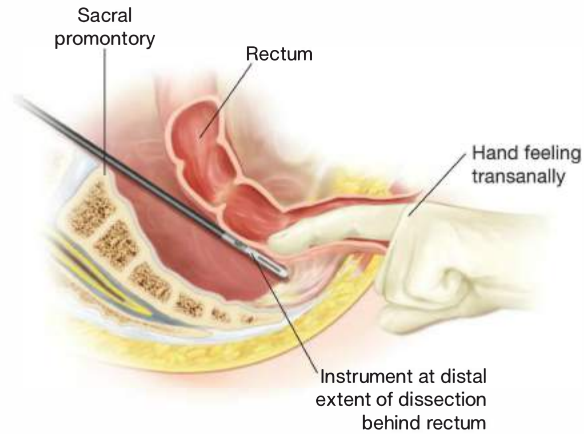

FIG 7 ● Digital rectal examination allows palpating an instrument placed at the distal end of dissection, confirming that the posterior dissection has reached the top of the anal canal.

- The rectopexy sutures (braided nonabsorbable or absorbable sutures) are placed starting just below the top of the promontory. While retracting the rectum anteriorly, three sutures are placed along the midline, from the presacral fascia to the back of the mesorectum, placing the most distal stitch first (**FIG 8**). SH needles will fit through 5-mm ports if the curve of the needle is slightly flattened.
- When placing these stitches, it is important to have the needle enter at a right angle to the bone and then turn the needle after the bone is felt so that a wide swath of presacral fascia is incorporated in the stitch (**FIG 8**). Pull up on the mesorectum and place the stitch through the back of the mesorectum to pull the rectum upward when tying the knots. It is helpful to use a knot pusher or an automatic tying device to tie the knots in the narrow confines of the presacral space.
- Another important tip is not to remove any misplaced stitches but instead to just tie them, as removal can result in significant bleeding from the presacral veins.

Closure

- Assess the abdomen for hemostasis; remove all ports and close skin incisions with absorbable suture.

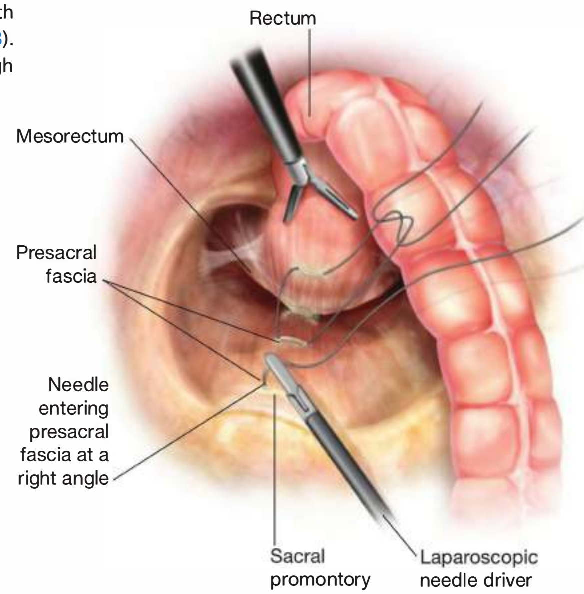

FIG 8 ● Stitch placement for rectopexy. The stitches are placed along the midline, starting with the first one a few centimeters distal to the promontory and moving upward. The needle should enter the presacral fascia at a right angle. When bone is felt, turn the needle to encircle a wide swath of presacral fascia. Pull up on the mesorectum and place the stitch through the back of the mesorectum to pull the rectum upward when tying the knots.

HAND-ASSISTED LAPAROSCOPIC SURGERY RESECTION RECTOPEXY

- Hand-assisted laparoscopic surgery (HALS) in colorectal surgery has the same short-term outcome advantages of conventional laparoscopic-assisted (LA) surgery over open surgery, including less pain, faster recovery, lower incidence of wound complications, and reduction of cardiopulmonary complications, especially in the obese and in the elderly.
- Advantages of HALS over conventional LA colorectal surgery include the following:
  - Reintroduces tactile feedback into the field
  - Shorter learning curves; easier to teach
  - Shorter operative times and lower conversion to open rates
  - Higher usage rates of minimally invasive surgery

Port Placement, Team, and Operating Room Setup

- Start by placing a hand access port through a 5- to 6-cm Pfannenstiel incision. Care is taken to avoid bladder injury (**FIGS 9**, **13**).
- Insufflate the CO_2 pneumoperitoneum; a 5-mm port is placed through the hand port.
- Insert a 5-mm supraumbilical camera port.
- Insert two 5-mm working ports in the right and left lower quadrants, respectively.
- The operating team and OR setup is otherwise identical as previously described (**FIG 4**).

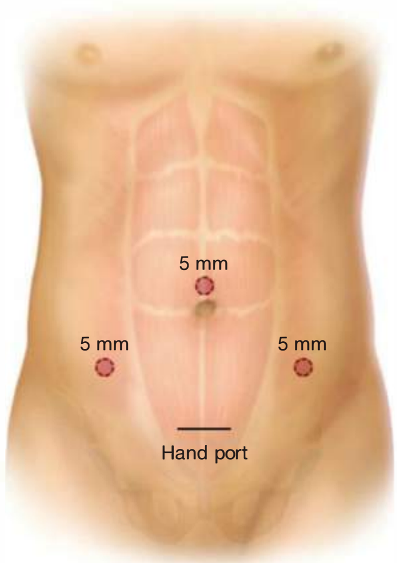

FIG 9 ● HALS rectopexy port placement. A 5-mm supraumbilical camera port is inserted for the 30-degree camera. Two 5-mm working ports are inserted in the right lower quadrant and the left lower quadrant. The hand port (GelPort) is inserted through a 5- to 6-cm Pfannenstiel incision.

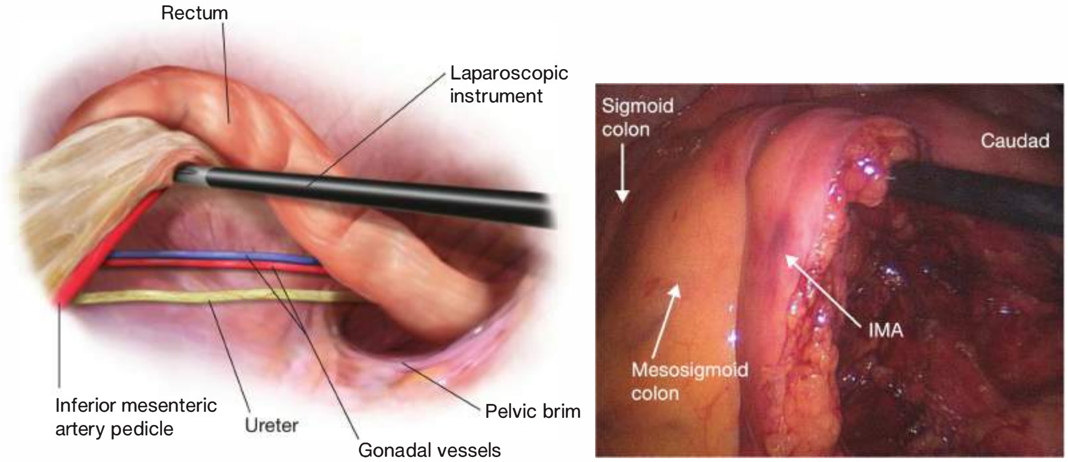
POSTERIOR DISSECTION

- The patient is placed in a steep Trendelenburg position with the left side up. Using your right hand, gently pull the small bowel out of the pelvis and placed it in the upper abdomen. A laparotomy sponge, inserted via the hand port, can be used to hold the small bowel out of the pelvis and also to clean the camera tip intracorporeally.
- The sigmoid colon and rectum are often very redundant and can be hard to manipulate. HALS greatly facilitates this maneuver. If necessary, insert an additional port for this purpose.
- Using the hand, the rectosigmoid junction is pulled toward the anterior abdominal wall and pubis, tenting out the peritoneum at the sacral promontory. This peritoneum is incised with cautery across the promontory and toward the posterolateral cul-de-sac on the right and left sides.
- The rectum is then lifted anteriorly toward the abdominal wall in order to reveal the alveolar plane in the presacral space located between the mesorectum and the presacral fascia (**FIG 6**). Dissect the presacral space distally with an energy device until reaching just above the anal canal. Digital rectal examination may be needed to confirm the distal extent of dissection is appropriate.
- Avoid penetration into the endopelvic fascia along the lateral pelvic wall, because this can lead to serious bleeding from the hypogastric vein and its branches. Also, dissecting into the presacral fascia could result in catastrophic bleeding form the presacral venous plexus.
- The sympathetic nerves should be identified and preserved intact in the retroperitoneum.
- Minimal dissection of the lateral rectal stalks should be performed.

Sigmoid Resection

- This step should only be performed if the patient has a redundant colon and severe constipation.
- The mesentery of the sigmoid colon is separated from the retroperitoneum bluntly by medial to lateral dissection starting at the original opening made in the peritoneum at the sacral. The inferior mesenteric artery is lifted up and the left ureter and gonadal vessel are identified and left intact in the retroperitoneum (**FIG 10**).
- Once this dissection reaches the abdominal side wall, the attachments between the sigmoid colon and the lateral peritoneum are divided.
- The mesentery to the bowel to be resected is divided with the LigaSure or Harmonic, staying close to the bowel until the top of the rectum is reached distally and the point appropriate for anastomosis is reached proximally. This proximal point is where the proximal colon reaches the rectum in the position it will be in after the rectopexy.
- The bowel is divided distally at the top of the rectum as defined by the splaying of the teniae coli. This division can be done with a laparoscopic gastrointestinal anastomosis (GIA), Contour, or thoracoabdominal (TA) stapler



A B

FIG 10 ● Schematic (**A**) and operative (**B**) pictures. Medial to lateral mobilization of the mesosigmoid colon. The mesentery of the sigmoid colon is separated from the retroperitoneum bluntly by medial to lateral dissection starting at the original opening made in the peritoneum at the sacral promontory. The inferior mesenteric artery (IMA) is lifted up and the left ureter and gonadal vessel are identified and left intact in the retroperitoneum.

placed through the hand port. This position is estimated by pulling the top of the rectum up to the top of the sacral promontory. The proximal bowel is then pulled through the hand port and is divided extracorporeally. A 31-mm end-to-end anastomosis (EEA) anvil is then placed in the open end of the descending colon.

- The end-to-end colorectal anastomosis with a 31-mm EEA (**FIG 11**) is performed after the rectopexy sutures are placed but before they are tied.
- An underwater air test is performed to check for anastomotic leak (**FIG 12**). Perform after tying the rectopexy sutures. Perform this test with a colonoscope so that the anastomosis can be viewed at the same time. An air leak would indicate a disruption in the anastomotic line and may necessitate revision of the anastomosis.
- If there is undue tension on the anastomosis, the lateral and retroperitoneal attachments to the descending colon should be divided.

Rectopexy

- The lid of the hand port can be left on or off for placement of the rectopexy sutures depending on surgeon preference.
- The rectopexy sutures are to be placed starting just below the top of the promontory. Along, braided nonabsorbable suture on an SH needle is used to perform

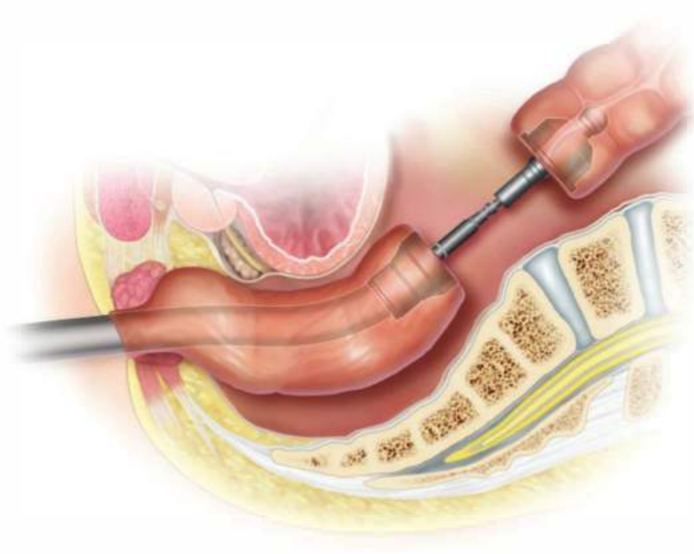


FIG 11 ● The end-to-end colorectal anastomosis is performed with a 31-mm EEA.

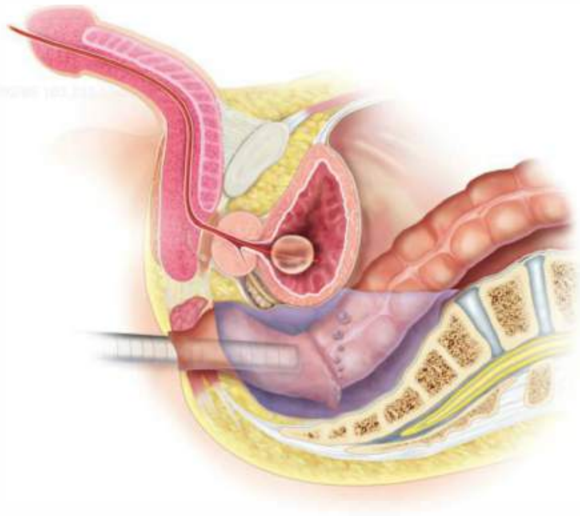

FIG 12 ● An underwater air test is performed to check for anastomotic leak. An air leak would indicate a disruption in the anastomotic line and may necessitate revision of the anastomosis.

suture rectopexy. Alternatively, absorbable suture or mesh can be used.

- The rectum is held out of the way with a retractor, and three sutures are placed in the midline from the presacral fascia to the back of the mesorectum, placing the most distal stitch first (**FIG 8**).
- When placing these stitches, it is important to have the needle enter the tissue at a right angle to the bone and then turn the needle after the bone is felt so that a wide swath of presacral fascia is encircled. Another tip is not to remove any misplaced stitches but instead to just tie them, as removal can result in significant bleeding from the presacral veins.
- The rectum should be pulled up (with any prolapse reduced) and the stitch should then be placed through the back of the mesorectum such that the rectum is hitched up higher on the sacrum than it was previously. This should be repeated for each of the three stitches.
- If a resection is being performed, place the sutures, tag them, and then tie them after performing the anastomosis.

Closure

- The rectus muscles and peritoneum can be approximated with absorbable suture or not.
- The anterior fascia is closed with running polydioxanone (PDS) sutures.
- The wound is irrigated and the skin is closed with running absorbable subcuticular sutures.
- The 5-mm port sites are closed with absorbable subcuticular sutures.

OPEN RECTOPEXY WITH OR WITHOUT SIGMOID RESECTION

Pfannenstiel Incision

- Make a 10-cm Pfannenstiel incision two fingerbreadths above the pubis. Divide the anterior fascia with cautery, taking care to leave the rectus muscles intact. This division should curve superiorly at the lateral edges so as not to divide the oblique muscles.
- Create a plane between the anterior fascia and the anterior surface of the rectus muscle using cautery and finger dissection while lifting up on the fascia with Kocher clamps (**FIG 13**). This plane should extend down to the pubis inferiorly and superiorly up about 6 cm.
- Find the midline between the rectus muscles and sharply enter the abdomen several centimeters from the pubis in order to avoid entering the bladder.
- With the bladder retracted medially, the posterior rectus sheet/peritoneum is incised inferolaterally in order

FIG 13 ● Pfannenstiel incision. The plane between the anterior fascia and the anterior surface of the rectus muscle has been created while lifting up on the rectus fascia with Kocher clamps. This plane should extend down to the pubis inferiorly and superiorly up about 6 cm.

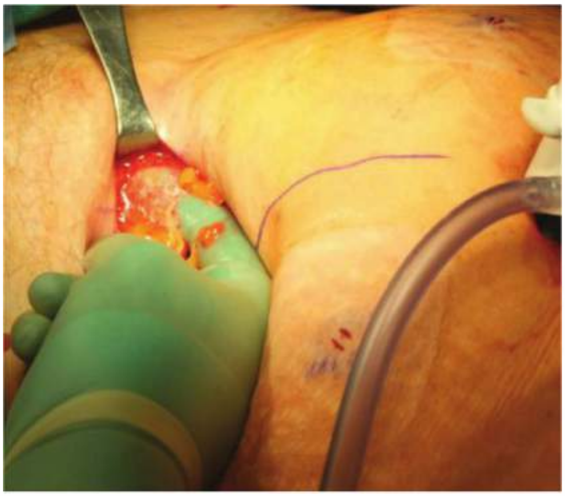

FIG 14 ● Pfannenstiel incision. The posterior rectus sheet/peritoneum is incised inferolaterally with the bladder retracted medially to avoid injuring the bladder.

to avoid injuring the bladder (**FIG 14**). This can be done bilaterally or on one side or the other.

- Place a wound protector (**FIG 15**).

Posterior Dissection

- Place the patient in Trendelenburg position. Place a Bookwalter (or similar) retractor for exposure.
- Pull the rectosigmoid forward and incise the peritoneum at the sacral promontory. At the top of the promontory, the sympathetic hypogastric nerves should be identified and preserved. They form a wishbone here and extend forward around the rectum (**FIG 16**).

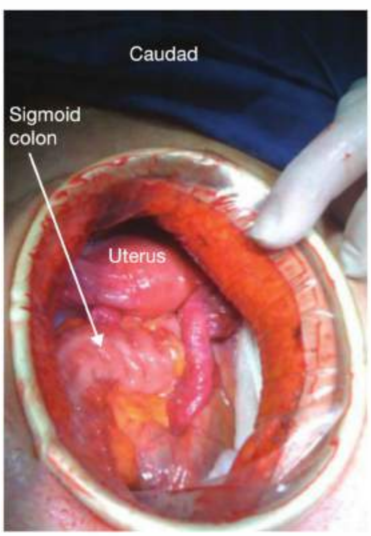

FIG 15 ● Placement of the wound protector.

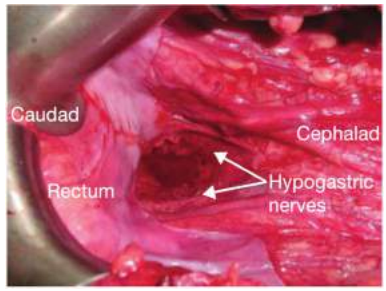

FIG 16 ● Identification of the hypogastric nerves. At the top of the promontory, the sympathetic hypogastric nerves should be identified and preserved. They form a wishbone here and extend forward around the rectum.

If these are divided in a male patient, the consequence is retrograde ejaculation.

- Place a St. Mark's retractor in this peritoneal opening, pull forward and superiorly on the rectum, and divide the alveolar plane between the mesorectum and the presacral fascia with the Bovie cautery, taking care to stay out of the presacral venous plexus (**FIG 17**).
- As the dissection proceeds, the St. Mark's retractor should be placed more distally so that appropriate tension is always maintained. This dissection should be carried out posterior to the rectum down to the level of the pelvic floor.
- The lateral stalks should be left intact as much as possible during this dissection. Useful tools for this dissection include the long tip for the Bovie as well as the extender that can be placed between the long tip and the handpiece and bariatric St. Mark's retractors.

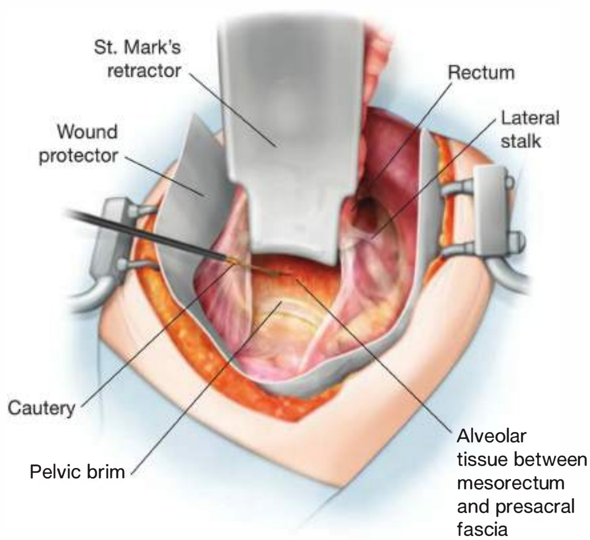

FIG 17 ● Exposure of the presacral space using the St. Mark's retractor. Place the retractor behind the mesorectum and pull forward and upward to reveal the alveolar plane of the presacral space. The dissection is carried down to the level of the pelvic floor; reposition the retractor frequently to maintain the proper tension to reveal the correct tissue plane.

- Check the extent of the distal dissection by placing one hand or surgical instrument in the abdomen at the most distal extent of the dissection and then reach under the drapes to place a finger in the anus to feel the other hand through the posterior rectal wall. The dissection should extend to the top of the anal canal.
- Any prolapse should again be reduced at this time.

Sigmoid Resection

- This step should only be performed if the patient has a very redundant sigmoid colon and severe constipation. The technique for open sigmoidectomy has been described elsewhere in this book.
- The bowel is divided distally at the top of the rectum as defined by the splaying of the teniae.
- The proximal point of transection is where the proximal colon reaches the proximal rectum in the position it will be in after the rectopexy. This position is estimated by pulling the top of the rectum up to the top of the sacral promontory.
- The colorectal anastomosis with 31-mm EEA stapler is performed after the rectopexy sutures are placed but before they are tied.

Rectopexy

- The rectopexy sutures are to be placed starting just below the top of the sacral promontory. Use a long, braided nonabsorbable suture on an SH needle to perform the suture rectopexy, or absorbable suture or even mesh that is attached to the promontory and then sutured to the rectum or mesorectum can also be used.
- The rectum is held out of the way with a retractor and three sutures are placed in the midline from the presacral fascia to the back of the mesorectum, placing the most distal stitch first.
- When placing these stitches, it is important to have the needle enter the presacral tissue at a right angle to the bone and then turn the needle after the bone is felt so that a wide swath of presacral fascia is encircled (**FIG 8**). Another tip is not to remove any misplaced stitches but instead to just tie them as removal can result in significant bleeding from the presacral veins.
- The rectum should be pulled up (with any prolapse reduced) and the stitch should then be placed through the back of the mesorectum such that the rectum is hitched up higher on the sacrum than it was previously. This should be repeated for each of the three stitches.
- Alternatively, the stitches can be attached to the lateral stalk on one side or the other.
- If a resection is being performed, place the sutures, tag them with hemostats, and then tie them after performing the anastomosis with a 31-mm EEA stapler.

Closure

- The rectus muscles and peritoneum can be approximated with absorbable suture or not.
- The anterior fascia is then closed with running PDS sutures.
- The wound is irrigated and the skin closed with running absorbable subcuticular sutures.

PEARLS AND PITFALLS

Diagnosis	■ Must differentiate rectal prolapse from prolapsing internal hemorrhoids
Posterior dissection	■ Must stay in the correct plane and in the midline; otherwise, severe bleeding may occur.
Sigmoid resection	■ Perform resection only in patient's very redundant sigmoids and with severe underlying constipation. ■ The anastomosis should be tension-free without redundancy.
Rectopexy	■ Always check and be sure that the rectal prolapse is reduced before performing the rectopexy. ■ Place sutures through presacral fascia below top of promontory. ■ Tie, rather than remove, misplaced presacral stitches to avoid bleeding.

POSTOPERATIVE CARE

- The orogastric tube is removed at the completion of the case.
- Patients are offered liquids the day of surgery and their diets are advanced to a general diet as tolerated. Reasons not to advance the diet include nausea, vomiting, and abdominal distention. Flatus is not needed for diet advancement but is preferred prior to discharge home.
- Length of stay varies, with laparoscopic and HALS suture rectopexy often being as short as 2 days and open resection rectopexy as long as 7 days.
- Chemical and mechanical prophylaxis for deep vein thrombosis should be started in the operating room and should be continued postoperatively.
- Early ambulation is important.
- Pain is managed with a combination of narcotic and nonnarcotic medications, starting with mostly intravenous medications and quickly converting over to oral medications.
- The Foley catheter is left in place 2 days due to the low pelvic dissection. Upon removal, the patient should attempt to void frequently and intermittent straight catheterization should be performed as needed for retention. Some patients will continue to need this at home.
- Patients should be placed on fiber and/or an osmotic laxative such as MiraLAX as soon as they are able to tolerate oral intake. The goal is one or two soft bowel movements a day such that straining is avoided. The medication can be titrated at home to reach this goal as not all patients have a bowel movement prior to discharge.

OUTCOMES

- Recurrence rates are very low, with most series reporting less than 5% recurrence.
- If recurrence occurs in the case of rectopexy alone, rectopexy can be performed again with or without resection.
- If recurrence occurs after resection and rectopexy, further attempts at repair must be chosen carefully so as not to devascularize any bowel.

COMPLICATIONS

- Pelvic bleeding in the postoperative period is avoided by meticulous technique and hemostasis. If it occurs and is not profuse, it will usually stop by withholding all anticoagulants.
- Wound infection is the most common complication and should be treated by opening the skin and packing the wound until healing occurs.
- The risk of anastomotic leak is 2% to 5%.

Chapter 48

Cytoreductive Surgery and Hyperthermic Intraperitoneal Chemotherapy for Peritoneal Surface Dissemination of Colorectal Cancer

Reese W. Randle Konstantinos I. Votanopoulos
Edward A. Levine Perry Shen John H. Stewart, IV

DEFINITION

- The term peritoneal surface disease (PSD) describes the intraabdominal dissemination of neoplasms to peritoneal surfaces and is a term complementary to peritoneal carcinomatosis.
- Cytoreductive surgery (CRS) and hyperthermic intraperitoneal chemotherapy (HIPEC) have been shown to be effective treatment options for a variety of epithelial primaries. The scope of this chapter is to analyze the role of CRS/HIPEC in the management of selected colon cancer patients with peritoneal dissemination.
- The operation is a two-step process:
  - Surgical resection (CRS) of involved organs and peritoneal surfaces, followed by
  - Delivery of heated chemotherapy (HIPEC) to the peritoneal cavity
- During HIPEC, a heated chemotherapy solution is circulated in the abdominal cavity to treat any cancer cells that may remain after CRS. Delivering chemotherapy at the time of cytoreduction allows a more complete distribution in the peritoneal cavity and exposes tumor-to-drug concentrations higher than that achieved with systemic chemotherapy.
- Thus, the theoretical advantage of CRS/HIPEC, which is now routinely performed in specialized centers, is that it treats macroscopic diseases surgically and microscopic diseases pharmacologically. The results of a prospective randomized trial testing this hypothesis are expected to be released soon.
- The goal for CRS/HIPEC applied to PSD from colon cancer is the complete cytoreduction of all macroscopic disease prior to perfusion with HIPEC. Therefore, appropriate candidates are identified based not only on their ability to tolerate aggressive CRS but also on the likelihood of obtaining a complete cytoreduction.
- Careful selection of patients can help ensure that only those who can expect to have the greatest benefits are subjected to the inherent risks of this treatment paradigm.

PATIENT SELECTION

- Patient selection is based predominantly on the extent of disease and the functional reserves of the patient.
- Preoperative evaluation includes complete history and physical, review of previously obtained pathology, and infused computed tomography (CT) of the chest abdomen and pelvis or dedicated abdominal magnetic resonance imaging (MRI). Preoperative lab work includes blood counts, electrolytes, liver function panel, and carcinoembryonic antigen (CEA) levels.
- Our selection criteria include the following:
  - The patient is medically fit to undergo CRS/HIPEC without signs of kidney, liver, or bone marrow dysfunction preoperatively.
  - The patient's Eastern Cooperative Oncology Group (ECOG) functional status is less than or equal to 2.
  - There is no extraabdominal disease or retroperitoneal disease.
  - There is low-volume peritoneal disease (preferably a peritoneal carcinomatosis index less than 14) that is potentially completely resectable.
  - Any parenchymal hepatic metastasis should be limited and should not require anatomic liver resection.
- Malignant ascites and bowel obstructions are predictors of incomplete resection and worse overall survival.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Infused CT of the chest, abdomen, and pelvis is the standard preoperative imaging study and helps to rule out extraabdominal disease, extensive hepatic metastases, and insurmountable small bowel involvement. Sites of impending obstruction may also be identified.
- Although the sensitivity of CT scan for detecting PSD is low, it is useful in determining overall operability. Solid disease components may be hidden in patients with large volumes of malignant ascites (**FIG 1**).
- MRI may detect PSD with up to 100% sensitivity, yet has a significantly high false-positive rate, especially after prior operations. This is because MRI is incapable of recognizing a difference between scar tissue and recurrent PSD.
- Positron emission tomography (PET) is rarely used given that sensitivity and specificity are prohibitively low, especially in patients with limited disease.
- Endoscopy can allow clinicians to tattoo second colonic primaries in less than 5% of the patients. Endoscopic ultrasonography is unlikely to change the management of these patients.
- Diagnostic laparoscopy can assist in determining the extent and stage of PSD prior to CRS/HIPEC.
- The peritoneal carcinomatosis index (PCI) is the most commonly used staging system for PSD. It provides a way to

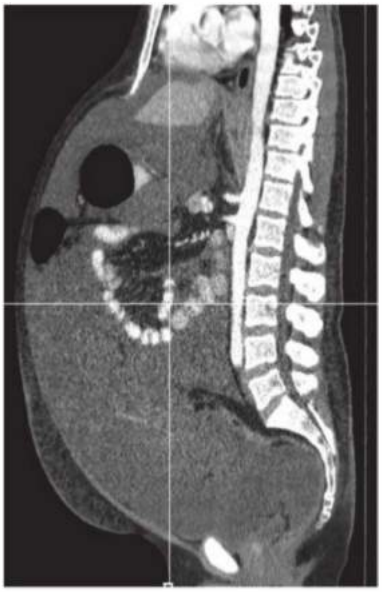

FIG 1 ● Infused CT of a patient with large volume of malignant ascites. The PCI is calculated based on the size of solid disease components but it is not possible to distinguish solid components from ascitic fluid in patients with a large volume of malignant ascites. In these cases, we use the ascites score to evaluate patients for the operation.

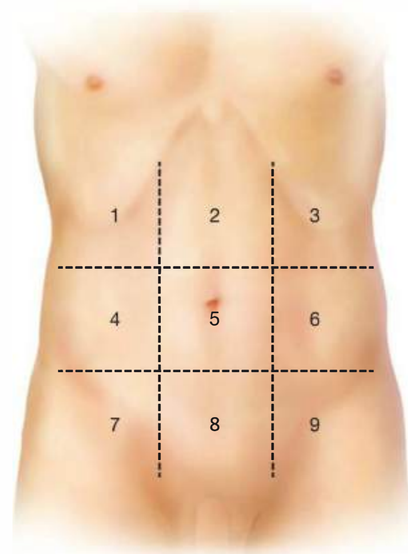

FIG 2 ● Schematic for calculating the ascites score. One point is assigned for the presence of malignant ascites in each of nine abdominal regions on supine CT. The nine regions correlate with those used to calculate the PCI.

standardize the extent of disease. It has been shown to have prognostic value and certain scores have been used as a cutoff in deciding when CRS/HIPEC is appropriate. Calculating the PCI involves dividing the abdomen into nine regions and the small bowel into four regions. For each region, a score of 0 (no tumor), 1 (tumor up to 0.5 cm), 2 (tumor up to 5 cm), or 3 (tumor >5 cm) is applied to assist in understanding tumor burden. Scores for each of the 12 regions are tabulated to derive the PCI score.

- We calculate ascites score in patients with voluminous ascites (**FIG 2**) based on preoperative imaging. Patient with colorectal primaries and ascites score greater than 3 (or three out of nine abdominal areas with ascitic fluid while on supine position on the CT table) have minimal chances to achieve a complete CRS. In these patients, we start the operation with diagnostic laparoscopy to establish resectability.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative assessment includes a history and physical, laboratory evaluation consisting of blood counts, comprehensive metabolic panel, CEA, and a blood type with crossmatch of four units of packed red blood cells.
- Splenectomy vaccines are routinely administered at least 2 weeks prior to the operation when splenectomy is anticipated.
- At the surgeon's discretion, ureteral stents may be placed prior to incision. This is generally appropriate for patients with a good possibility of ureteral involvement, prior retroperitoneal surgical exploration, or large volume of disease.
- A bowel preparation is routine. Patients with a bowel obstruction may benefit from the use of enemas.
- Prophylactic antibiotics are administered prior to induction of anesthesia.
- Both mechanical and pharmacologic deep vein thrombosis (DVT) prophylaxis is instituted as appropriate.

Positioning and Team Setup

- The majority of patients are placed supine. In cases of rectal cancer, induced PSD at modified lithotomy position is preferred (**FIG 3**).
- In the modified lithotomy position, the legs are placed in Allen or Yellofin stirrups. All pressure points are padded to prevent neurovascular injuries and/or calf myonecrosis.
- The thighs are positioned level with the abdomen, as this allows placement of a self-retaining retractor without creating excessive pressure between the retractor and the patient's thighs.
- The perineum is positioned flush with the edge of the operating room table.
- The arms are placed in a neutral position and supported with suitable armrests.
- The surgeon starts at the patient's right side, with the assistant standing to the patient's left side and with the scrub nurse standing to the surgeon's right side (**FIG 4**). If the patient is in a modified lithotomy position, a second assistant would be standing in between the patient's legs.

FIG 3 ● Patient positioning. If a large bowel resection is anticipated, the patient is placed on a modified lithotomy position, with the legs on Yellofin stirrups. The thighs are positioned level with the abdomen, as this allows placement of a self-retaining retractor without creating excessive pressure between the retractor and the patient's thighs. The arms are tucked. All pressure points are padded to prevent neurovascular injuries and/or calf myonecrosis.

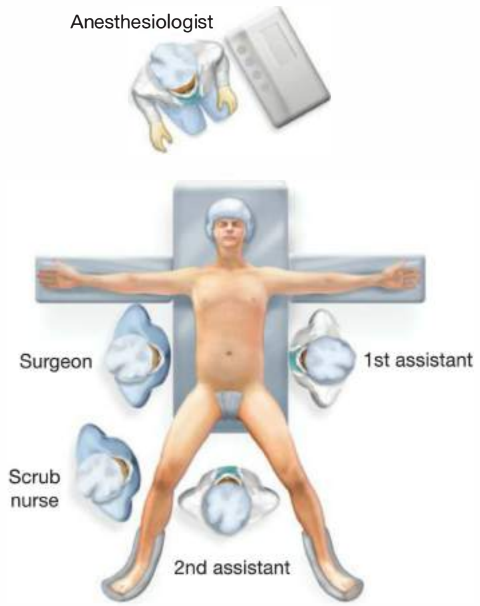

FIG 4 ● Team setup. The surgeon starts at the patient's right side, with the assistant standing to the patient's left side and with the scrub nurse standing to the surgeon's right side. A second assistant, if available, stands in between the patient's legs.

CYTOREDUCTIVE SURGERY

- After prepping and draping the abdomen, an incision is made from the xiphoid to the pubis to facilitate complete exposure of the peritoneal cavity.
- If the falciform ligament is present, it is resected in continuity with the round ligament prior to placing a fixed retractor (Bookwalter or bilateral Thompson).
- All adhesions from previous operations are lysed to allow all areas of the peritoneal cavity to be exposed to HIPEC.
- It is important at this point to proceed with a detailed mapping of the distribution of disease prior to commencing with any organ resection. Invasion of major vascular retroperitoneal structure or disease at the porta hepatis should not be undertaken for colon cancer–induced PSD.
- CRS is then undertaken to remove all visible tumor deposits if possible. Only peritoneal surfaces involved by tumor deposits are stripped from the abdominal wall using electrocautery.
- The greater omentum is routinely removed as it is nearly always a site of tumor deposits in patients with carcinomatosis (FIG 5). Any other involved tissue or organ not vital to the patient is also removed. During resection of the lesser omentum (if there is no gross involvement), we

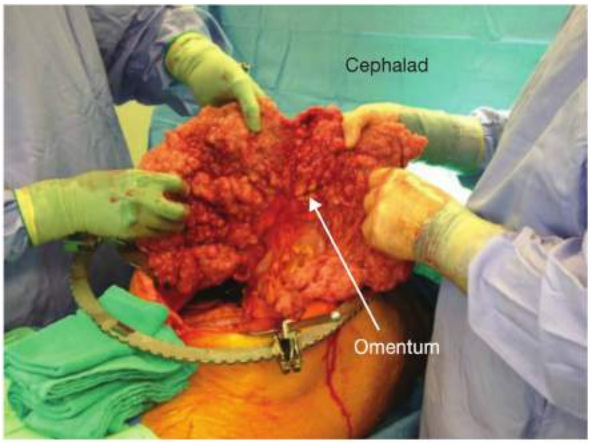

FIG 5 ● Intraoperative photograph of a patient with peritoneal carcinomatosis. Thickening of the omentum from tumor implants is referred to as "omental cake."

attempt to preserve the vagal branches going to the stomach. This will spare the patient a long-lasting gastroparesis and will significantly improve postoperative quality of life.

- Splenectomy is performed in case of direct involvement or any identified involvement of the left hemidiaphragm in order to facilitate a complete diaphragmatic stripping. Attention should be taken to avoid injury to the tail of the pancreas. In case of a distal pancreatectomy, a drain should be left in place. Even though the incidence of pancreatic leak is not higher with CRS/HIPEC, the associated mortality is significantly higher and should be taken into consideration.
- If during the procedure the surgeon feels complete cytoreduction is not possible or carries undue risk for the patient, the operation is aborted or tailored to delay bowel obstruction, as incomplete CRS offers no survival advantage in colon cancer–induced PSD.
- If a bowel resection is required, no data exist regarding the timing of creating an anastomosis; thus, any anastomosis required could be made prior to or following HIPEC. Required ostomies are created following HIPEC.
- We encourage the use of diverting loop ileostomies in cases where a low anterior resection (LAR) with primary anastomosis is performed.

GRADING THE RESECTION

- The degree of resection is judged by the surgeon at the conclusion of the cytoreduction.
- Residual disease is evaluated by measuring the diameter of the largest remaining tumor deposits.
- The two classification systems in use are the R status of resection and the completeness of cytoreduction (CC) score (Table 1). Complete cytoreduction of all gross disease is designated R0 or R1 or CC-0.
- We define complete CRS as no macroscopic evidence of disease at completion of CRS and we group R0/R1 resections together. We very rarely claim R0 resection in peritoneal carcinomatosis, maybe only in oligometastatic peritoneal disease. In addition, the pathologist cannot practically evaluate the margins, of the plethora of specimens, that CRS produces.

Table 1: Grade of Resection

R Status	Diameter of Largest Remaining Tumor Deposits	Completeness of Cytoreduction Score
—	0 mm	CC-0N—no visible disease following neoadjuvant chemotherapy
R0—clear margins R1—involved margins		CC-0S—no visible disease remains
R2a	2.5 mm	CC-1
	5 mm	CC-2
R2b	>5 mm–20 mm	
R2c	>20 mm–25 mm	
	>25 mm	CC-3

The two classification systems in use are the R status of resection and the completeness of cytoreduction (CC) score. Complete cytoreduction of all gross disease is designated R0 or R1 or CC-0.

HYPERTHERMIC INTRAPERITONEAL CHEMOTHERAPY

- Deciding whether or not to proceed with HIPEC is based on the degree of resection achieved but is also influenced by institutional protocols. Although HIPEC has a role in patients following a complete cytoreduction, it is unlikely to prolong survival following incomplete cytoreduction. We do, however, perfuse patients with massive malignant ascites identified at exploration even if a complete cytoreduction is not achieved. This helps prevent the return of the ascites and is of palliative benefit for the patient.
- Several factors that influence the efficacy of the chemotherapy include dose, timing, distribution, temperature, tumor responsiveness, tumor size, systemic chemotherapy, and prior surgery.
- The ratios of peritoneal drug concentrations to plasma drug concentrations are dependent both on the molecular weight and water solubility of the particular chemotherapy (Table 2). The most commonly used chemotherapeutic agents for colon cancer are mitomycin C (MMC) and oxaliplatin.
- Heating the chemotherapy increases the penetration of agents into tumor deposits and enhances their cytotoxic effects. The desired temperature of the perfusate in the abdomen ranges from 40°C to 42°C. During HIPEC, the patient is cooled to prevent systemic hyperthermia. Lowering the room temperature and using room temperature intravenous fluids accomplish this passive cooling.
- Perfusion for colon primaries at our institution is generally maintained for 120 minutes with MMC or oxaliplatin. Perfusion times may be decreased to avoid systemic absorption in patients deemed to be particularly susceptible. Factors that may make a patient more

Table 2: Chemotherapeutic Agents Used in Hyperthermic Intraperitoneal Chemotherapy for Colorectal Cancer

Agent	Molecular Weight	Peritoneal Fluid Concentration to Plasma Concentration
Floxuridine	246 Da	2000:1
Mitomycin C	334 Da	75:1
Oxaliplatin	397 Da	25:1

susceptible to drug toxicity include extensive peritonectomy, poor performance status, or old age.

- The perfusate is drained following the designated time period for perfusion. The abdomen is explored once again and anastomoses or ostomies are created. We do not routinely place drains, with the exception of patients undergoing distal pancreatectomy. The abdomen is closed and the procedure is concluded.
- Several techniques for perfusing with HIPEC have evolved. All consist of a closed circuit to maintain consistent hyperthermia and temperature monitoring (FIG 6A,B). There is insufficient evidence to support one technique over another.

Hyperthermic Intraperitoneal Chemotherapy Delivery Modalities: The Closed Abdominal Technique

- The closed technique is one of the two most commonly used HIPEC techniques.
- This technique involves the placement of inflow and outflow catheters through the skin prior to suturing the skin closed in a temporary yet watertight manner (FIG 7).
- Temporarily closing at the level of the skin while leaving the fascia open allows contact of the perfusate to the likely contaminated subcutaneous tissue on either side of the incision.

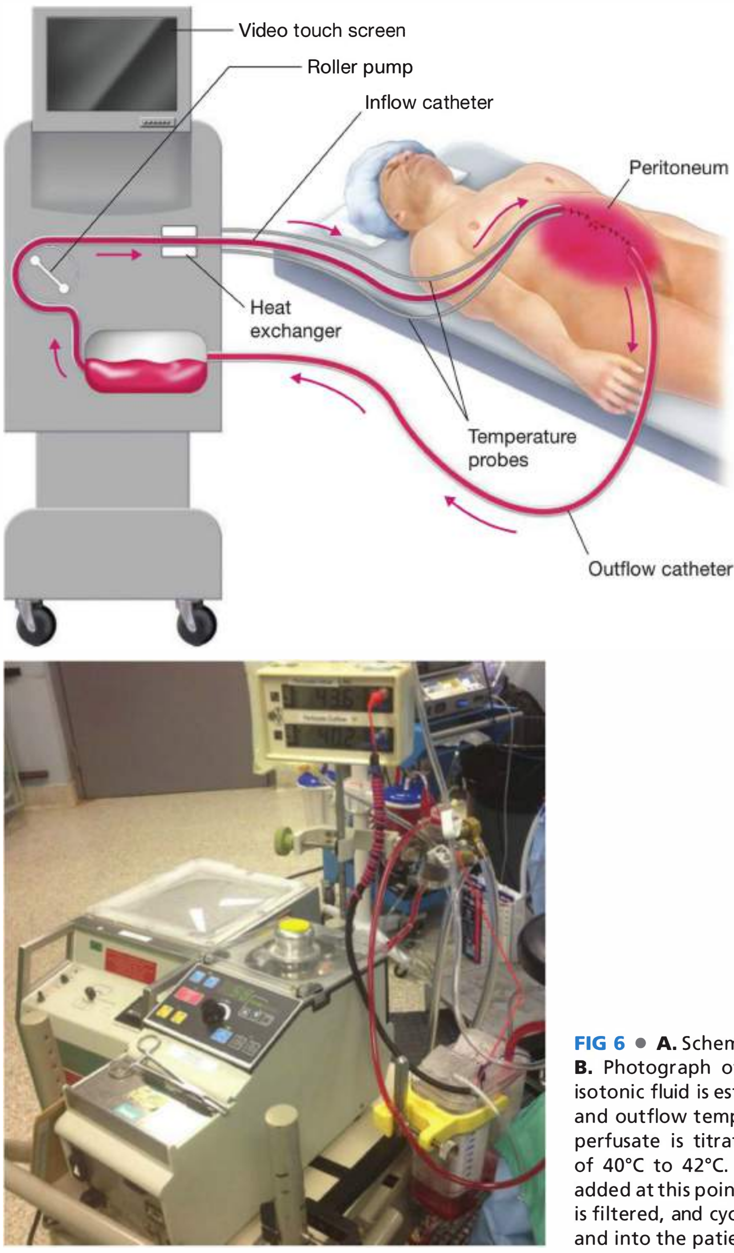

FIG 6 ● **A.** Schematic of a HIPEC perfusion circuit. **B.** Photograph of the perfusion circuit. Flow of isotonic fluid is established into the patient. Inflow and outflow temperatures are monitored and the perfusate is titrated to an outflow temperature of 40°C to 42°C. The chemotherapeutic agent is added at this point. The perfusate exits the patient, is filtered, and cycled back through the heat pump and into the patient for the set period of time.

FIG 7 ● A photograph depicting the closed abdominal technique. There are two inflow and two outflow cannulas that allow the abdomen to be in continuity with the perfusion circuit. The abdomen has been closed temporarily with a running suture at the skin level.

- The operating room personnel massage the abdomen (gently shaking it in a back-and-forth rocking fashion) to help distribute the perfusate throughout the abdomen (**FIG 8**).
- The increased pressure in the closed technique theoretically provides deeper penetration of the chemotherapy into tissues.
- For these reasons, the closed technique is our preferred approach to delivering HIPEC.

Hyperthermic Intraperitoneal Chemotherapy Delivery Modalities: The Open, or Coliseum Technique

- The open technique is also a commonly used HIPEC technique.
- This HIPEC technique involves suturing plastic sheeting circumferentially around the patient's skin incision and securing it to the fixed retractor (**FIG 9**). This expands the potential space with a "coliseum-like" device, which allows the bowel to float freely in a larger volume of perfusate.
- This technique theoretically increases exposure of all surfaces to the chemotherapy.
- The open technique allows the surgeon to manipulate the intraabdominal contents and may facilitate a more even distribution of heat and agent throughout the abdomen.
- Due to concern regarding exposure of operating room personnel to the chemotherapeutic agent with the open technique, specialized education and training of involved personnel is mandatory. Other safety efforts include restriction of operating room traffic, smoke evacuators, filtration masks, and waterproof gowns.

Hyperthermic Intraperitoneal Chemotherapy Delivery Modalities: Other Techniques

- Other modalities of perfusion have been developed in an attempt to combine the advantages of both the open and closed techniques but are not widely used.
- These techniques may provide more even drug and temperature distribution; however, they are generally complex and do not eliminate all safety risks to operating room personnel.

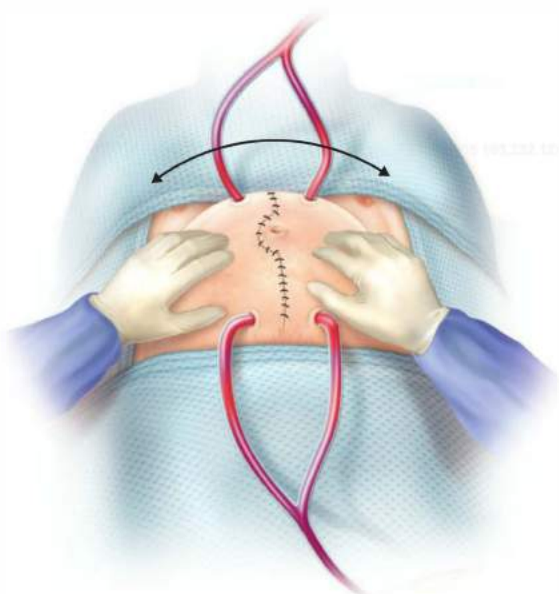

FIG 8 ● Distribution of the perfusate. The operating room personnel massage the abdomen (gently shaking it in a back and forth rocking fashion) to help distribute the perfusate throughout the abdomen.

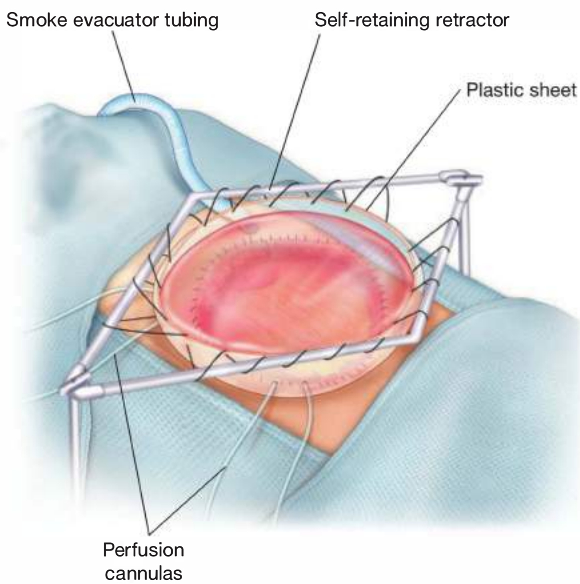

FIG 9 ● The open or "coliseum" HIPEC technique involves suturing plastic sheeting circumferentially around the patient's skin incision and securing it to the fixed retractor. This expands the potential space with a "coliseum-like" device, which allows the bowel to float freely in a larger volume of perfusate.

PEARLS AND PITFALLS

CRS/HIPEC goal	■ Complete cytoreduction prior to HIPEC infusion
Patient selection	■ It is critical to select appropriate candidates. Important elements to assess include the following: ■ Patient's performance status ■ Extent and distribution of disease ■ Consider use of laparoscopy.
CRS	■ Remove everything with tumor deposits: (nonvital) organs and peritoneum. ■ If a bowel resection is required, an anastomosis may be created prior to or following HIPEC. ■ Required ostomies are created following HIPEC. ■ The two predominating classification systems are used: R status of resection and the CC score.
HIPEC	■ Perfuse for 120 minutes at 40°C to 42°C. ■ Temperature >42°C greatly increases morbidity/mortality. ■ The closed abdomen and open (coliseum) techniques are most frequently used.
Postoperative care	■ Close ICU monitoring is required. ■ Postoperative complication rates are high: A high index of clinical suspicion is required.

POSTOPERATIVE CARE

- The goal is for extubation in the operating room, followed by hemodynamic support and close fluid monitoring in the intensive care unit (ICU).
- Seventy-five percent of our patients require close monitoring in ICU postoperatively for a median stay of 1 day, whereas 25% are admitted directly to the floor.
- Total parenteral nutrition is not routinely initiated postoperatively. A nasojejunal feeding tube is often but not always placed in the operating room for early initiation of trophic feeds.
- Broad-spectrum intravenous antibiotics are not continued postoperatively.
- Patients are kept NPO until exhibiting return of bowel function. Nasogastric tubes are used as necessary.
- The Foley catheter is removed within 48 hours; however, it is kept for 5 days in cases where an LAR was performed and for 10 days in cases of a cystectomy or bladder repair.
- Patient-controlled analgesia (PCA) or thoracic epidural analgesia is used postoperatively at the discretion of the surgeon.
- Mechanical and pharmacologic DVT prophylaxis is started on the day of the operation.
- Aggressive chest physical therapy is instituted. Early ambulation is encouraged.
- The median hospital stay for our first 1,000 CRS/HIPEC patients is 8 days.
- Postdischarge follow-up: Patients are discharged home with 2 weeks of prophylactic enoxaparin and are initially seen for a postoperative checkup 2 weeks following discharge from the hospital. Follow-up thereafter includes an examination, tumor markers, and CT imaging every 3 months.

COMPLICATIONS

- Given the extent of the surgical resection required to achieve adequate cytoreduction, morbidity is significant. Major morbidity over the last 5 years for our institution is 27% with 3.8% mortality.
- Complications are frequently divided into two groups: secondary to the operation itself or toxicity from the chemotherapeutic agent.
- The complications of CRS essentially depend on the combination of organs resected and are similar with that described in the general surgery literature. The gravity of the complication may be significantly worse and depends on the physiologic reserves of the patient (which are commonly depleted), the extent of CRS, ECOG, and impact of chemotherapy.
- Twenty-three percent of patients are likely to require a blood transfusion at some point during their operation or hospitalization.
- Predictors of morbidity include older age, higher PCI, greater number of visceral resections, poorer performance status, and higher drug dose.
- Morbidity rates are related to the experience of the center performing CRS/HIPEC.
- Common causes of death are bowel perforation, respiratory failure, bone marrow suppression, thromboembolic events, and sepsis.
- Preoperatively, diabetes, the presence of ascites, bowel obstruction, and poor performance status are predictors of increased mortality rates.
- Despite the significant rates of morbidity and mortality, CRS/HIPEC remains the only hope many of these patients have for long-term survival. Therefore, any legitimate evaluation of the complications following CRS/HIPEC must be compared to the inherent complications of PSD and its natural history without such treatment.

OUTCOMES

- The CC has been shown to be an important independent predictor of survival. The average rate of complete cytoreduction among high-volume centers is about 60% to 75%.
- Predictors of incomplete cytoreduction include poor performance status, disease outside of the peritoneal cavity, more than three hepatic metastases, biliary or ureteral obstruction, multifocal bowel obstructions, the presence of malignant ascites, and extensive disease in the gastrohepatic ligament.

- A consensus statement on the locoregional treatment of colorectal PSD recommends CRS/HIPEC as the treatment of choice for patients without distant metastatic disease and in whom complete cytoreduction is deemed feasible.
- CRS/HIPEC in our institution has a median survival of 33.6 months in colorectal cancer patients who achieved a complete CRS and 21.2 months if CRS/HIPEC is performed with synchronous hepatic resection of limited liver disease. This has to be compared with the 10 to 14 months median survival obtained with second-line chemotherapy and the 3 months median survival obtained with third-line chemotherapy for stage IV colorectal cancer patients.
- It is important to mention that systemic chemotherapy and CRS/HIPEC are complementary treatment and not in lieu of each other.
- These patients should be treated in a multidisciplinary fashion. Multiple lines of chemotherapy result in decrease in ECOG functional status, which is a well-documented predictor of increased postoperative morbidity and mortality. Conversely, upfront CRS/HIPEC resulting in major morbidity will deprive the patient from timely administration of systemic chemotherapy.
- Despite these results, HIPEC for this cohort has not been universally accepted in the oncology community and controversy remains.
- Patient quality of life is another key outcome following CRS/HIPEC. Our quality-of-life data indicate that patients return to their baseline between 3 and 6 months postoperatively. The expected decrease in quality of life immediately following such therapy and its duration should be communicated to patients considering CRS/HIPEC.

MAIN POINTS OF CYTOREDUCTIVE SURGERY/HYPERTHERMIC INTRAPERITONEAL CHEMOTHERAPY FOR PATIENTS WITH PERITONEAL SURFACE DISEASE FROM COLON CANCER

- CRS/HIPEC involves surgical resection of all seeded organs and peritoneal surfaces followed by heated chemotherapy within the abdomen.
- When planning CRS/HIPEC for patients with PSD from colonic primary lesions, appropriate patient selection hinges on the feasibility of obtaining a complete cytoreduction and the patient's ability to undergo the procedure.
- The sensitivity of preoperative CT in determining distribution of disease is small.
- The goal of CRS/HIPEC is the removal of all visible disease prior to perfusion with HIPEC. Incomplete cytoreduction offers no survival benefit in patients with PSD from colonic primary lesions.
- Many factors influence the efficacy of HIPEC. There are also many ways to perform HIPEC, each with their own advantages and disadvantages.
- Close monitoring is required postoperatively, as complication rates are high. Clinicians should maintain a high index of suspicion for complications.
- CRS/HIPEC may offer a survival benefit in low-volume patients with colon cancer–induced PSD when a complete cytoreduction is obtained. This treatment modality should be offered in addition to systemic chemotherapy.

Part 5

Operative Techniques in Breast, Endocrine, and Oncologic Surgery

Chapter 1

Fine Needle Aspiration of a Breast Mass

Judy C. Pang   Claire W. Michael

DEFINITION

- Fine needle aspiration (FNA) biopsy is a percutaneous procedure that uses a fine gauge needle with or without a syringe to sample fluid from a cyst or extract cells from a solid palpable mass for cytologic analysis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A focused history should be obtained from the patient including duration of the mass, changes in size, associated pain, or fluctuations of the mass with menstrual cycle. Prior history of trauma or malignancies should also be ascertained. On physical examination, localizing the mass as within the breast parenchyma, lower axilla, or subcutaneous/cutaneous tissue of the chest wall is important. The differential diagnoses may be different. In addition, noting any skin changes such as redness, warmth, or edema is also helpful. Determining the size and quality of the mass as well as depth and relation to other structures is essential for an adequate sample while minimizing complications. There are no absolute contraindications to FNA.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Mammographic and ultrasound findings can be helpful in arriving at an accurate diagnosis. Knowing whether a lesion is solid or cystic can help select the appropriate needle and syringe. For lesions that are nonpalpable or difficult to palpate, image-guided (i.e., ultrasound) FNA is recommended to ensure proper sampling of the mass.

DIFFERENTIAL DIAGNOSIS

- Benign (i.e., fibroadenoma, cyst)
- Malignant (i.e., carcinoma, lymphoma)
- Atypical (core biopsy or surgical excision required for definitive diagnosis)

NONOPERATIVE MANAGEMENT

- For patients who opt not to undergo a biopsy, short-term follow-up (4 to 6 months) with repeat imaging and clinical examination to document stability or changes is recommended.

SURGICAL MANAGEMENT

- Alternative procedures to FNA biopsy are core needle biopsy and surgical excision of mass.
- For solid masses, FNA biopsy provides cells for cytology, whereas core needle biopsy obtains tissue. In situations where an experienced cytopathologist is not available or tissue architecture is necessary to make a diagnosis (e.g., differentiating between in situ and invasive disease), core needle biopsy is preferred.
- Surgical excision should be reserved for cases where FNA or core needle biopsy was inconclusive. It may be considered for small breast masses where the patient is strongly desirous of excision.

Preoperative Planning

- Prior to the FNA, the location of the palpable mass should be confirmed with the patient. The mass should be examined in the upright and supine position to determine the ideal position for the biopsy.

Positioning

- The patient may be upright or supine depending on the location of the mass. The patient should be positioned to optimize palpation and sampling of the mass.

Approach

- FNA can be performed using (1) a needle, syringe, and syringe holder; (2) a needle and syringe; or (3) a needle only.

EQUIPMENT

- Alcohol pads to cleanse the skin and gauze pads to apply pressure after completion of the procedure
- Local anesthetic is optional.
- Beveled hypodermic needles
  - A 23-gauge needle is preferred and typically the one to start with. If inadequate material is obtained, a 22-gauge needle can be used especially for lesions with minimal stroma (i.e., lymphoma, melanoma) or a 25-gauge needle for rubbery or fibrous masses (i.e., fibroadenoma).
  - The length of the needle is typically 5/8 in to 1½ in, which is just long enough to reach the target. Shorter needles are easier to manipulate because they will not bend.
- A slip-tip syringe is best as it is easy to handle and provides a good seal. A Luer lock syringe may also be used, but it can be difficult to remove the needle. A 10-mL syringe is preferred as it allows the hand to be closer to the target and only 2 to 4 mL of suction is needed for aspiration. For larger cystic lesions, a 20-mL syringe may be advantageous.
- A syringe holder allows for one-handed grip and application of suction leaving the other hand free to stabilize the target.
- Glass slides and cover slips
- Slide holder for air-dried slides

- Ninety-five percent ethanol (EtOH) in a jar for fixation of slides or spray fixative. If the jar is not slotted for separating slides, using paper clips on alternating slides can achieve the same goal.
- There are different rapid stains that can be used for adequacy checks including toluidine blue, rapid hematoxylin and eosin, rapid Papanicolaou for fixed slides, and Giemsa and Diff-Quik for air-dried slides.
- Needle rinses can be performed in RPMI (cell block or flow cytometry for lymphoma), 10% buffered formalin (cell block), or CytoLyt (thin prep).

FINE NEEDLE ASPIRATION USING NEEDLE, SYRINGE, AND SYRINGE HOLDER[1,2]

- Carefully palpate the mass to estimate the size and depth as well as assess the structures nearby to avoid (i.e., major blood vessels, bone, and lung especially with small breasts).
- Fix the mass firmly in place with the fingers.
  - For large lesions, use the thumb and opposing finger (**FIG 1**).
  - For smaller lesions, place the forefinger and middle finger on top of the mass and then spread them apart, stretching the skin (**FIG 2**).
- Plan the angle of the needle at the entrance point of the skin and determine the depth of penetration.
  - If the needle enters at 90 degrees to the mass, the needle should penetrate the skin on top of the mass (**FIG 3A,B**).
  - If the needle enters at a 30- to 45-degree angle, which is oftentimes more comfortable and practical, compensate for the acute angle by penetrating the skin adjacent to the mass and not on top of the mass (**FIG 4A,B**).
  - When entering at 90 degrees, penetrating too deep with the needle can potentially result in a pneumothorax. If this is a concern (e.g., mass near the chest wall), a 30- to 45-degree angle is preferred.
  - To stabilize the instrument, rest the barrel of the syringe on the forefinger of the palpating hand or use the thumb to stabilize the syringe as you enter the mass. Once the needle is in the mass, the thumb can be removed (**FIG 4A**).
- Extracting material
  - For cystic lesions, applying suction without back and forth movement is sufficient.
  - For solid masses, 15 to 20 excursions are made before suction is released and the needle is removed from the mass. If blood is seen at the hub, the number

FIG 1 ● Fixation of a large mass using the thumb and opposing finger.

FIG 2 ● Fixation of smaller mass using forefinger and middle finger.

FIG 3 ● **A,B.** Needle entering 90 degrees to the mass should penetrate the skin on top of the mass.

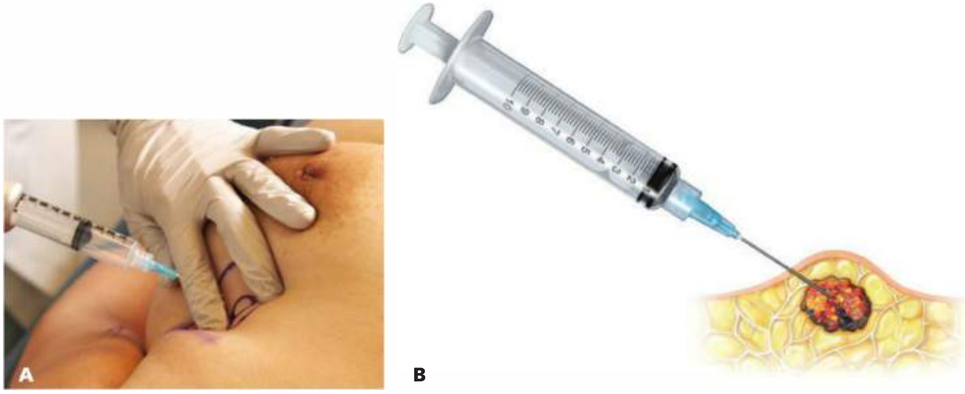

FIG 4 ● **A,B.** Needle entering 30 to 45 degrees to the mass should penetrate the skin adjacent to the mass and not on top of the mass.

of excursions should be limited and suction released before reaching 15 to 20. Always release the suction before pulling the needle out of the patient; otherwise, all the material will flow into the barrel of the syringe, which will be very difficult to extract (**FIG 5**).

- Adequate sampling
  - To sample different areas of a well-defined large lesion, it is preferable to make separate passes to sample different areas. This is also preferable in well-defined lesions. In ill-defined targets, especially fibrocystic changes of the breast, it is best to redirect while sampling in a fanlike fashion. To avoid tearing the tissue and causing bleeding, the needle should be retracted to the surface of the target (but still in the patient) before redirecting (**FIG 6**).
  - Typically, two to three passes are adequate. Additional passes are performed if the target is large or the sample is inadequate. However, typically more than three passes is not recommended as often times the yield of diagnostic material decreases with each subsequent pass due to blood. The first pass is traditionally the best.
- Zajdela's technique, which uses only the needle without a syringe or syringe holder (**FIG 7A**). This technique is ideal for small targets as it increases sensitivity to the difference in consistencies between normal breast tissue and the lesion that cannot be appreciated as well with a syringe and syringe holder. In addition, it is less bloody. However, this technique often yields less material than when suction is used, and there is a risk of overflow of material if the lesion is cystic. A syringe (without the plunger) can be used if needed (**FIG 7B**).

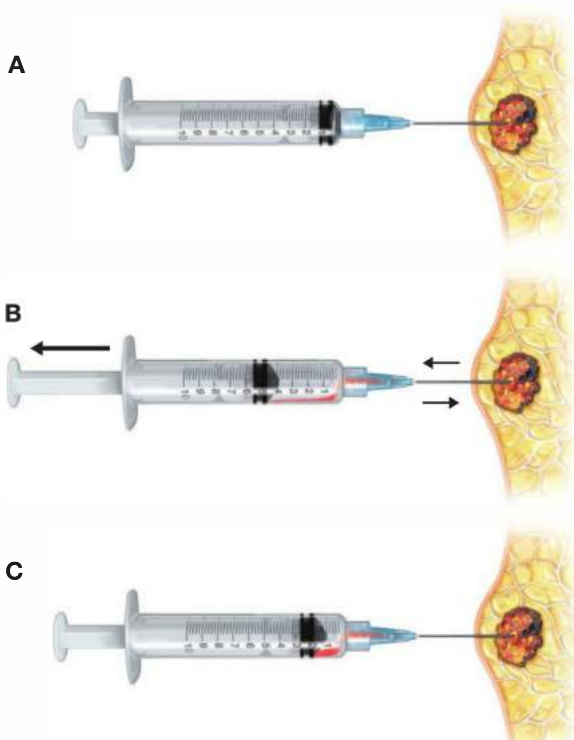

FIG 5 ● **A.** Needle placed in mass. **B.** Withdraw plunger creating 2 to 4 mL of vacuum/suction and perform 15 to 20 excursions. **C.** Release the plunger/suction before pulling needle out of the patient.

FIG 6 ● To sample different areas, redirect the needle in a fanlike fashion.

FIG 7 ● Zajdela's technique using only a needle **(A)** or a needle and a syringe without the plunger **(B)**.

PREPARING SLIDES[1,2]

- Expulsion of material
  - The needle is first disconnected from the syringe (**FIG 8**). The plunger is then pulled back all the way before reattaching the needle (**FIG 9A,B**). If using the Zajdela technique with the needle and syringe, disconnect the needle from the syringe before putting the plunger back into the syringe.
  - With the tip of the needle on the slide (bevel down), the plunger is forcefully pushed so that all the material is on one slide (**FIG 10A,B**). If there is abundant material, the plunger can be pushed slowly so that only a small amount of material is placed on each slide. The slides should be labeled with patient identifiers (i.e., name and birth date) with a pencil.
  - If there is remaining material in the hub, it can be rinsed for cytocentrifugation (in CytoLyt) or cell block (10% buffered formalin or RPMI) (**FIG 11**). If additional smears are desired, the flip technique can be used where the needle is secured in the rubber top of a Vacutainer tube. The hub is then flicked repeatedly onto a slide. Droplets of the material on the slides can then be smeared. (**FIG 12**).
- Smearing techniques
  - Rest the edge of a second slide on top of the slide that contains the aspirate material (**FIG 13**).

FIG 8 ● Disconnect needle from syringe.

FIG 9 ● **A,B.** The plunger is pulled back all the way **(A)** before reattaching the needle **(B)**.

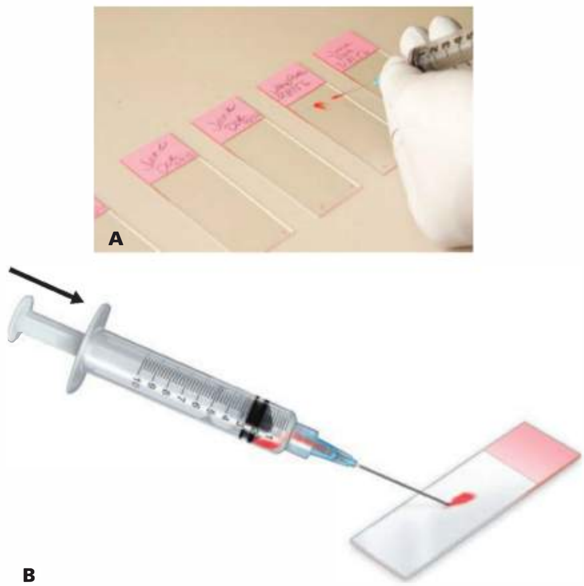

FIG 10 ● **A,B.** With the tip of the needle on the slide (bevel down), the plunger is forcefully pushed so that all the material is on one slide. If there is abundant material, the plunger can be pushed slowly so that only a small amount of material is placed on each slide.

FIG 11 ● The needle can be rinsed in RPMI, 10% buffered formalin, or CytoLyt.

FIG 12 ● Secure the needle in the rubber top of a Vacutainer tube. Flick the hub repeatedly onto a slide.

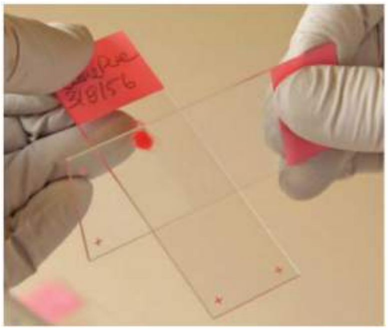

FIG 13 ● Rest a slide on top of the slide that contains the aspirate material.

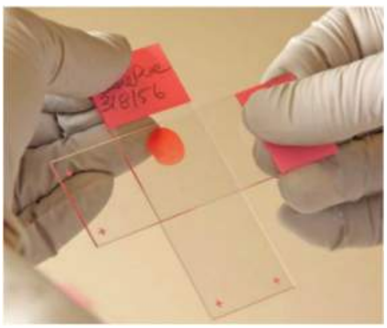

FIG 14 ● Rotate the top slide so that it is parallel to the bottom slide.

- Rotate the top slide so that it is level with the bottom slide (**FIG 14**).
- Keeping both slides level, apply light pressure and slide the top slide over the bottom slide (**FIG 15**).
- The end product should be a slide with material in an oval configuration of even thickness (**FIG 16**). Virtually, all the material should be on the bottom slides. Microscopically, the cells should be well preserved with intact cytoplasm. If too much pressure is applied, there will be crushed nuclei and few cells with preserved cytoplasm. If the slides are not maintained level to each other, the material will be scraped and lost and distortion will be present.

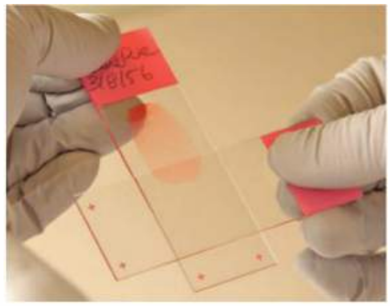

FIG 15 ● Apply light pressure and slide the top slide over the bottom slide.

FIG 16 ● End product with material in an oval configuration.

- Other techniques
  - Place a clean slide exactly parallel to the bottom slide containing the aspirate material and slide apart. The material will be present on both slides (also produces good smears) (**FIG 17A,B**).
  - For bloody aspirates, tilt the slide and allow the blood to drain into collecting media (**FIG 18A,B**). The particulates remaining on the slide is then scraped with the edge of another slide and then smeared onto a separate slide (**FIG 18C,D**). Alternatively, the particulates on the original slide can be smeared directly with a separate clean slide (**FIG 18E**).

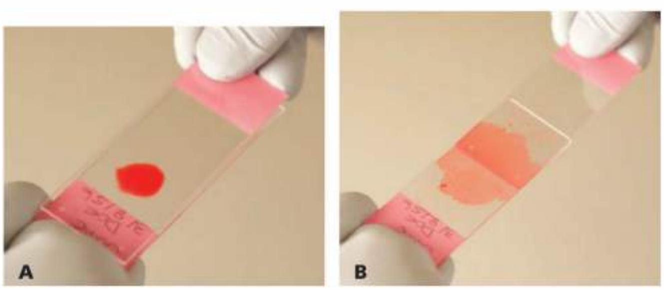

FIG 17 ● **A,B.** Place a clean slide exactly parallel to the bottom slide containing the aspirate material and slide apart.

FIG 18 ● **A.** Bloody aspirate. **B.** Tilt the slide and allow the blood to drain into collecting media. **C.** Scrape remaining particulates on the slide with the edge of another slide and then smear onto a separate slide **(D)** or smear the particulates on the original slide directly with a separate clean slide **(E)**.

FIX SLIDES

- The slides should be immersed in 95% EtOH or fixed by spray fixation (**FIG 19**). This should be done as quickly as possible after smearing the slides to prevent air-dry artifact. Alternatively, slides may be left to air dry without fixation. Ideally, both air dried and fixed slides should be made for cytologic evaluation.

FIG 19 ● Fix slides immediately in 95% liquid EtOH or spray fix.

PEARLS AND PITFALLS[3]

Indications	■ Palpable masses: A brief history and focused physical examination should be performed. ■ Diagnostic: primary neoplasms (benign vs. malignant), tumor recurrence, secondary or metastatic tumors, inflammatory diseases (uncommon), atypical epithelial lesions (require additional studies) ■ Therapeutic: evacuation of simple cysts
Major diagnostic pitfalls	■ False negative: small focus of carcinoma arising in a background of a predominantly benign lesion (i.e., fibrocystic change), carcinoma arising in a complex proliferative lesion (i.e., papilloma), well-differentiated carcinomas, rare tumor types, extensively necrotic or cystic carcinomas, sampling error, inadequate smears ■ False positive: fibroadenoma, papilloma/papillary lesions, atypical ductal hyperplasia, pregnancy-associated/lactational changes, fat necrosis, collagenous spherulosis, skin adnexal tumors
Major limitations	■ Inability to distinguish between invasive and in situ carcinoma ■ Accuracy is often dependent on the size of the lesion (less sensitive if $<$0.5 cm). ■ Low accuracy in tumors with a predominant necrotic/cystic component ■ Lack of specific diagnosis for majority of benign lesions ■ Need for biopsy (core or excisional) of all lesions with an "atypical" diagnosis ■ Ability to perform hormone receptor and *HER-2/neu* analysis can only be done with accuracy if an adequate sample is obtained.

POSTOPERATIVE CARE

- Pressure should be applied to the site for a few minutes to assure hemostasis, and then a sterile dressing is applied.

OUTCOMES

- 80% to 100% sensitivity, with a specificity of over 99%
- 3% to 5% false-negative and 0.5% to 2% false-positive rate
- Implementing the "triple test" is essential (correlation of clinical, radiologic, and cytologic findings)

COMPLICATIONS

- Low complication rate and most complications are minor
- Pain
- Bleeding/hematoma
- Infection
- Vasovagal reaction
- Pneumothorax
- Epithelial displacement/tumor seeding
- Artifacts occurring after aspiration may interfere with radiographic interpretation and histologic evaluation of surgical resection (epithelial displacement can mimic invasive carcinoma).

Chapter 2 Wire Localized Breast Biopsy

Michael S. Sabel

DEFINITION

- The wire-localized excisional biopsy (or needle-localized biopsy) is used to obtain tissue for the diagnosis of a nonpalpable, image-detected abnormality. There are various methods for localizing breast lesions for excision, including wire localization, cutaneous markers, and radiocolloid occult lesion localization (ROLL). Wire localization is the most frequently used method and is described in this chapter.
- It is preferable to use image-guided biopsy as a first step (stereotactic biopsy or ultrasound or magnetic resonance imaging [MRI]-guided biopsy), as this avoids surgery in patients with benign disease and allows for a definitive oncologic operation in patients with malignant disease. Thus, the wire-localized excisional biopsy should be limited to patients who failed image-guided biopsy or are not suitable candidates. Wire-localized lumpectomy is a similar procedure for patients who have already been diagnosed with breast cancer, where the goal is a complete excision of the cancer with an adequate margin of surrounding normal tissue. For wire-localized lumpectomy, often, two wires are needed to "bracket" the cancer in order to assure complete removal.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A bilateral breast exam should be performed in all patients for whom wire-localized breast biopsy is being contemplated for two reasons. First, to assess whether or not the lesion is truly nonpalpable. If the abnormality is palpable, then wire localization will not be necessary. If an abnormality is palpated, it is critical to review with the radiologist to be sure that the palpable abnormality corresponds to the imaging abnormality being recommended for biopsy. The second reason for bilateral breast examination is to make sure there are no other palpable occult abnormalities that may also require biopsy.
- For patients with biopsy-proven cancer who are to undergo wire-localized lumpectomy, a thorough history and physical examination is necessary to make sure they are suitable candidates for breast conservation therapy (BCT). Contraindications to BCT include prior radiation, collagen vascular disease, first or second trimester of pregnancy, multicentric cancer, or widespread calcifications (see Part 5, Chapter 5, Lumpectomy).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The preoperative imaging is essential to the procedure. Prior to the decision to perform a wire-localized breast biopsy, the breast imaging should be reviewed to determine whether the patient is a suitable candidate for an image-guided biopsy, as this is the preferable first step. The patient's allergies, medications (specifically aspirin or anticoagulants), or the presence of a bleeding diathesis should be reviewed. Contraindications to stereotactic core needle biopsy include an inability to adequately visualize the target lesion or an inability of the patient to remain in the position required for the procedure. Some patients may exceed the weight limit for the stereotactic table. Other factors that may preclude stereotactic core needle biopsy include higher breast density; lesions close to the skin, chest wall, or axilla; or the presence of breast implants.
- Prior to coming to the operating room (OR), the patient undergoes needle localization under image guidance. After local anesthesia, a rigid introducer needle with a hooked wire within it is directed toward the site of the abnormality using biplanar mammography (**FIG 1A**) or ultrasound (**FIG 1B**). The rigid needle is then removed, leaving the wire secured by the hook so it is not easily withdrawn or redirected (**FIG 2A,B**).
- In many cases, a wire-localized excision is recommended after an image-guided core needle biopsy–demonstrated atypia (lobular carcinoma in situ [LCIS], atypical ductal hyperplasia [ADH], atypical lobular hyperplasia [ALH], or flat epithelial atypia [FEA]). It is also often recommended after a needle biopsy of papilloma or radial scar. In these cases, a fraction may upstage to in situ or invasive cancer.[1–6] It is good to review the pathology and indications for the biopsy prior to the procedure.

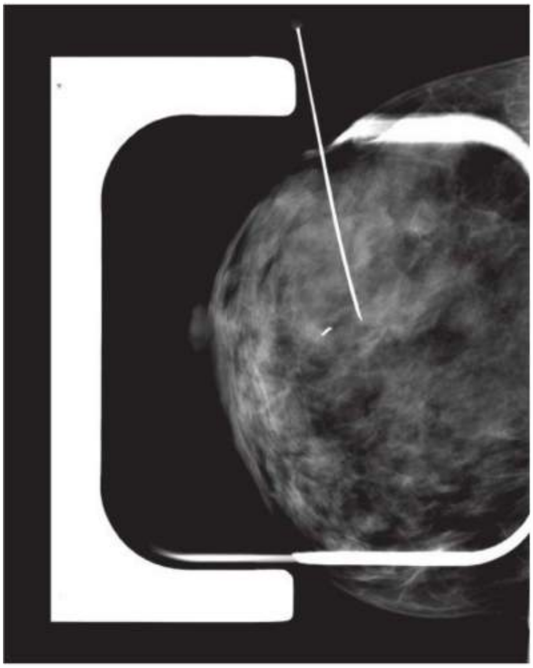
SURGICAL MANAGEMENT

Preoperative Planning

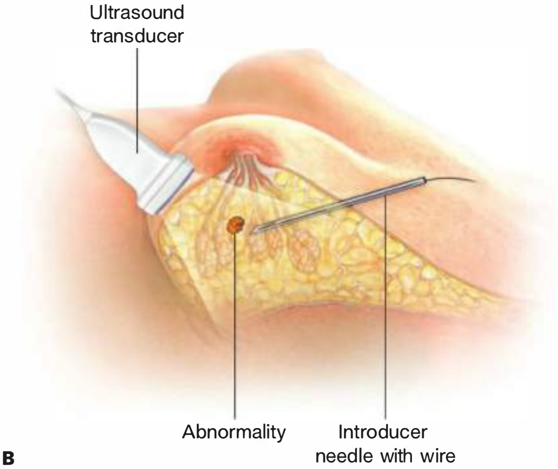
- Performing a breast exam after the localization will be difficult, as the wire will be secured by a variety of methods that will preclude physical exam. These should not be removed until the patient is positioned in the OR to minimize the chance of dislodging the wire during transport.
- Prior to taking the patient back to the OR, the localization films should be reviewed. Specifically, the surgeon should note the proximity of the abnormality to the wire, the direction of the wire from the point of skin entry, and how far the lesion is from the skin, as this may impact the degree of sedation (if any).
- Although the risk of infection after breast surgery is low, it tends to be higher than average for a clean surgical procedure, and several studies have shown that antibiotic prophylaxis significantly reduces the risk of postoperative infection.[7]

Positioning

- The patient should be positioned supine. Often, the localization wire is placed laterally, so the ipsilateral arm may need to be at 90 degrees.
- Once the patient is on the OR table and positioned, the tape and dressings securing the wire should be removed carefully as not to dislodge the wire. A gentle breast exam can be performed at this point to see if the lesion is palpable. In addition, light palpation while watching the external portion of the wire can give the surgeon an idea of what direction the wire is heading.

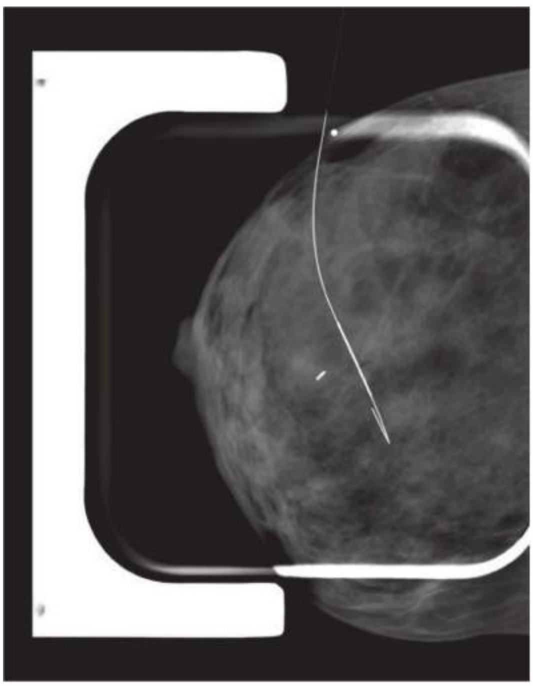


A

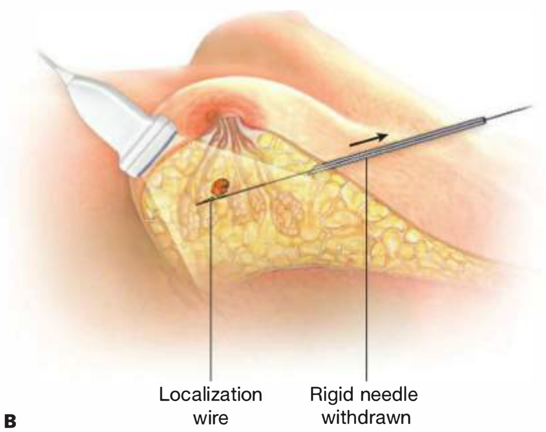


B

FIG 1 ● Placement of the rigid needle using biplanar mammography **(A)** or ultrasound **(B)**.



A



B

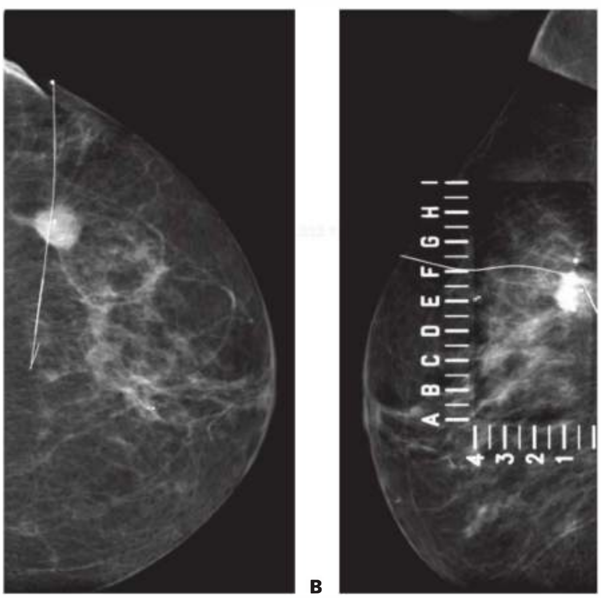
FIG 2 ● **A,B.** The rigid needle is withdrawn, leaving the wire in the location of the abnormality.

- The localization wire is often quite long and with a significant portion outside of the skin. The case will be facilitated by cutting the wire to a more workable length. Care must be taken not to advance the wire or pull the wire back (or out). It is also important not to cut the wire so close to the skin that it disappears. Secure the wire at the level of the skin prior to cutting with a wire cutter (**FIG 3**).

FIG 3 ● The wire is secured at the level of the skin while excess wire is cut. It is important not to dislodge the wire as well as to leave an adequate amount.

ANTICIPATING THE LOCATION OF THE ABNORMALITY

- After the dressings have been removed, the surgeon uses the site and direction of the wire along with the craniocaudal (CC) and lateral–medial (LM) views to determine the location of the abnormality in the breast. A small BB is usually placed at the site where the wire enters the skin, so it is possible to estimate how far through the breast tissue the wire extends. Remember, the breast is compressed during the mammography but not on the OR table, so the measurement on the film may not be exact. It is often helpful to identify the nipple on the mammogram as an additional landmark.
- The CC view (**FIG 4A**) demonstrates both the anterior–posterior and the lateral–medial location of the abnormality but gives no information regarding the superior–inferior location. With a laterally placed wire, the CC view can be used to estimate how deep the lesion is and how medial (especially when also using the nipple as an additional landmark).
- The LM view (**FIG 4B**) demonstrates the anterior–posterior orientation as well as the superior–inferior but gives no information regarding the lateral–medial location. Again, with a laterally placed wire, the deviation from the skin BB to the hook of the wire can be used to assess whether the wire is heading superiorly or inferiorly.
- Using both views, the surgeon should also note where the abnormality is in relation to the wire. Typically, the radiologist attempts to place the reinforced portion of the wire in close proximity to the lesion. It is crucial to know the relative proximity of the wire to the lesion and in what direction the wire sits relative to the lesion.



A B

FIG 4 ● The localization films show the relationship between the skin, the wire, and the abnormality. In the CC view **(A)**, the *dot* shows the entry point in the skin. The film shows the lesion to be posterior and lateral, but this film does not reveal the anterior–posterior position. The hook and reinforced portion of the wire are distal (medial) to the lesion. In the LM view **(B)**, you can again see the lesion is posterior, but now you can see that it sits superiorly. It may seem like the wire travels through the breast for some distance but most of that is external. The *white dot* shows where it enters the skin.

SKIN INCISION AND IDENTIFICATION OF THE WIRE

- Using both the preoperative imaging and examination of the breast, the surgeon can estimate the direction of the wire and the distance to the reinforced portion of the wire. Using a water-soluble marker, an incision should be marked out (**FIG 5**). For lesions close to where the wire enters the skin, the incision can be planned at the entry site. Otherwise, the incision should be placed directly over the predicted site of the mammographic abnormality.
- When marking the incision, it should be kept in mind that if this lesion is malignant, you may be returning for a reexcision lumpectomy or a mastectomy. Therefore, the incision should be placed in a way that does not compromise that. For lesions near the nipple–areolar complex, a circumareolar incision is cosmetically appealing, but excessive tunneling is discouraged as this will also complicate a reexcision lumpectomy if cancer is present.
- The incision should be kept small at first, as it can be lengthened later if need be (**FIG 6**). As these are typically performed with just local anesthesia or light sedation, the skin is anesthetized prior to any incision.

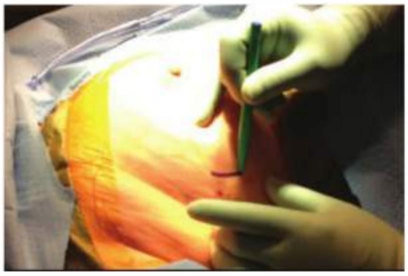


FIG 5 ● An incision is marked out over the anticipated site of the abnormality, keeping in mind a reexcision lumpectomy or mastectomy should the pathology return as malignant.

FIG 6 ● A small incision is made in the skin after infiltration of local anesthesia.

EXCISION

- The goal of the wire-localized excisional biopsy is to make the diagnosis while removing as little breast tissue as possible. If the CC and LM views suggest that the lesion is deep to the incision, the dissection is continued posteriorly so as to avoid removing excessive tissue anterior to the lesion and wire (**FIG 7A**). For more superficial lesions, flaps should be elevated shortly after incision but kept thick enough to avoid concavity at the site (**FIG 7B**).

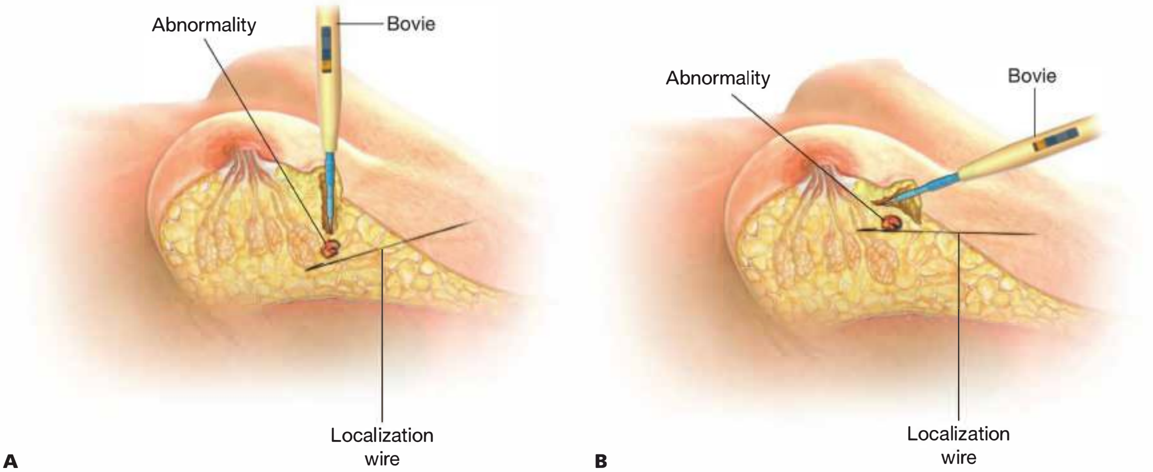

FIG 7 ● The subcutaneous fat and breast parenchyma are divided with cautery. For deep lesions **(A)**, dissect a fair distance to avoid taking excessive tissue anterior to the lesion (causing concavity). For superficial lesions **(B)**, thick flaps should be elevated shortly after incision.

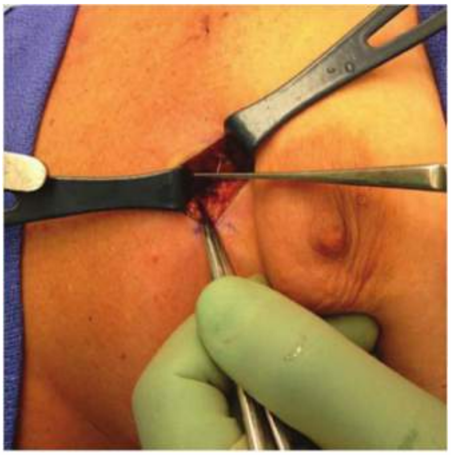

FIG 8 ● The wire is identified proximal to the anticipated site of the abnormality.

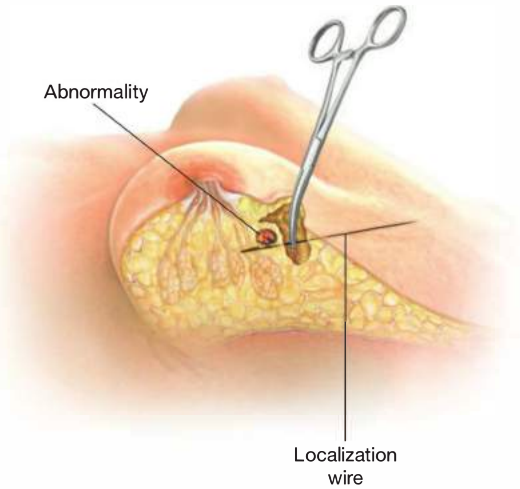
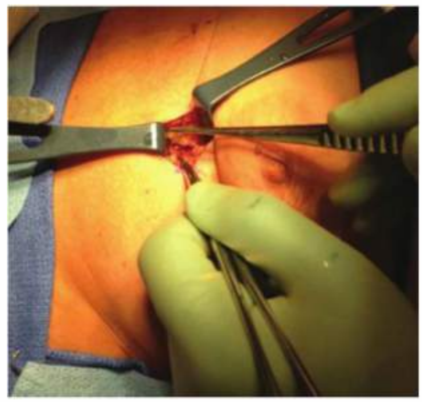
- If the incision does not pass through the entry site of the wire, the next step is to identify the shaft of the wire proximal to the lesion. Dissection is carried down to the wire, taking care not to land on top of the abnormality but rather on the wire proximal to the abnormality (FIG 8).
- Once the wire is identified, it is grasped with a hemostat on the specimen side, and the shaft of the wire is retracted into the wound. Take care to secure the wire adequately so it is not dislodged (FIG 9A,B).
- At the point where the wire enters the breast, grasp the tissue with an Allis clamp. Be careful to grasp above or below the wire and not the wire directly, as retraction on the clamp may dislodge the wire (FIG 10).
- Dissection then continues parallel to the wire, maintaining a circumference of approximately 1 cm of breast tissue around the wire. This is modified based on the size of the abnormality and the relationship between the wire and the lesion. For example, for a lesion sitting approximately 1 cm anterior to the wire, a larger margin is taken anteriorly, whereas a smaller margin can be taken deep to the wire.
- For mammographic masses, palpation along the wire will often allow the surgeon to identify the abnormality and proceed with excision, simplifying the procedure.
- Dissection continues until you are confident you are past the location of the abnormality and the specimen can be transected (FIG 11). Often, the wire will be encountered during this step, so take care not to divide the wire, potentially leaving the hooked end in the patient. If the wire is identified at this point, visualize where on the wire you are. If you are at the hook and the films show the hook is distal to the lesion, you should be fine. If you encountered the reinforced portion of the wire, grasp the remaining tissue in the direction of the wire and continue the dissection until you are past the hook.



A



B

FIG 9 ● **A.** The wire is secured at the breast with a hemostat. **B.** Forceps are then used to pull the external portion of the wire through the skin and out of the wound.

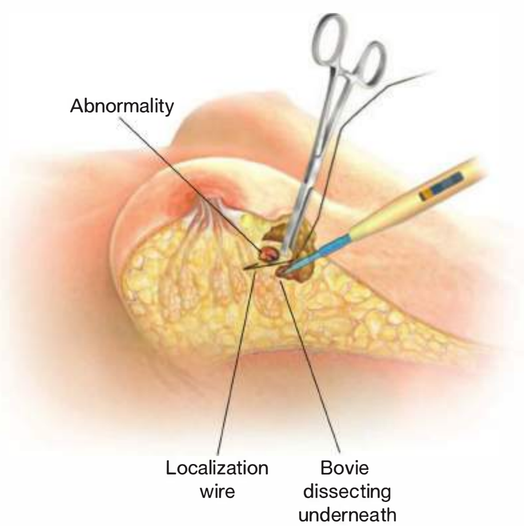


FIG 10 ● An Allis clamp is used to grasp the breast tissue (do not grab the wire) and dissection continues parallel to the wire in all directions.

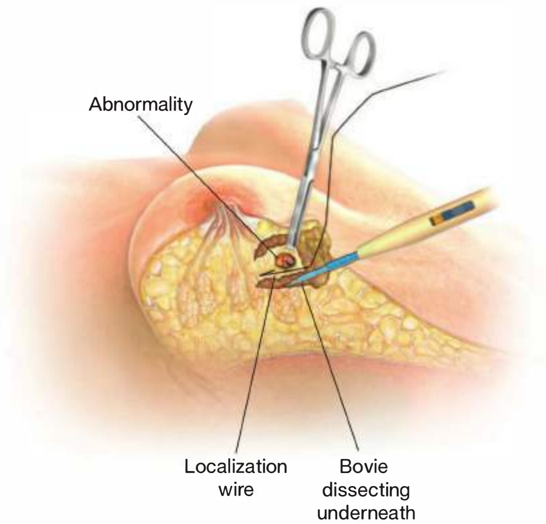

FIG 11 ● Once the circumferential dissection is past where you estimate the lesion to be, the specimen is transected, taking care not to divide the wire (and leave the hook).

ORIENTATION

- Immediately upon removing the lesion, maintain the orientation and place 2-0 silk sutures for the pathologist. If this returns as cancer, this allows for simple reexcision of any involved margin as opposed to a reexcision of the entire cavity. It is often preferable to place one or two orienting sutures before complete removal of the specimen.
- Three sutures are recommended to orient the mass correctly for the pathologist and avoid errors.[8] We recommend placing a short suture superiorly, a long suture laterally, and a double suture deep posteriorly (**FIG 12**).
- It is also often beneficial to place radiopaque clips on the specimen to allow for orientation of the lesion on the specimen mammograms. For example, if the wire enters laterally, placing a single clip superiorly and a double clip posteriorly allows you to orient the specimen on the films (**FIG 13A,B**). In the case of a wire-localized lumpectomy for cancer, this allows for reexcision of a potentially close margin. For a biopsy, if the abnormality is not within the specimen, this may help the surgeon identify in what direction additional tissue should be sampled.

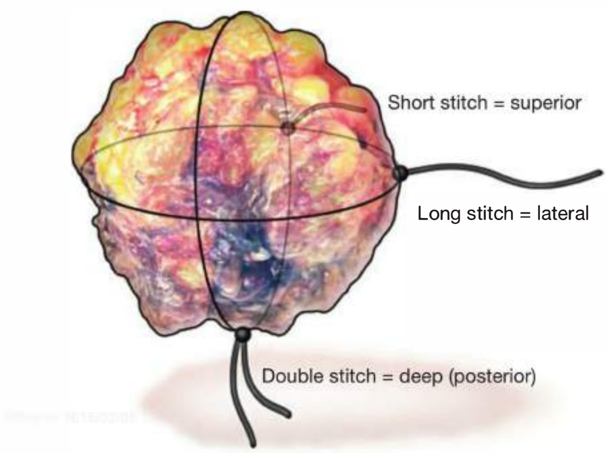

FIG 12 ● The lesion is oriented with three marking sutures prior to sending to radiology for specimen mammography.

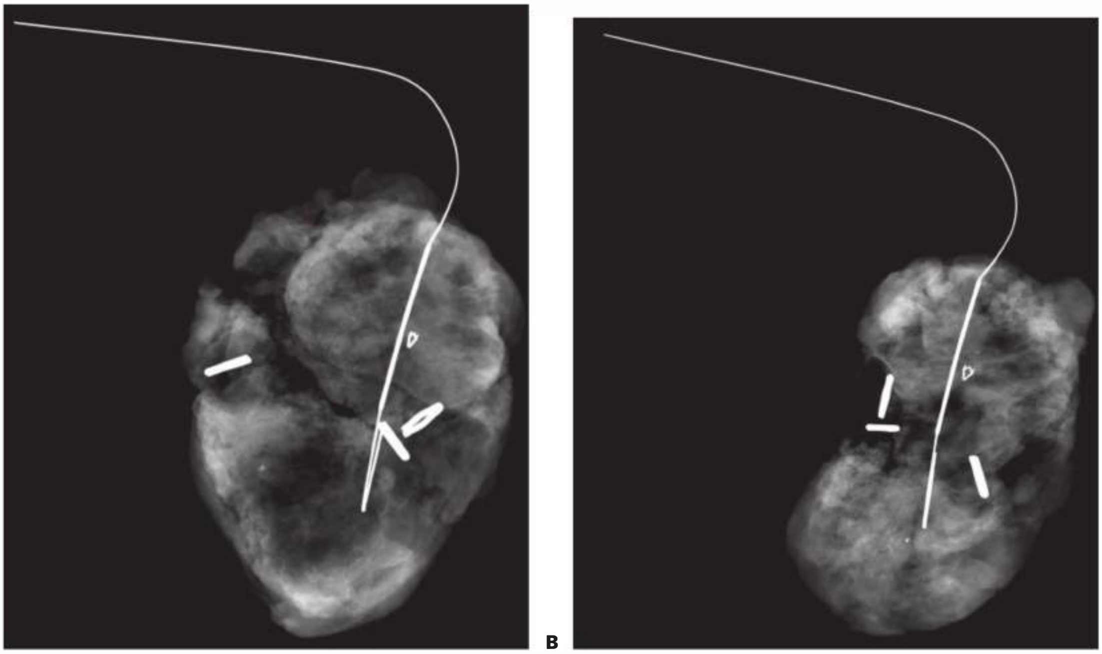

FIG 13 ● **A,B.** Specimen mammography shows the clip and wire to be completely removed.

SPECIMEN RADIOGRAPHY AND ADDITIONAL TISSUE

- Specimen radiography is performed to confirm that the area of concern has been removed (**FIG 13A,B**). The specimen mammogram should demonstrate the presence of the microcalcifications of concern or the presence of a clip placed within the specimen. It should also show that the entire wire has been removed. If the wire becomes separated from the specimen, send both to radiology to document its removal.
- If the lesion is identified on specimen radiography, the wound can be closed. If the lesion is not present, then additional tissue should be excised and sent to radiology. It may be clinically evident what area needs further excision based on exposure of the wire during the dissection. The use of radiopaque clips on the specimen, as well as other landmarks on the original mammograms, may also help identify where to excise additional tissue.
- If a second specimen fails to identify the lesion, it becomes a judgment call whether to continue or abandon the procedure. For ultrasound-visible lesions, intraoperative ultrasound may be able to identify the abnormality. In the case of a clip that should have been in the specimen, sometimes these can get dislodged and suctioned out. Filtering and x-raying the fluid in the suction canister can sometimes reveal a dislodged clip. Otherwise, it may be prudent not to continue and plan on reimaging and, if necessary, returning to the OR rather than taking an excessive amount of breast tissue.

CLOSURE

- Once the biopsy is complete, hemostasis is assured and the wound is irrigated with saline.
- For an excisional biopsy, the surgeon should *not* try to reapproximate the breast tissue. The cavity will fill with seroma and fibrin, and ultimately, fibrous tissue, which will maintain the normal contour.
- The incision is closed with absorbable deep dermal sutures, followed by either a subcuticular stitch or tissue adhesive. Drains should not be used.

PEARLS AND PITFALLS

Indications	■ Image-guided biopsy is the preferred approach to the nonpalpable abnormality. Review the case with the radiologist to confirm whether this is an option.
Placement of incision	■ Keep in mind that if malignant, the patient may need a reexcision lumpectomy or mastectomy. Orient your incision with this in mind.
Identifying the wire	■ Take care not to move or dislodge the wire during the positioning, prepping, and draping of the patient. ■ Identify the wire early and secure it while bringing it into the wound so that it does not become dislodged during the procedure.
Excision	■ Grasp the tissue, not the wire, while excising the lesion so as not to accidently pull the wire out. ■ During dissection, palpate the area to identify the mass or if you are too close to the wire.
Specimen mammography	■ Three orientation sutures are necessary to avoid error. ■ Clips can help orient the specimen on the mammography so as to guide a reexcision.
Closure	■ Do not try to reapproximate the breast tissue or place a drain.

POSTOPERATIVE CARE

- After a breast biopsy, the patient should be placed in a breast binder or supportive brassiere. This helps sustain hemostasis and relieves tension on the skin closure imposed by the weight of the breasts. The patient should be encouraged to wear the support bra day and night for 1 week after surgery.

OUTCOMES

- In experienced hands, the failure rate of wire-localized biopsy is low, although published reports suggest the wire localization failure rate can range from 0% to 20%. Factors associated with failure include lesion type and size, distance from the wire, breast shape and size, and volume of excised tissue.[9–11]

COMPLICATIONS

- Seroma
- Hematoma
- Infection (cellulitis or abscess)
- Pneumothoraces (rare)
- Retained wire fragments
- Failure to identify abnormality

Chapter 3

Subareolar Duct Excision

Amy C. Degnim

DEFINITION

- Subareolar duct excision is defined as the surgical removal of lactiferous ducts in the immediate subareolar space. The terms "major duct excision" or "central duct excision" refer to excision of the entire bundle of ducts contained within the central nipple stalk; microdochectomy refers to selective excision of a single abnormal duct.

ANATOMY

- The lactiferous ducts drain converging ducts from lobes of the breast gland and serve as a conduit for milk egress via the nipple during lactation (**FIG 1**). Most women have approximately 7 to 20 ducts that are distinct and functional sources of milk during lactation. At the base of the nipple, the lactiferous ducts widen centrally in a spindle shape over a short distance. This region is called the lactiferous sinus and can expand in lactation to 8 mm as a reservoir for milk. Surrounding the lactiferous ducts is a system of smooth muscle fibers that contract in response to nipple stimulation and oxytocin release, facilitating milk flow through the nipple.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Subareolar duct excision is undertaken in cases of abnormal nipple discharge for two purposes:
  - To obtain diagnostic biopsy tissue and rule out malignancy
  - To provide resolution of the bothersome discharge
- Abnormal, or "pathologic," nipple discharge is characterized by the following features:
  - Discharge from a single duct
  - Spontaneous discharge
  - Clear or bloody discharge

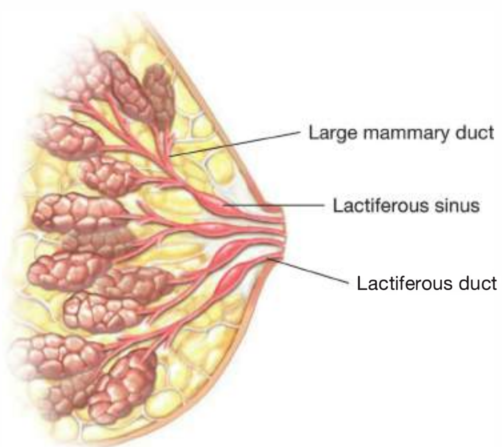

FIG 1 ● Normal anatomy of subareolar lactiferous ducts and sinuses.

- The history should be focused on questions to determine the laterality and quality of the discharge as well as whether it is spontaneous or only occurs with manual expression.
- Physical exam should include a thorough examination of both breasts and axillae.
- In addition, a detailed examination is necessary for both nipple–areolar complexes and the subareolar tissues.
- Inspect the nipples for crusting, bloodstained ducts, or any visible protuberances or nodules.
- The deep tissue of the areolae should be palpated carefully for any small nodules and to determine if subareolar pressure results in nipple discharge.
- The nipple itself should be palpated by rolling the nipple between the thumb and forefinger in order to best detect any small nodules located centrally within the nipple stalk. This should be performed first for the breast without discharge to set a normal comparison to the breast that is symptomatic.
- If no discharge has been identified up to this step of the examination, then attempt should be made to elicit discharge from both nipples, by applying pressure to the areola at the base of the nipple, then grasping the base of the nipple between the thumb and forefinger and drawing upward with gentle pressure.
- Throughout the examination, for any nipple discharge observed, its location (o'clock position) and quality of the fluid should be noted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All women with abnormal nipple discharge should undergo diagnostic mammogram and ultrasound. Prior to the imaging studies, the imaging team should be informed about the symptom of nipple discharge and which breast is affected.
- Because nipple discharge can be associated with underlying malignancy, the primary purpose of diagnostic imaging is to look for possible signs of malignancy. Another goal of imaging is to evaluate the subareolar tissues for any findings that would explain the presence of nipple discharge.
- Generally, subareolar ducts are not visible with ultrasound unless they are abnormally dilated. A small nodule visualized within a dilated subareolar duct indicates a likely diagnosis of intraductal papilloma (**FIG 2**).

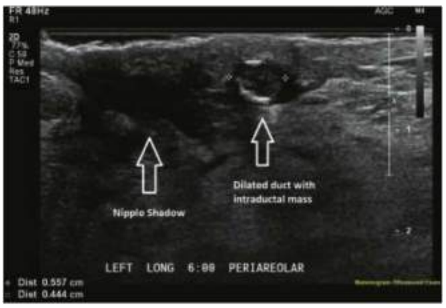

FIG 2 ● Ultrasound of a subareolar nodule.

- Evaluation with magnetic resonance imaging (MRI) is controversial. It detects more lesions than standard imaging for women with nipple discharge but is imperfect in ruling out malignancy associated with nipple discharge.[2]
- Ductography can be considered as a diagnostic test. This is a radiographic procedure that entails cannulation of the duct with abnormal discharge, then injection of contrast dye with immediate mammographic imaging. This procedure can identify and map out abnormal ducts and identify some intraductal filling defects, but it does not provide diagnostic tissue. For these reasons, it is not a required component of the evaluation and is intentionally avoided in some practices. Although it may help to localize the etiology of the discharge, it cannot reliably exclude malignancy or eliminate need for duct excision.[3]
- Another approach to diagnostic evaluation is via ductoscopy, a microendoscopic procedure to directly visualize the duct(s) with discharge. This requires special equipment and skill, with a learning curve for technical success. Ductoscopy can help to identify lesions and guide excision but has not been proven in large numbers of women to improve diagnosis to the point that duct excision can be avoided.[4,5]

DIFFERENTIAL DIAGNOSIS

- Intraductal papilloma
- Duct ectasia
- Carcinoma, either invasive or ductal carcinoma in situ
- Paget's disease

NONOPERATIVE MANAGEMENT

- Nonoperative management can be considered for cases of nipple discharge when
  - The discharge occurred on only one occasion and was not reproducible on examination
  - Both mammogram and ultrasound show no abnormalities.[6,7]
  - In this case, 3-month follow-up history and physical examination is recommended.
- Alternately, if imaging identifies a benign-appearing lesion and percutaneous core biopsy confirms a benign intraductal papilloma with complete or near complete removal by imaging, then observation is also appropriate with follow-up imaging in 3 months.

SURGICAL MANAGEMENT

- Subareolar duct excision removes the lactiferous ducts under the nipple, the primary connection between the nipple and the milk-producing lobules of the breast, so patients must be counseled that lactation from the operated breast should not be possible after surgery.
- Selective and focused excision of the single abnormal duct may be performed in an attempt to preserve other ducts for future lactation, but due to the very close proximity of the remaining ducts, scar tissue from the operation may still impair future lactation.
- In women who are past childbearing age, a plan to remove the entire bundle of subareolar ducts is preferred because future lactation is not needed, and this approach reduces the chance of recurrent discharge from another duct and need for repeat operation in a field of scar tissue.
- The patient should be informed of the possibility of a diagnosis of malignancy yet reassured that benign findings are most likely.

Preoperative Planning

- For subareolar mass lesions that are nonpalpable and identified only by imaging, preoperative localization with either a wire or a radioactive seed should be performed to ensure intraoperative guidance to the target.
- Before surgery, patients should be counseled that they may experience continued discharge in the first few weeks postoperatively, as postoperative fluid in the subareolar space may discharge via the nipple duct until healing is complete. This should resolve completely by 4 to 6 weeks.

Positioning

- The patient should be positioned supine.
- The ipsilateral arm is generally positioned at approximately 90 degrees, although the arm could also be tucked based on the patient's body habitus and preferences of the anesthesia team.

Approach

- The general approach is to dissect under the areola toward the nipple, isolate and excise the central duct bundle, and follow any abnormal ducts to complete removal, along with simultaneous excision of any nonpalpable lesions identified on preoperative imaging.

INCISION PLANNING

- In general, incisions are placed at the areolar edge.
- An incision at the inferior areolar edge is preferred if possible for better cosmesis, especially if the involved duct is located centrally on the nipple surface and the imaging does not demonstrate any abnormalities (FIG 3).
- Otherwise, incisions can be placed along the areolar border in the o'clock position of the abnormality, for either a peripherally located duct with discharge or if there is an imaging abnormality a few centimeters from the nipple.

FIG 3 • Incision at inferior areolar border.

- The length of the incision should be large enough that the surgeon has adequate visualization of the subareolar space without requiring excess retraction and ischemia of the areolar edge. Depending on the areolar size, the incision may go up to 50% of the circumference of the areola, but a shorter incision is preferred when possible to help preserve blood supply to the nipple and areolar dermis.
- Prior to incision, correct surgical site and plan should be confirmed with the operative team.

DUCT CANNULATION

- Once the field is prepped and draped, attempt should be made to cannulate the involved duct.
- A fine lacrimal duct probe (4-0) should be held ready in the dominant hand for cannulation prior to expressing the nipple discharge.
- The nipple should be grasped between the thumb and forefinger of the nondominant hand at the nipple base and drawn upward gradually (**FIG 4**). If no discharge is seen, increasing pressure can be applied to a reasonable degree. The goal is to elicit a single tiny drop of fluid at the skin surface; a smaller drop of fluid will be more helpful in identifying the location of the abnormal duct (**FIG 5**).
- The nipple should be pulled away from the breast gently in order to elongate the subareolar lactiferous sinus and improve the chance of cannulation (**FIG 6**).
- The lacrimal duct probe should be gently probed along the nipple skin surface at the site of the expressed fluid. The goal is to find the opening rather than make a false passage; the probe will slide easily into the duct once it is in the right location (**FIG 7**).

FIG 6 ● Cannulation technique.

FIG 4 ● Manual expression of nipple discharge.

FIG 7 ● Cannulated duct with probe advanced.

FIG 5 ● Visible tiny drop of fluid at nipple surface.

- The probe should be gently advanced as far as it will easily go. If it does not pass greater than 1 cm beyond the nipple skin surface, then the depth of the cannulation should be noted as a sign that there may be a very superficial obstructing mass lesion.
- If no discharge is identified or if the duct cannot be cannulated despite several attempts, the procedure should proceed to incision.

INCISION

- Prior to incision, local anesthetic can be used but should not be injected directly into the area of the subareolar ducts. If used, it should be injected intradermally directly at the planned incision site (no more than 1 mL) and additionally in a peripheral fashion into the four quadrants of the breast to create a local field block.
- The skin should be incised sharply with a scalpel, taking care to maintain a blade angle that is perpendicular to the skin.
- The incision should be deepened a few millimeters into the subcutaneous fatty tissue (**FIG 8**).

FIG 8 ● Incision into subcutaneous tissue.

ELEVATION OF THE AREOLAR SKIN FLAP

- The areolar skin edge is then retracted superiorly (skin hooks or sutures could be used), and dissection proceeds in the direction of the nipple toward the central duct bundle (**FIG 9**).
- Care should be taken to perform the dissection at a depth to preserve some subcutaneous fatty tissue under the areolar skin, as this will help to protect the viability of the areolar skin and nipple. Similarly, the lateral edges of the dissection field should narrow as the central duct bundle is approached (**FIG 10**).
- Attention should be paid to the location of dissection and its proximity to the nipple, looking closely for the ducts, which appear as narrow vertical tubular or strand-like structures. The ducts may be visibly discolored (**FIG 11**).

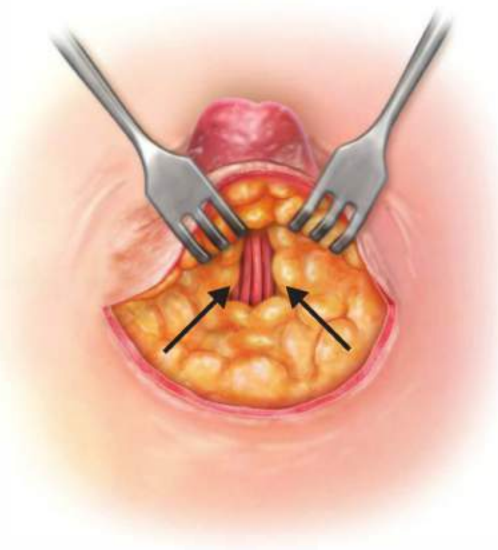

FIG 10 ● Narrowing the dissection field toward the nipple.

FIG 9 ● Retraction of the skin flap.

FIG 11 ● A visibly abnormal duct with discolored intraluminal fluid.

ISOLATION AND EXCISION OF THE CENTRAL DUCT BUNDLE

- Dissection then proceeds in vertical fashion on the lateral sides of the duct bundle under the nipple. This should proceed to the far side of the nipple (**FIG 12**).
- The duct bundle should be palpated between the thumb and finger to confirm the presence of the duct probe and any other small palpable nodules.
- The central duct bundle should then be transected at the deep aspect of the nipple dermis. If using electrocautery, the "cutting" mode should be chosen at a low energy setting to minimize thermal damage to the nipple dermis.
- As the duct bundle is transected, the cannulating probe will be identified. It may be withdrawn if it becomes difficult to maintain its position in the duct (**FIG 13**).
- The duct bundle should be retracted away from the breast, dissecting circumferentially around the duct bundle to a depth of approximately 4 to 5 cm or farther along a particular grossly abnormal duct (**FIG 14**).
- The tissue specimen should be transected at its base and oriented for the pathologist (**FIG 15**).
- The open wound should be palpated for any abnormalities, and the nipple dermis should be palpated between the thumb and finger to ensure that there are no any superficial nodules present that were not excised. In the event of a small nodule within the nipple dermis, a tiny skin incision in the nipple can be made to remove the lesion.

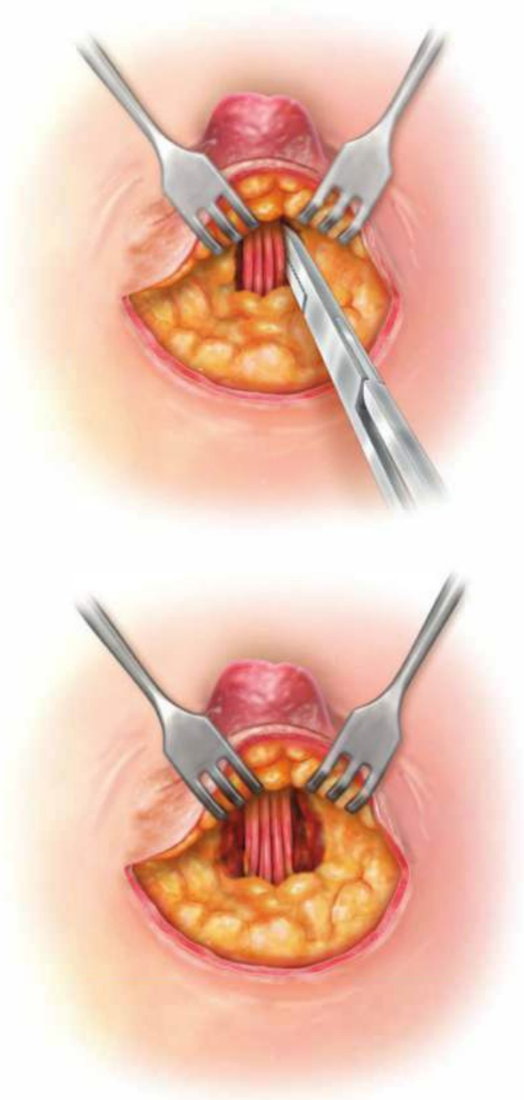

FIG 12 ● Vertical dissection along both sides of the duct bundle.

FIG 13 ● Transection of the ducts just deep to the nipple dermis.

FIG 14 ● Dissection of ducts deeper into the breast parenchyma.

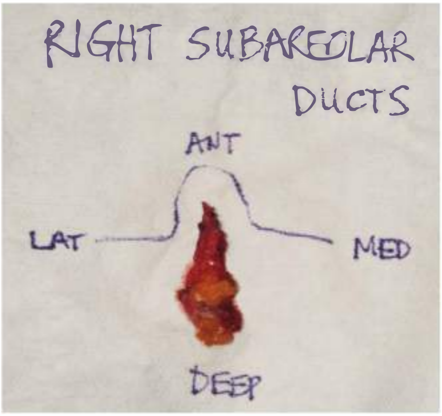

FIG 15 ● Orientation of the specimen.

CLOSURE

- After hemostasis, the parenchymal and subcutaneous tissue defect in the subareolar region must be closed in order to avoid nipple retraction in the healing phase. If there is a solid buttress of tissue underlying the nipple–areolar complex, the nipple will be less likely to retract.
- The parenchymal closure may be performed as a simple direct approximation of tissues, in whatever orientation results in least tension and absence of skin dimpling (FIG 16). If the defect is larger, it may require a small local tissue advancement flap or undermining of the breast gland from the skin. In that case, it is preferable to avoid further dissection under the areolar skin and obtain donor tissue from the other side of the cavity.
- If the nipple is effaced, it may be helpful to place a purse-string stitch in the deep dermis around the nipple base to recreate the normal nipple shape and prevent nipple retraction in the healing phase (FIG 17).
- The skin should be closed in two layers, with buried interrupted sutures in the deep dermis and subcutaneous tissue, followed by a running intradermal stitch in the skin edge. Care should be taken to place the deep dermal sutures so that the areolar skin edge is at or slightly above the breast skin edge (but not lower) (FIG 18), or the nipple–areolar complex will have a sunken-in appearance. If the areola is small, resulting in an incision with greater curvature, the final layer of skin closure should use multiple shorter bites (FIG 19).

A

B

FIG 16 ● Closure of the deep tissue. **A.** Medial-to-lateral closure, **(B)** superior-to-inferior closure.

FIG 17 ● Purse-string suture in the deep dermis of the nipple.

FIG 18 ● Appearance after closure of the deep dermal layer of incision, with the areolar edge at or above the breast skin.

FIG 19 ● Intradermal suture for final layer of closure.

- Adhesive dressings on the dermis of the nipple itself should be avoided. If an incision was required in the nipple dermis for an intradermal nodule, the nipple incision should be closed with fine interrupted nonabsorbable sutures.
- Dressings that create excess pressure on the nipple should also be avoided. If a pressure dressing is desired, it should have a "donut" opening for the nipple.

PEARLS AND PITFALLS

Preoperative counseling	■ Preoperative counseling should address ■ Focused duct excision versus excision of the entire duct bundle ■ Inability to lactate after surgery from the operated breast ■ Likely pathologic findings ■ Possible nipple discharge in the postoperative healing period
Incision planning	■ Inferior areolar edge is preferred.
Subareolar dissection	■ Be careful to preserve subcutaneous fat under the areolar skin and to limit dissection to as narrow a field as possible to reduce risk of skin necrosis.
Closure	■ Proper closure of the deep and superficial tissues under the nipple–areolar complex is critical to avoid nipple retraction with healing, and consider a purse-string stitch to reestablish normal nipple projection.

POSTOPERATIVE CARE

- The incision should be kept clean and dry.
- Clothing that creates excess pressure on the nipple should be avoided, and patients may choose to use a donut-type foam dressing to relieve any pressure on the nipple.
- Showering is permitted.
- If any nonabsorbable sutures were placed in the nipple skin, they are removed at 1 week.

OUTCOMES

- Subareolar duct excision for abnormal nipple discharge is highly successful, with resolution of discharge in the vast majority. Recurrent discharge is reported in the range of less than 5%.[8]
- Pathology findings are most often benign (papilloma or duct ectasia), but malignancy is found in the range of 0% to 20%.[8,9]
- The likelihood of successful lactation after duct excision is not well characterized.

COMPLICATIONS

- Bleeding and infection are possible complications after every surgical procedure but are rare with this procedure. Avoidance of antiplatelet therapies and anticoagulants per surgical routine will help to minimize risk of bleeding, and a single preoperative dose of intravenous antibiotics is recommended prophylactically.
- Skin necrosis is also rare but devastating if it occurs; for this reason, careful attention should be paid to preserving blood supply to the areolar tissue and limiting the extent of dissection under the areolar skin, with focused excision of the central ductal tissue.

Chapter 4

Cryoablation of Breast Fibroadenomas

Cary S. Kaufman

CRYOABLATION TREATMENT FOR BREAST FIBROADENOMAS—OVERVIEW

- Cryoablation is a minimally invasive, innovative treatment for breast fibroadenomas. The treatment is performed in an office setting rather than an operating room, resulting in a cost-effective and patient-friendly procedure with little to no scarring. Published reports demonstrate that cryoablation as primary treatment for breast fibroadenomas is safe and effective and at long-term follow-up, demonstrates progressive resolution of the treated area, with excellent patient and physician satisfaction (Table 1).
- About 80% of the approximately 1.3 million biopsies performed annually in the United States reveal benign conditions, primarily benign tumors or fibrocystic change. The most common benign breast tumor is a fibroadenoma.[1–3]
- Although not life threatening, benign breast tumors can cause fear, anxiety, and discomfort in the patient, and definitive treatment is often desired.[3–5]
- Fibroadenomas consist of a proliferation of epithelial and connective tissue elements within the lobular region of the breast. They are usually sharply demarcated from the adjacent breast tissue and give the clinical and imaged appearance of being encapsulated.[5]
- They often grow to a size of 2 to 3 cm and are multiple in 20% of women.[4,6–9]
- Approximately 10% of women will experience a fibroadenoma in their lifetime. Although most common in young women, fibroadenoma occurs in every age-group from adolescents to octogenarians.[1,2,7,10,11]

DIFFERENTIAL DIAGNOSIS

- These benign breast tumors have a classic physical examination: rubbery texture, smooth and well defined, circular to oval, and freely moveable within the breast.
- Other breast lesions that may have similar clinical presentations include phyllodes tumors, juvenile fibroadenomas, breast cancer (particularly medullary carcinomas), or breast cysts. Diagnosis is resolved by imaging and core needle biopsy.
- Cryoablation has only been proven effective for biopsy-proven fibroadenomas (Table 2).[12–16]

Table 1: Potential Advantages for Cryoablation in the Treatment of Fibroadenoma

Reasons to consider ablation techniques:
Small puncture incision
A procedure not surgery
Less scarring
Minimal discomfort
Less invasive
Less expensive

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with small- to medium-sized single tumors that are not too close to the skin or nipple are appropriate candidates for cryoablation. Indications and contraindications are listed in Table 3.
- The target lesion must be clearly visible with ultrasound and not be within 1 cm of the skin or immediately deep to the nipple.
- A histologic diagnosis using a core biopsy should demonstrate a classic fibroadenoma without atypia. Other histologic lesions are not appropriate for cryoablation.
- Tumors should be measured in three dimensions and the longest dimension used to calculate freezing time (**FIG 1**).
- It is important to discuss with the patient the process of cryoablation and the progressive resorption of the residual necrotic debris over time (**FIG 2**).
- The candidate should not currently have breast cancer in the ipsilateral breast and be otherwise healthy. She should not be pregnant, breastfeeding, or have breast implants.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- If the patient is in the mammography screening age-group, a pretreatment screening mammogram should be obtained and be normal except for the fibroadenoma (**FIG 3**).
- There are classic imaging findings of fibroadenoma on both ultrasound and mammography, but histology is needed for an accurate diagnosis[1,3,9,17] (**FIGS 3** and **4A,B**, ultrasound and mammogram of a fibroadenoma).
- The differential diagnosis includes the larger and faster growing juvenile fibroadenomas and phyllodes tumors.[1,7,9]
- Large-core needle biopsy is the diagnostic method of choice because of the need to differentiate between benign and malignant tumors in general and fibroadenoma from phyllodes tumor in particular.[1,9]

MANAGEMENT OPTIONS

- There are three treatment options for a confirmed fibroadenoma: (1) serial observation ("watchful waiting"), (2) surgical removal, and (3) cryoablation. Surgery for fibroadenoma provides definitive treatment while confirming the diagnosis and eliminating patient anxiety and future monitoring. Drawbacks to surgical excision include patient discomfort, anesthetic and surgical recovery, skin incision and potential scarring as well as operating room costs.[18]
- On the other hand, many women choose serial observation with the advantages of no surgical pain, avoidance of the operating room and anesthesia, less cost, and only a minimal scar from the large-core needle biopsy. Drawbacks to conservative management include ongoing patient anxiety regarding the presence and potential growth of a lump, the inconvenience of serial office visits, and the confusion of physical examination and mammography evaluations caused by the mass effect.[7,19]

Table 3: Indications and Contraindications for Cryoablation for Fibroadenomas

Inclusion criteria for fibroadenoma cryoablation:
1. Lesion must be sonographically visible.
2. Diagnosis of fibroadenoma must have histologic confirmation.
3. Lesion size must be <3 cm in largest diameter.

Contraindications for cryoablation:
1. Pathology suggestive of phyllodes tumor or malignancy
2. Poor ultrasound visualization
3. Pathologic diagnosis of fibroadenoma nonconcordant with imaging or physical examination

Note: After cryoablation, patients should be followed with ultrasound assessment and physical examination at 6, 12, 18, and 24 months postprocedure.

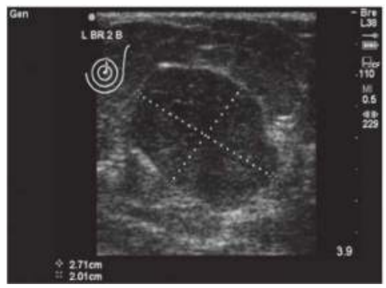

FIG 1 ● Ultrasound of fibroadenoma prior to treatment. Size, position, and two orthogonal views are taken.

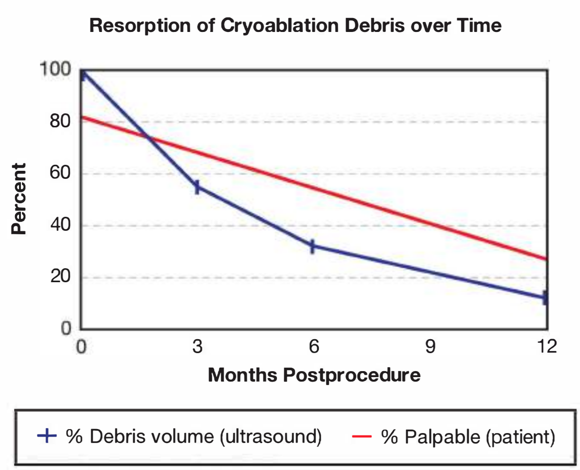

FIG 2 ● Postcryoablation resolution of palpable and ultrasound-visible cryolesion over the first year. Most cryolesions fully dissolve over the year, but tumors larger than 2 cm will take longer to resorb.

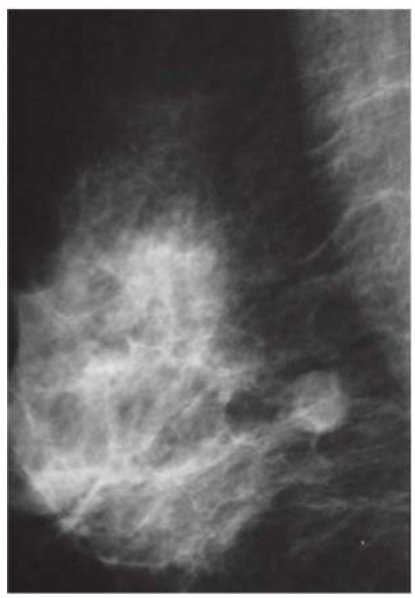

FIG 3 ● Mammogram demonstrating oval fibroadenoma.

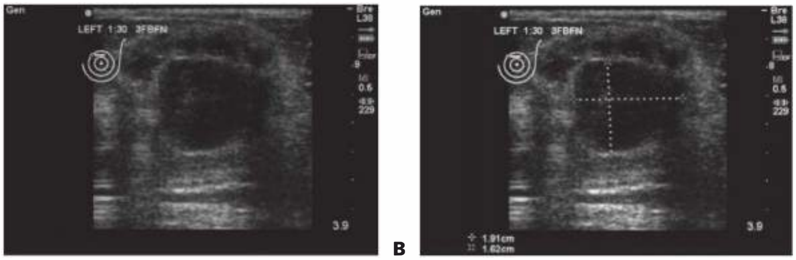

FIG 4 • **A,B.** Classic ultrasound image of fibroadenoma demonstrating well-defined borders and homogeneous solid mass with edge shadowing.

- Cryoablation for fibroadenoma has the advantage of being an office-based procedure with no need for systemic anesthesia, minimal discomfort, skin incision similar to the core biopsy site, and the expectation of lower overall costs of treatment compared with surgical excision. Drawbacks include slow progressive resorption of residual palpable debris.
- Multiple reports in the United States and Europe of favorable outcomes make cryoablation for fibroadenoma an attractive alternative for patients.[12–16,20] As a result of these reports, the American Society of Breast Surgeons has produced a statement in support of cryoablation as an acceptable alternative method of treatment of fibroadenoma.[21]

POSITIONING AND PROCEDURE DESCRIPTION

- Prior to the procedure, the cryoablation machine should be prepared, which typically includes filling the Dewars with liquid nitrogen.
- Cryoablation is an office-based sterile procedure with preparation similar to that of an ultrasound-guided core needle biopsy. Have a sterile cryoprobe available and a sterile field setup with equipment similar to that needed for core needle biopsy. In addition to the sterile instruments, multiple syringes of sterile saline should be available for injections to distance the skin away from the cryoprobe during the procedure.
- The cryoprobe should be tested just prior to use. A backup probe should be available in case the probe tests defective. During the test, no air bubbles should be discharged from the tip of the probe.
- Most cryoablation devices have an automated treatment program that is based on the longest tumor dimension to calculate treatment times. To initiate the automated treatment protocol on the cryoablation device, enter the fibroadenoma size measurement into the cryomachine.
- Note the distance beyond the fibroadenoma that the probe must extend for the symmetric distribution of the freezing.
- Identify the ideal skin entry site to create a cryoprobe pathway along the long axis of the fibroadenoma with adequate circumferential distance for the cryoprobe iceball to be entirely within the breast and away from the skin.
- Inject local anesthetic in the skin and along the path toward the fibroadenoma. Infiltrate some local anesthetic deep to and around the periphery of the target lesion. Some local is valuable beyond the target for the "past-pointing" of the cryoprobe beyond the tumor.
- Use a no. 11 scalpel blade to make a 3-mm entry site for the cryoprobe.
- Carefully place the tested cryoprobe along the desired track into and through the fibroadenoma (**FIG 5A**). This may take some time to be sure the cryoprobe lies within the center of the fibroadenoma. Before a final pathway is chosen, be sure that the cryoprobe lies in the mid-center

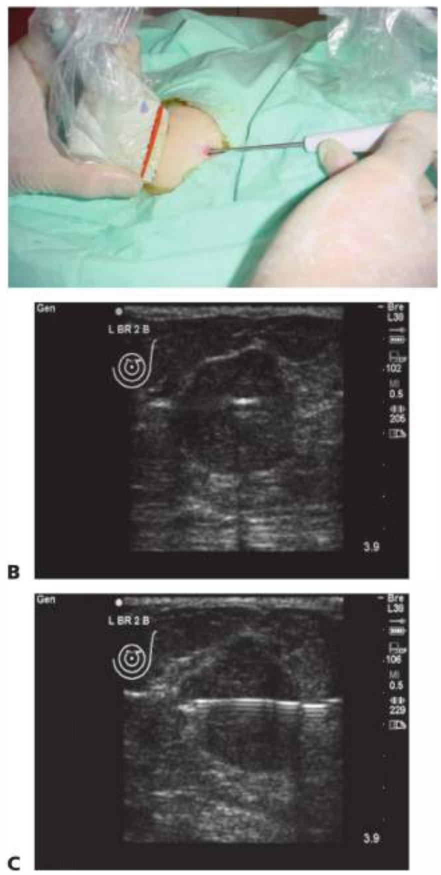

FIG 5 • **A.** Ultrasound examination of probe placement to confirm central location within fibroadenoma. **B.** Ultrasound view of probe in tumor via transverse image. **C.** Ultrasound view of probe in tumor via longitudinal image.

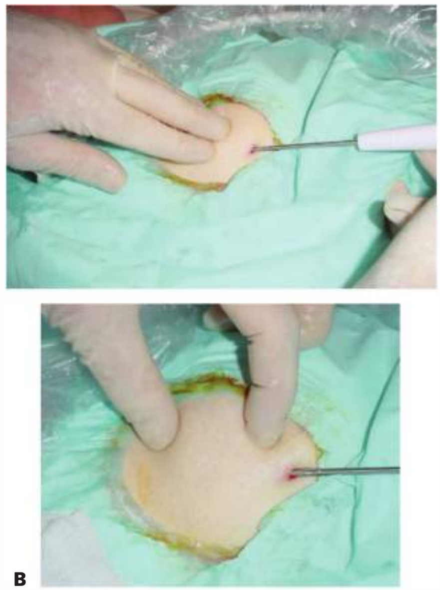
of the target lesion. Move your targeting ultrasound in all directions to confirm cryoprobe central placement both longitudinally and transversely (**FIG 5B,C**, two orthogonal ultrasound views of position of cryoprobe within fibroadenoma).

- Some fibroadenomas are very dense, causing the cryoprobe to deviate off the desired central pathway. It may take repeated efforts to place the probe in the center of a very rubbery tumor.
- One method to facilitate central probe position is to obtain a core needle biopsy just prior to placing the probe. If the core needle biopsy is obtained from the desired central pathway, it will be easier to place the treatment cryoprobe in the same path.
- Once the cryoprobe has adequately been placed and the distal "past-pointing" has been measured, you are ready to initiate the cryoablation sequence.
- Press the start button and use the ultrasound unit to document the development of the iceball. Obtain multiple measurements, especially iceball size, at the end of each of the three phases of treatment: first freeze, thaw, and second freeze (**FIG 6A,B**).

A
B

FIG 6 ● **A.** During procedure, surgeon holds both cryoprobe and ultrasound transducer. Continuous visualization of both cryoablation machine and ultrasound image is required. **B.** Ongoing ultrasound monitoring of skin bridge is necessary. Avoid pressing skin too close to iceball formation with ultrasound transducer.



A
B

FIG 7 ● **A.** Use of palpation over iceball to confirm skin is moveable and not frozen to iceball, which can cause skin damage. **B.** Palpation of iceball during cryoablation confirming skin not attached to iceball.

- During the procedure, continuously monitor the skin bridge to be sure skin does not get frozen and attached to the iceball. Freely inject saline between the iceball and the skin to "lift" the skin away from the developing iceball. Skin that becomes attached to the iceball may be injured and result in scar.
- Tips to avoid skin injury during cryoablation include the following: (1) Touch and move the skin horizontally overlying the iceball formation to confirm there is a large subcutaneous portion of mobile fat separating the iceball from the skin. Repeated movement of the skin overlying the iceball confirms it is not becoming attached (**FIG 7A,B**). (2) Avoid continuous pressure of the monitoring ultrasound transducer pushing the skin down onto the developing iceball narrowing the distance between the iceball and the skin; (3) move the distal end of the cryoprobe toward the posterior (chest wall) direction so that the distance from the developing iceball to the skin is maximized. (4) If you wish more distance from the iceball to the skin, inject saline between the skin and iceball to lift the skin away from the iceball development. This can be done repeatedly as needed. Avoid adherence of the skin to the iceball at all times.
- The treatment consists of two high freeze cycles separated by a thaw cycle. Each cycle is usually the same length of time, for example or e.g., 8 minutes each for a total treatment time of 24 minutes.
- The cryoablation device will freeze high for the first and second freeze cycles. During the freezing, continuous ultrasound monitoring will visualize an iceball growing as it envelopes the target lesion. At the end of the first freeze, the iceball will be much larger than the targeted tumor (**FIG 8A–D**).

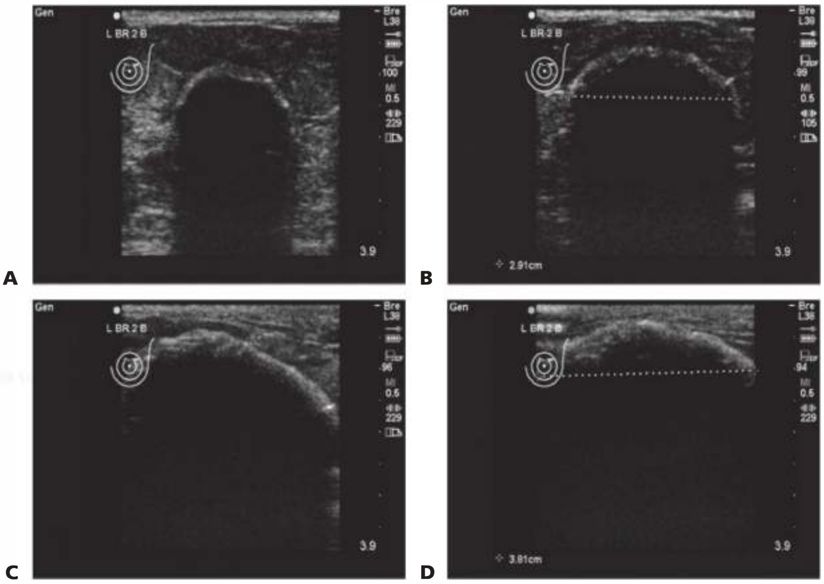


FIG 8 ● Serial Ultrasound Images of Cryoablation **A.** During initial iceball development. **B.** Transverse view of iceball at the end of first freeze cycle. **C.** Longitudinal view of iceball at end of second freeze cycle. **D.** Transverse view of iceball after cryoprobe removal.

- When the automated cryoablation machine reaches the end of the second freeze, it will automatically go into a warming mode. The cryoprobe cannot be removed while it is frozen. The tip of the probe will warm after about 30 seconds of warming so that the cryoprobe may be gently removed.
- At the end of the procedure, the patient will still be able to feel a firm frozen area, which is the iceball (**FIG 9**) that will thaw within an hour, but there will still remain a palpable mass, which is the residual necrotic debris. It will take several months for the debris to be resorbed.
- A Steri-Strip is placed on the entry wound similar to a core needle biopsy dressing. Careful not to place a tight adhesive bandage on the area because it will swell significantly over the next 2 days and blisters can develop. (see "Postoperative Care").

FIG 9 ● Immediate posttreatment palpation of iceball.

PEARLS AND PITFALLS

Lesion location	■ If the target lesion is close to the chest wall, then after placement of the probe during the initial icing phase, lift directly up off the chest wall with the probe in the tumor. This will allow the iceball to form without attachment to the pectoralis major. After the iceball is adequately formed, about 2 minutes into the freezing, you can release the traction away from the chest wall. ■ If the lesion is located close to the skin but away from the nipple, then after placing the probe into the tumor and confirming satisfactory position, inject lidocaine in the space between the skin and the tumor. Try to spread your fluid within the remaining space between the skin and the tumor. After you have over 1 cm of fluid in the ultrasound "window," proceed with freezing. Be ready to inject further saline/lidocaine during the freezing period for the first 4 minutes. Thereafter, the iceball will be unlikely to get too much bigger until the second freeze. ■ On concern during treatment is that there is a progressive iceball enlargement, and frequent skin reassessment must be made to avoid freeze injury. An easy way to tell if the iceball is getting too close to the skin is to examine the mobility of the skin over the iceball. If the skin has much movement, (similar to the skin of your hand over your knuckles) then the iceball is not too close. If there is limited horizontal movement of the skin, inject more fluid. If there is no skin movement, stop the procedure until you can inject more fluid and create a better bridge.

Patient selection	■ Avoid freezing lesions immediately deep to areola and close to the true nipple, especially if the patient is a young woman who wishes to breastfeed in the future. During the cryoablation, the immediate surrounding tissues may be injured or destroyed. This usually is not a problem within the body of the breast, because a small surrounding margin of normal breast tissue is often removed with fibroadenoma excision. But when the immediate surrounding tissue includes major milk ducts, one must be cautious in treating that patient. There is little experience of treating these patients and later determining the ability of these women to breastfeed. ■ There is anecdotal data on cryoablation of nonfibroadenomas. Although early in our experience, other lesions were treated with success, the current acceptable indications for cryoablation are for treatment of fibroadenomas. In the small series of nonfibroadenoma patients, they responded similar to the fibroadenoma cryoablated patients. However, a clinician would have little clinical support if there were complications on a nonfibroadenoma patient. We would refrain from treating those patients. ■ **Treating fibroadenomas during pregnancy.** There is little data on cryoablation during pregnancy. Rapidly growing or painful lesions should consider surgery during pregnancy, whereas others may wait.
Multiple tumors	■ For two tumors close together in the same quadrant, both less than 2 cm, it is possible to place the probe through both lesions at one time and treat both simultaneously. If they cannot be treated simultaneously, then using the same probe in the same quadrant would be reasonable if the entry site were unchanged. If there are two separate punctures to be made or if the lesions are in different quadrants of the same breast, then two separate probes would be optimal. When treating fibroadenomas of both breasts, two separate probes should be used.
Unable to place probe without undue force	■ Some fibroadenomas are very dense and seem to forbid entry of the cryoprobe. The best approach is to reevaluate your entry site and your options to "hold" the tumor in place while you advance the probe into it. One must be cautious to avoid past-pointing and pushing through the tumor once the probe enters it fully. One technique is to start the probe into the lesion, and then use your opposite hand to manually brace the tumor while you advance the probe slowly with your dominant hand. A slow twisting of the probe may allow the cryoprobe to enter the lesion. Use plenty of lidocaine. If it seems impossible to enter the lesion, consider temporarily removing the cryoprobe and using a spring-loaded core needle to take a few "bites" of the tumor at the planned site of cryoprobe entry. By creating a small-bore hole with the needle biopsy device, the cryoprobe may be able to enter the tumor more easily. Care to keep the cryoprobe sterile while you use the core biopsy tool.

POSTOPERATIVE CARE

- Bandage dressing over the entry site is very important to absorb some fluid that may drain out of the entry site. The treatment is essentially a burn of the interior of the breast. As with other burns, the area will swell over the next 2 to 3 days. A dressing over the area must accommodate the skin stretching and tissue swelling; otherwise, there will be blistering of the skin where tape or other adhesive dressings are placed.
- The entry site is closed with a Steri-Strip. Over the Steri-Strip can be placed a couple 2 × 2 gauze pads and then all covered with a Tegaderm-like adhesive waterproof dressing. Be careful not to stretch the adhesive dressing over the gauze because the tissue will swell. Stretch the skin and lay the unstretched dressing over the gauze so that the swelling of the skin over the next couple days will not create blistering at the corners of the dressing from a sheer effect that occurs with tissue swelling under a tight Tegaderm-like plastic. Do not stretch the Tegaderm-like plastic dressing on the skin but rather stretch the skin as you place the unstretched Tegaderm-like dressing over the gauze.
- Immediately after the procedure, patients have a cold firm spot on their breast, which is numb. They typically are able to drive themselves home after a few minutes of relaxation while getting dressed, since no sedation is necessary.
- Inform the patient that her tissue will swell significantly over the next few days, which may also be tender. Local treatments of ice packs and ibuprofen will aid in decreasing the swelling. Patients who are warned of the swelling and local tenderness will less likely be alarmed when it occurs.
- Sometimes, surrounding tissue is damaged and swells more than expected. If the lesion was on the chest wall, cryoablation of pectoralis muscle will be more painful than breast tissue ablation. Supportive pain medicine will allow this to resolve. In other patients, there is significant swelling in and around the cryoablated tissue. This is more likely with longer ablations or larger areas of normal breast tissue ablated. This occurs with cancer ablations due to longer treatment times. With tissue swelling, one must be cautious of skin taping or Steri-Strips during these first few days. Due to the swelling, there may be a sheering force on the skin by the tape, and skin blisters may occur. This is strictly due to tape applied too tight for the amount of tissue swelling that may occur. Avoid tape close to the cryoablation area. Pain may be due to blisters forming under the tape.
- Due to the complete destruction of all cells within the cryoablation target, all blood cells will lyse and exude their hemoglobin into the tissues. The entire treated area will turn a deep shade of red-purple merging to yellow green over the next week to 10 days. An informed patient will not be alarmed when these color changes occur. By 2 weeks, all the color is gone (**FIG 10A–C**).
- The patient is advised to call the office as needed for the first 5 days to let us know of the changes that have been described.

FIG 10 • **A–C.** Clinical images of patient postcryoablation at 1 week, 1 month, and 6 months. Note, the ecchymosis extends in a larger area than the fibroadenoma due to the lysis of blood cells in the area but resolves promptly.

It is not likely at all to have a significant posttreatment hemorrhage or infection. However, patients might think both of these events might be happening due to the typical changes postcryoablation.

- After these initial changes, the patient will be able to feel a firm oval mass at the site of the cryoablation zone. It will not be very tender but will be larger than the patient's original lesion or, if it was nonpalpable prior to cryoablation, it is now palpable to the patient. Knowing this change in physical exam will occur is helpful to prevent the patient's concern when they first palpate the area after the initial swelling is gone.

Long-Term Postprocedure Management

- After the initial healing period, the patient enters a long-term resolution phase. During this time, the patient will have very slow resolution of the residual mass left by the necrotic central cryoablative zone. Typically, there is little pain in the area. Properly informed patients express little concern when feeling the persistent cryonecrotic mass over several months as it resolves (**FIG 2**).
- Follow-up office visits. Some clinicians treat the patients and simply advise the patients of expected local changes in the breast and do not follow their patients in the office. This is not the advised method of follow-up, but some clinicians just wait for patients to call or return as needed. This method creates unnecessary anxiety in the patient and likely decreases patient satisfaction. We recommend regular follow-up exams for 1 year after cryoablation.
- As time goes on, patients are seen less frequently to confirm the residual mass is decreasing as well as to reassure the patient that all is well. The first posttreatment visit is about 2 to 4 weeks after the cryoablation. Next visit is 2 months later. Next visit is 3 to 4 months after that. Thereafter, every 3 to 6 months until the lesion has disappeared.
- With each visit, the area is examined with or without focal ultrasound measurements. With each exam, note the size of the residual cryonecrosis and reassure the patient of slow and progressive absorption.
- Most patients are younger than 40 years and not candidates for routine mammographic screening. If they are older than 40 years, preferably, their most recent mammogram was just prior to their cryoablation. Routine screening may follow. The first mammogram postcryoablation will have imaging changes from the procedure. If the imager is unaware of the treatment, they will note increased density and mass effect with indistinct margins in the area of the previously benign-appearing lesion. The unaware imager may consider the image BIRADS 4 and suggest a biopsy. However, clarifying the treatment events will modify the reading to either BIRADS 3 or 2, suggesting serial follow-up imaging.[22,23]
- The speed of resorption of the residual cryoablation debris relates to the original size of the target lesion. For tumors less than 2 cm, the area normally disappears within 1 year posttreatment. For those larger than 2 cm, it may take longer than a year. Almost all lesions over 2 cm are not palpable by 2 years. Ultrasound visualization of the residual cryoablated tissue remains visible for longer periods but that is similar to surgical scar seen by ultrasound. Ultrasound identification of the treated area is difficult to find by 3 years.
- Long-term (over 3 years) imaging changes vary from no evidence of treatment to residual scar similar to surgical biopsy changes. Mammograms may occasionally show focal calcifications in the area or radiating fibrosis, but the most common mammographic image is fatty replacement of the treatment area.[22] Ultrasound imaging most often demonstrates nonspecific breast tissue with some areas of hypoechoic scar over time. The iceball is usually at least 30% larger than the treated lesion then slowly resorbs. The tissue within the iceball becomes firm and much more noticeable than the prior tumor. Nonpalpable tumors become palpable immediately. Over the first 1 to 2 months, these areas will start to decrease in firmness. It will not be until about 6 months before they dissolve. Continue to reassure the patient that the firmness they feel is normal and expected. Anxiety of finding a new mass when none was present previously can readily undo the benefits of the procedure.
- Some patients may have a persistent firm mass for 6 to 9 months. If the cryoprobe was placed accurately and the treatment given properly, these patients will need to wait for the expected resolution of the palpable mass. For lesions over 2 cm, it will take over 6 months before their lesions start to noticeably decrease in size. Signs of a successful cryoablation include no growth in the palpable mass after the first month, and that after 6 months, there seems to be a slight softening of the mass, although it is difficult to notice. There should be no progressive measurable growth in the "mass." Reassurance is necessary for both the doctor and the patient during this time. By 9 months, it is clear that the cryolesion is getting smaller and the firmness is decreasing. By 12 months, there is noticeable change, even if the

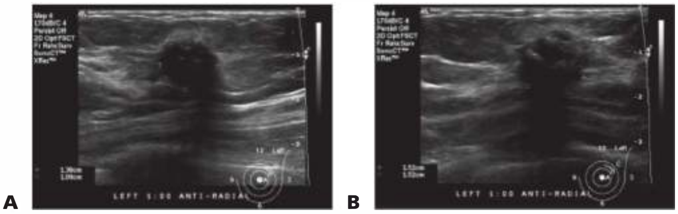

FIG 11 ● A,B. Ultrasound images of cryoablation site 4 years after treatment. Site is smaller and has residual scar of necrotic debris where lesion had previously been.

lesion is not gone. Progressive decrease in size is noticeable on ultrasound and palpation (FIG 2).

- The ultrasound picture of cryoablated tissue is similar to surgical scar. There is typically an irregular hypoechoic shadowing mass, noticeably more suspicious on ultrasound than prior to cryoablation, but smaller than original lesion. The clues of normalcy are that there is no progressive growth but slow and progressive decrease in overall size. These lesions are followed but not biopsied unless there is growth (FIG 11A,B).

OUTCOMES

- Many reports have demonstrated the effectiveness of cryoablation of fibroadenomas. These reports are consistent in their results in properly chosen patients. After treatment, clinical and imaging evidence of the lesion slowly resorbs until the area disappears. Imaging evidence of the targets also disappears (Table 2).
- After initial positive reports of this technique, a Current Procedural Terminology (CPT) code was assigned to this process. Many payers reimbursed for this procedure. However, due to limited use of this method of treatment, many payers reversed their acceptance of payment and reclassified this procedure as investigational. Yet, the data supporting this method of treatment as acceptable has been repeated in the peer-reviewed literature in many sites. The few negative comments are mostly reports of slow resorption of the treated lesion.

COMPLICATIONS

- Most complications can be prevented, or said another way, most complications are iatrogenic. These include choosing a patient who has too narrow a window between the skin and the lesion, making skin injury more likely.
- Other complications include blistering on the skin due to swelling of the skin under adhesive from Steri-Strips or the Tegaderm-like dressing.
- Although ecchymosis and swelling is expected, significant hemorrhage and infection is quite rare.

Chapter 5 Lumpectomy for Breast Cancer

Michael S. Sabel

DEFINITION

- Lumpectomy is defined as the complete excision of a breast tumor with an adequate margin of surrounding normal tissue. Lumpectomy plus breast irradiation are the essential components of successful breast conservation therapy (BCT). Lumpectomies for nonpalpable cancers require wire localization. Other terms for lumpectomy include partial mastectomy, tumorectomy, or tylectomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- For BCT to be successful, it must be possible to (1) obtain negative surgical margins around the tumor while still maintaining a cosmetically acceptable result and (2) safely deliver radiation therapy. A thorough history and physical examination is necessary to carefully select patients for BCT. Absolute contraindications to BCT are listed in Table 1.
- A thorough history should be performed prior to treatment, including a detailed past medical history, present medications and allergies, and a personal and family history of cancer.
- Prior radiation to the breast is a contraindication to BCT. For patients who may have had chest wall radiation for indications other than a prior breast cancer (such as mantle radiation for Hodgkin disease), it may be helpful to obtain the prior records and review the fields treated. These patients may be eligible for a partial breast irradiation technique (Part 5, Chapter 7).
- Patients with a history of autoimmune or collagen-vascular diseases, such as scleroderma, lupus, or dermatomyositis, may have abnormal reaction to radiation therapy, which significantly compromises the cosmetic outcome. For some types of collagen-vascular disease, such as Raynaud phenomenon, rheumatoid arthritis, or Sjögren's syndrome, the response to radiation is not as severe and these patients may be considered for BCT.
- A detailed family history is critical to assess the risk of a future breast cancer, and consider genetic counseling and testing. High-risk patients may want to consider bilateral mastectomy as they are at considerable risk of a second primary cancer. The data is mixed regarding the local recurrence rate among patients with a known or suspected BRCA 1 or 2 mutations who opt for BCT. Some, but not all, studies suggest an increased risk.[1,2] The decision to pursue BCT in known BRCA1/2 carriers should be made following extensive discussion with a genetic counselor.

Table 1: Absolute Contraindications to Breast Conserving Surgery

Unable to receive radiation therapy
Previous chest wall irradiation
Need to deliver radiation during pregnancy
Scleroderma or active systemic lupus erythematosus
Multicentric disease
Diffuse suspicious calcifications on mammography
Inability to achieve adequately negative margins

- Patient age, nodal status, histologic tumor type, tumor grade, and extensive intraductal component (EIC) are not contraindications to BCT as long as negative margins can be obtained.
- If an adequate lumpectomy can be performed, prior breast augmentation with breast implants are not an absolute contraindication, and radiation can be delivered to the augmented breast using standard techniques and doses. However, capsular contraction is a risk. If the tumor is close to the implant, preventing negative margins (cancers sometimes invade the fibrous capsule around the implant), the implant may need to be removed.
- A complete, bilateral breast examination should focus on both assessing the cosmetic implications of lumpectomy and identifying additional areas of concern to rule out multicentric disease. Any additional suspicious masses should be biopsied, and cancer ruled out, prior to proceeding with BCT.
- The size of the mass relative to the size of the breast, location of the mass, proximity to the skin and amount of skin needed to be resected, and symmetry of the breasts should be noted. For some patients with a large tumor relative to the size of the breast, neoadjuvant chemotherapy may be considered to downstage the primary tumor. For other patients in whom a poor cosmetic outcome with standard lumpectomy is predicted, an oncoplastic approach should be considered (Part 5, Chapter 6).
- A detailed examination of the bilateral axillary, supraclavicular, and cervical lymph nodes should be undertaken, and any suspicious lymphadenopathy worked up prior to surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients require bilateral mammographic evaluation, with appropriate magnification views, within 3 months of surgery (**FIG 1**). The tumor size, the presence of microcalcifications, and the extent of calcifications outside of the mass should be noted. Some patients with palpable cancers may still require wire localization of the calcifications to assure complete removal at the time of lumpectomy.
- Any additional areas of abnormality should be worked up and biopsied to rule out multicentric cancer. Multicentric disease is typically a contraindication to BCT; however, patients with two tumors close enough that they can be removed in one specimen with an acceptable cosmetic outcome can still be considered candidates for BCT.
- The use of magnetic resonance imaging (MRI) to determine eligibility for BCT has been increasing. Although MRI may more accurately determine the extent of the tumor or identify multicentricity, particularly in women with dense breast tissue (for whom mammography is less sensitive), its use is

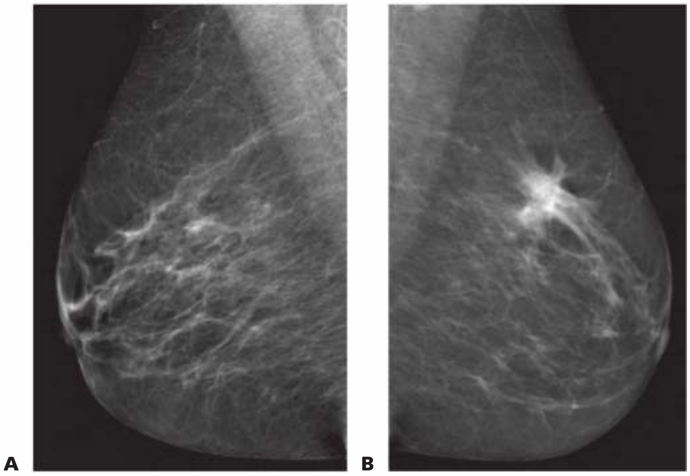

FIG 1 ● Bilateral mammogram demonstrating a left breast cancer. **A.** Right breast. **B.** Left breast.

controversial. MRI is highly sensitive but has limited specificity and is limited in its ability to visualize ductal carcinoma in situ (DCIS). Studies have shown that the use of MRI appears to increase the mastectomy rate without decreasing reexcision or local recurrence rates.[3] The need for MRI should be evaluated on a case-by-case basis.

- Accurate histologic assessment of the primary tumor, including histologic subtype and hormone receptor status, is necessary in evaluating the breast cancer patient for suitability for BCT. This is best accomplished through a core needle biopsy rather than fine needle aspiration biopsy or excisional biopsy.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to taking the patient back to the operating room, the presence of the palpable cancer should be confirmed with the patient. In the preoperative area, the mass should be examined in both the upright and supine positions.
- With the patient in the supine position, the mass should be carefully marked.
- Although the risk of infection after breast cancer surgery is low, it tends to be higher than average for a clean surgical procedure, and several studies have shown that antibiotic prophylaxis significantly reduces the risk of postoperative infection.[4]

Positioning

- Lumpectomy is often performed in conjunction with a sentinel lymph node biopsy. Therefore, the patient should be positioned supine with the ipsilateral arm at 90 degrees.
- If intraoperative analysis of the sentinel lymph node and possible axillary lymph node dissection is planned, the ipsilateral arm should be prepped into the sterile field. Otherwise, the ipsilateral arm can be secured.
- If sentinel lymph node biopsy is to be performed in conjunction with lumpectomy, then the blue dye should be injected at this point. The skin is prepped with alcohol and either isosulfan or methylene blue dye is injected peritumoral (see Part 5, Chapter 8, Sentinel Lymph Node Biopsy for Breast Cancer) (**FIG 2**).

FIG 2 ● Peritumoral injection of blue dye prior to lumpectomy for performance of sentinel lymph node (SLN) biopsy.

PLACEMENT OF INCISION

- The skin incision should be placed directly over the palpable mass (**FIG 3**). One should avoid excessive tunneling. This may compromise the margins and make a reexcision for close or positive margins unnecessarily difficult.
- When there is adequate distance between the skin and the tumor, skin does not need to be removed. However, when the tumor is close to the skin, an ellipse of skin over the tumor should be removed with the lumpectomy specimen.
- In the upper hemisphere of the breast, curvilinear incisions following the Langer lines (the normal lines of tension in the skin) are ideal. In the lower hemisphere, the incisions can either be circumareolar or radial (**FIG 4**). For smaller tumors in relatively larger breasts, where there is adequate breast parenchyma, curvilinear incisions are acceptable. However, when skin or a fair amount of tissue is to be removed, curvilinear incisions will collapse the breast inferiorly so that the nipple points downward. In this situation, radial incisions will result in less distortion of the nipple–areolar complex.
- All incisions must be planned with an eventual mastectomy in mind should attempts at breast conservation fail (**FIG 5**). The incision size needs to be adequate to remove the mass and surrounding margin. Using a small incision for cosmetic benefit results in excessive manipulation of the tumor and involved margins that require reexcision.

FIG 3 ● Placement of incision within the Langer lines of the breast directly over the palpable cancer. The incision is planned large enough to remove the cancer without excess manipulation.

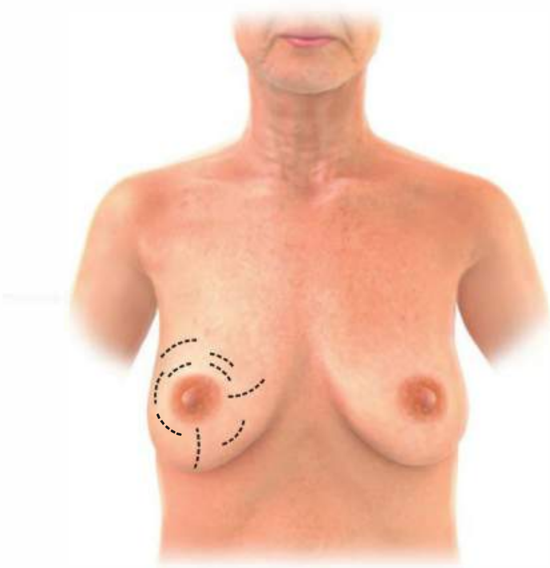

FIG 4 ● Potential lines of excision for breast lumpectomy. In the upper hemisphere of the breast, curvilinear incisions are best, keeping within the Langer lines of the skin. In the lower hemisphere, either curvilinear or radial incisions are acceptable.

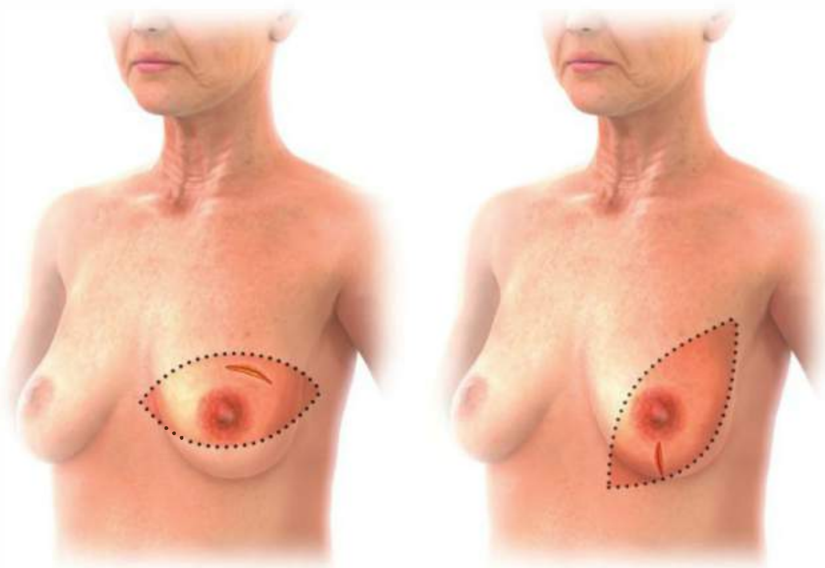

FIG 5 ● Potential mastectomy incisions if breast conservation fails. Lumpectomy incisions should be planned with a possible mastectomy in mind should negative margins not be attainable.

SKIN INCISION AND RAISING OF FLAPS

- An incision is made in the skin going just deep to the dermis. For lesions closer to the skin, skin flaps should be immediately elevated in all directions over the mass (FIG 6). Adequate subcutaneous fat should be left on the flaps, which should get progressively thicker as the flaps are elevated (approximately 45 degrees). Excessively thin flaps lead to excessive retraction and concavity with radiation and should be avoided by excising the skin over the mass.
- For deep-seated tumors, after dividing the skin, the breast tissue may be divided straight down to approximately 1 cm over the mass before beginning the dissection around the tumor (FIG 7).

A

B

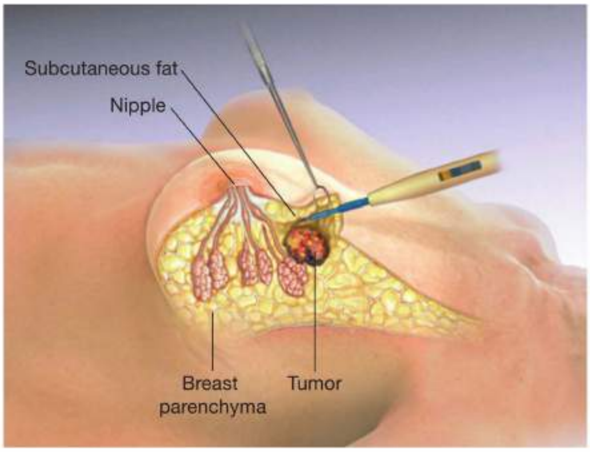

FIG 6 ● Raising of flaps over the tumor. Excessively thin flaps should be avoided. The flaps should get thicker as they are elevated.

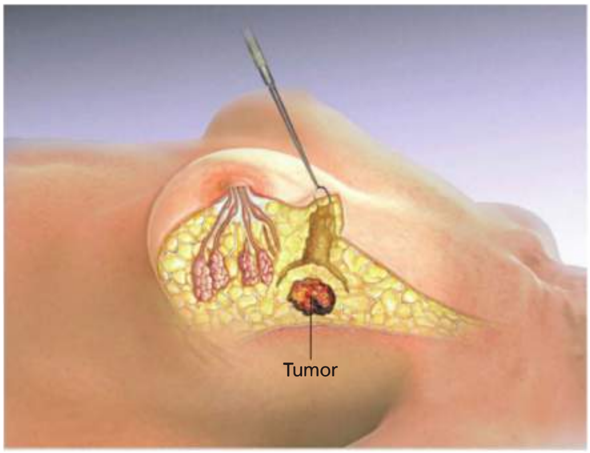

FIG 7 ● The breast parenchyma is divided until approximately 1 cm above the tumor before dissecting around the tumor for a deep-seated tumor.

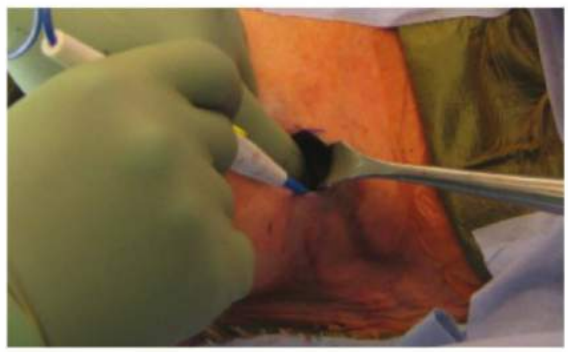
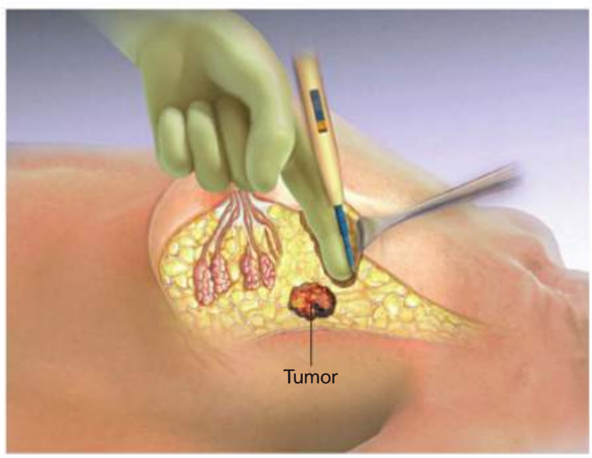
EXCISION

- The excision is then carried out with the goal of maintaining 1-cm grossly free margins around the mass. This is best accomplished by retracting the mass with the index finger of the nonoperative hand so you are constantly aware of the margin and maintaining a 1-cm rim of normal breast tissue or fat as dissection continues toward the chest wall (**FIG 8A,B**).
- The tissue is divided circumferentially around the mass. Once it is free, it can usually be elevated out of the wound (**FIG 9**). The skin incision must be large enough so that the resected portion can be easily brought out; struggling to deliver a mass through a small incision leads to excessive manipulation and positive margins on final pathology.
- Before the lesion is completely removed from the body, the specimen should be oriented with 2-0 silk sutures. Orientation is critical so that if reexcision for close or positive margins are needed, this can be limited to just the involved margin (as opposed to reexcising the entire cavity). Three sutures are necessary to orient the mass correctly for the pathologist and avoid errors (**FIG 10**).[5] At this juncture, we recommend placing a short 2-0 silk suture at the superior margin and a long silk suture at the lateral margin (**FIG 11**).
- The specimen is now completely removed by dividing the deep margin (**FIG 12**). For lesions close to the chest wall, the deep margin should include the fascia of the pectoralis major muscle. In rare cases, excision of some of the pectoralis is necessary to assure a negative deep margin. Once excised, a third double-stranded orientation suture is placed at the deep margin (**FIG 13**).



A



B

FIG 8 ● With the tumor retracted with the index finger, the surgeon dissects around it, maintaining 1 cm of normal breast tissue around the tumor.

FIG 9 ● The entire tumor is excised circumferentially and delivered from the wound.

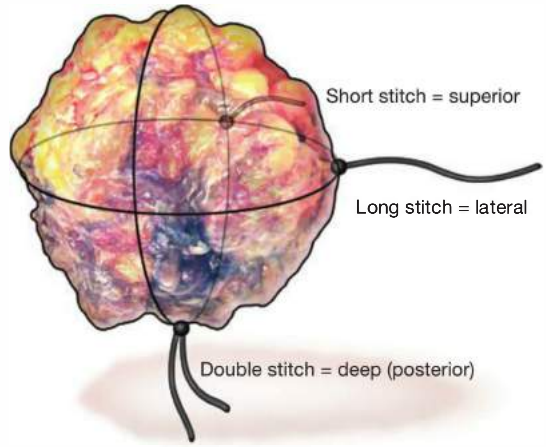


FIG 10 ● Three suture marking system for lumpectomy specimens. A 3-0 silk short stitch is placed superiorly, a long stitch is placed laterally, and a double stitch is placed deep (posteriorly).

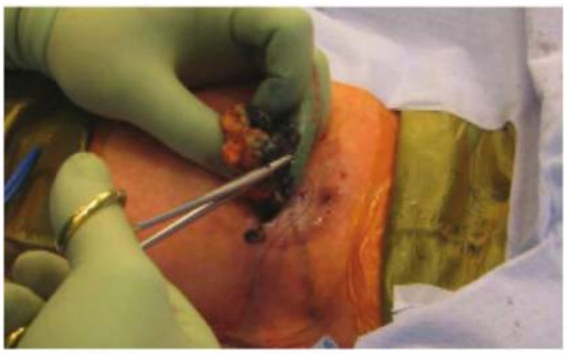

FIG 11 ● Marking sutures are placed prior to complete excision of the specimen so as not to lose the orientation.

FIG 12 ● The posterior tissue is divided last, completing the lumpectomy.

FIG 13 ● Lumpectomy specimen with marking sutures.

INTRAOPERATIVE MARGIN ANALYSIS

- Without intraoperative margin analysis, reexcision rates to obtain negative margins can be as high as 30% to 50%. Intraoperative margin analysis is highly recommended to minimize reexcision rates to as low as 10%.[6] After orientation, the margins of the specimen are inked using six colors and then sectioned at 2- to 3-mm intervals (**FIG 14**).
- After gross examination of the margin status, sections are taken for each suspicious margin (**FIG 15**). Sections 6- to 7-μm thick are cut on a −20°C cryostat and stained with a rapid hematoxylin and eosin technique (with two levels of each tissue block examined). Any margins in which invasive or in situ carcinoma extend to within 2-mm are reported to the surgeon (**FIG 16**).
- A reexcision of the close margin can then be performed by grasping the top of the margin with an Allis clamp and excising back another 0.5 to 1 cm around the hemisphere in need of reexcision (**FIG 17A,B**). The new margin should be appropriately marked for the pathologist (**FIG 18**).

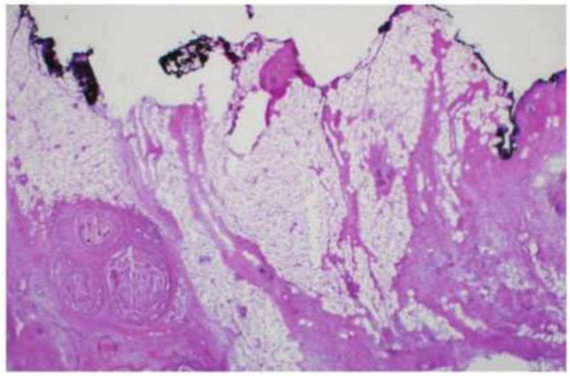

FIG 16 ● DCIS is identified close to the margin. This information is relayed to the surgeon so a reexcision of that margin can be performed.

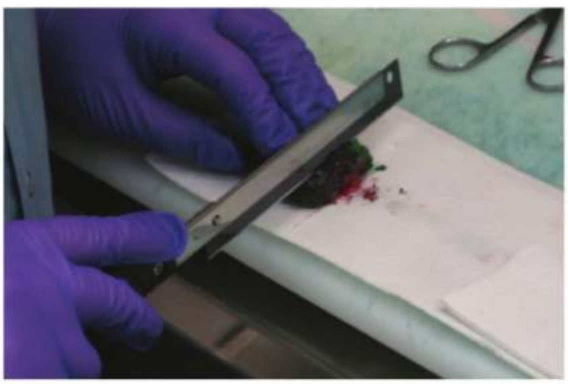

FIG 14 ● The specimen is inked with six colors and sectioned for intraoperative margin analysis.

FIG 15 ● The sections are grossly examined for involved margins.

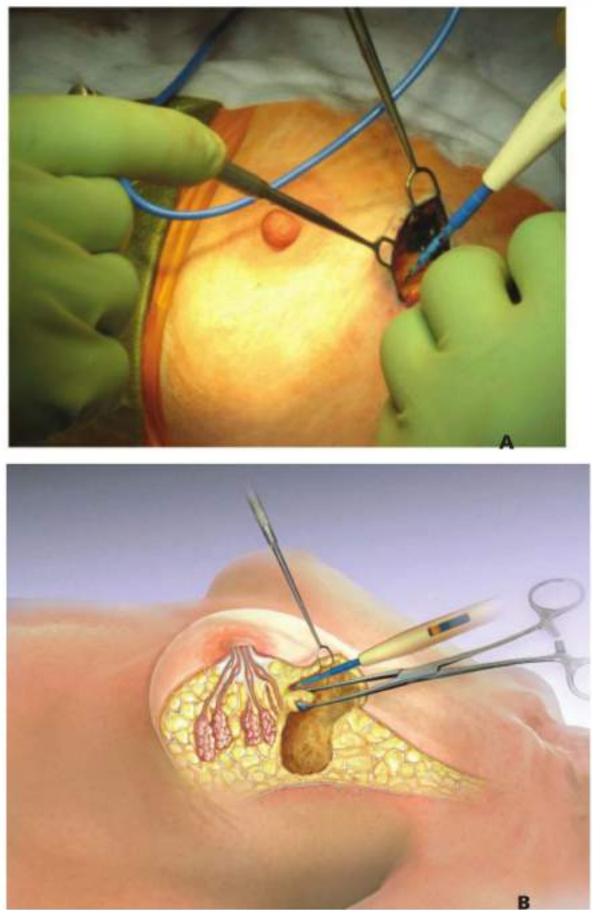

FIG 17 ● **A.** An additional inferior margin is obtained based on the intraoperative margin analysis. **B.** The top of the cavity is grasped with an Allis and the entire hemisphere is excised approximately 1 cm back from the cavity.

FIG 18 ● A marking stitch designating the new, true margin after reexcision.

CLOSURE

- Once the lumpectomy is complete, hemostasis is assured and then surgical clips are placed within the cavity at the six anatomic locations (anterior, posterior, medial, lateral, superior, and inferior) (**FIG 19**). This helps in the planning of radiation therapy, particularly for a boost or for partial breast irradiation.
- For the standard lumpectomy, the surgeon should *not* try to reapproximate the breast tissue. The cavity will fill with seroma and fibrin, and ultimately fibrous tissue, which will maintain the normal contour. For large defects, oncoplastic techniques can be considered, which are discussed in Part 5, Chapter 6.
- The incision is closed with absorbable deep dermal sutures, followed by either a subcuticular stitch or tissue adhesive (**FIG 20**). Drains should not be used.

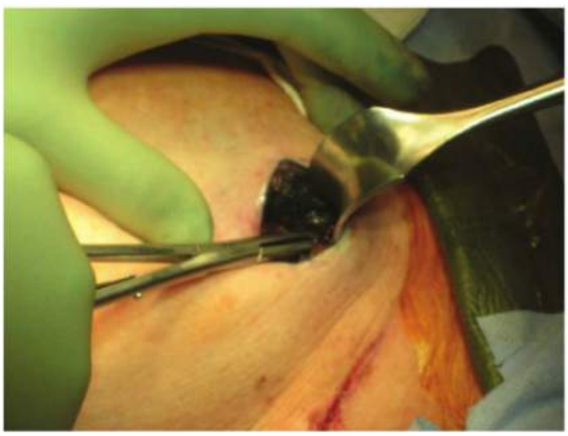

FIG 19 ● Clips are placed around the lumpectomy cavity to aid in the delivery of radiation.

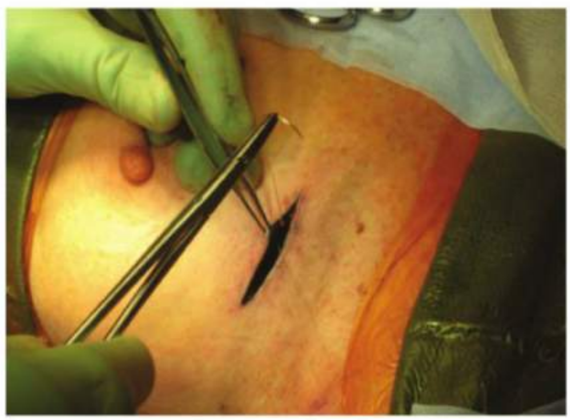

FIG 20 ● The skin is reapproximated with absorbable deep dermal sutures.

PEARLS AND PITFALLS

Indications	■ A complete history and physical and review of the breast imaging should take place to assure the patient is a suitable candidate for BCT. ■ Suspicious lesions on exam or imaging should be biopsied prior to proceeding with BCT.
Placement of incision	■ Incisions should be created, keeping in mind a possible mastectomy should BCT fail. ■ In the inferior portion of the breast, radial incisions can give superior cosmetic outcomes compared to curvilinear incisions. ■ Make the incision large enough to remove the tumor without excessive manipulation. This decreases the close/positive margin rate and the need for reexcision.
Raising of flaps	■ Thin flaps will lead to excessive retraction and concavity after radiation. Avoid them by excising the skin over the tumor with the lumpectomy. ■ Flaps should get progressively thicker as they are raised.
Excision	■ Maintain at least 1 cm of grossly normal margins around the mass throughout the excision. ■ Intraoperative margin analysis can greatly reduce reexcision rates, leading to lower mastectomy rates and improved cosmetic outcome.
Orientation	■ Three orientation sutures are necessary to avoid error. ■ Place two sutures before complete excision of the tumor to avoid losing the orientation.
Closure	■ Do not try to reapproximate the breast tissue or place a drain.

POSTOPERATIVE CARE

- After a lumpectomy, the patient should be placed in a breast binder or supportive brassiere. This helps sustain hemostasis and relieves tension on the skin closure imposed by the weight of the breasts. The patient should be encouraged to wear the support bra day and night for 1 week after surgery.

OUTCOMES

- Long-term recurrence rates after lumpectomy and radiation therapy range from 5% to 22%, compared with 4% to 14% for mastectomy. Survival rates are equivalent.[7]
- Among women undergoing lumpectomy and radiation, excellent or excellent/good cosmetic results were noted at 3 years in 73% and 96%, respectively.[8] This is primarily driven by the volume of breast tissue resected, with scores higher among women with less than 35 cm^3 resected compared to women with greater than 85 cm^3.[9,10]

COMPLICATIONS

- Seroma
- Hematoma
- Infection (cellulitis or abscess)
- Altered sensation to the nipple
- Close or positive margins
- Poor cosmetic outcome

Chapter 6 Oncoplastic Breast Surgery

Kristine E. Calhoun Benjamin O. Anderson

DEFINITION

- Breast-conserving therapy was first introduced as a treatment option for women with breast cancer beginning in the 1970s, with multiple clinical trials having since demonstrated equivalency in terms of overall survival between lumpectomy with radiation and mastectomy.[1,2]
- For breast conservation to be effective, the cancer must be resected with adequate surgical margins while simultaneously maintaining the breast's shape and appearance. Unfortunately, satisfying these dual goals may prove to be challenging.[3]
- In a traditional lumpectomy, the skin is opened, the tumor removed, and the wound closed without any specific effort being made to obliterate the internal cavity. Closing the remaining fibroglandular tissue may result in cosmetic defects if alignment of the breast tissue is suboptimal. Although such an approach may work well for smaller tumors, declivity of the skin and/or displacement of the nipple–areolar complex (NAC) may be the end result if the lesion removed from the breast is sizable.
- In 1994, Werner P. Audretsch was one of the first to advocate the use of "oncoplastic surgery" for repair of partial mastectomy defects by combining the techniques of volume reduction with immediate flap reconstruction.[4] Although initially used to describe partial mastectomy combined with large myocutaneous flap reconstruction using the latissimus dorsi or the rectus abdominis muscles, oncoplastic surgery currently refers to a series of surgical approaches that use partial mastectomy and breast flap advancement to address tissue defects following wide resection.
- The most widely used techniques, which will be described in this chapter, include the parallelogram mastopexy lumpectomy, batwing mastopexy lumpectomy, lateral segmentectomy lumpectomy, donut mastopexy lumpectomy, reduction mastopexy lumpectomy, and the central lumpectomy.[3,5]

ANATOMY

- One of the fundamental challenges for the oncoplastic breast surgeon is to determine how the individual cancer is distributed within the breast and to assess whether the lesion can be resected as a single en bloc fibroglandular resection.
- The modern anatomic analysis of ductal anatomy suggests that the number of major ductal systems is probably fewer than 10. The size of ductal segments can be incredibly variable, with some presenting as a narrow "pie slice" of tissue; in other cases, a single ductal segment can occupy up to 25% of the total breast volume.[6]
- Not all ducts pass radially from the nipple to the periphery of the breast, as some travel directly back from the nipple toward the chest wall. Single ductal segments may radiate to the sternal (medial) and clavicular (superior) aspects of the breast, with two or three ductal branches layered on each other, creating a fuller pad of fibroglandular tissue in the axillary (lateral) and abdominal (inferior) aspects of the breast.[7] Although the ductal branches appear to interdigitate with each other within the breast parenchyma, the segments do not communicate with each other via ductal anastomoses.
- In contrast to breast ductal anatomy, the fibroglandular tissue of the breast has a rich anastomotic circulatory bed, which allows oncoplastic resection and mastopexy fibroglandular advancement to be safely performed with minimal threat to tissue viability. This well-collateralized breast vasculature allows the surgeon to remodel large amounts of fibroglandular tissue within the skin envelope without major risk of breast devascularization and subsequent necrosis.
- The axillary and internal mammary arteries are the most common origins of the arterial blood supply of the breast. By maintaining communication with one of these two arterial connections, adequate blood supply to the breast parenchyma is maintained during tissue advancement and mastopexy closure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients should undergo standard preoperative history and physical, with special attention given to any prior breast surgical history, including the placement and location of breast implants.
- Tissue biopsy, preferably using core needle sampling, should be performed and conclusive proof of malignancy documented, with mandatory internal review of all external pathology slides required at our institution.
- Every effort should be made to make the tissue diagnosis by needle sampling, as an excisional biopsy scar may complicate the placement of the subsequent lumpectomy incision.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients considered for oncoplastic lumpectomy should undergo a standard preoperative breast imaging workup, which typically includes a combination of mammography and ultrasound, with or without breast magnetic resonance imaging (MRI). Although mammography may underestimate the extent of disease, especially if ductal carcinoma in situ (DCIS) is present, it is still warranted and is often the initial diagnostic study.[8]
- Although still controversial, the use of MRI may contribute greatly to the surgeon's ability to preoperatively determine the extent of disease present, especially for more mammographically subtle or occult cancers. Compared with mammographic and ultrasound images, the extent of disease seen on MRI may correlate best with the extent of tumor found at pathologic evaluation.
- Although sensitivity is high, MRI has a low specificity of 67.7% in the diagnosis of breast cancer before biopsy.[9] Up to one-third of MRI studies will show some area of enhancement

that needs further assessment but ultimately prove to be histologically benign breast tissue.[3]

- For cancers containing both invasive and noninvasive components, a combination of imaging methods (mammography with magnification views, ultrasonography, and/or MRI) may yield the best estimate of overall tumor size.[10]

SURGICAL MANAGEMENT

- The indications, as well as the contraindications, for oncoplastic surgery are the same as those of traditional breast-conserving surgery. In general, such techniques are only offered to those otherwise believed to be breast preservation candidates, including patients with single quadrant disease and individuals who can tolerate and have access to postsurgical radiation therapy.
- The techniques described in this chapter are easily learned and implemented by breast surgeons, even those lacking formal plastic surgery training.

Preoperative Planning

- While planning oncoplastic resections, as with traditional lumpectomy, the surgeon needs to accurately identify the area requiring removal, which is often aided by the use of preoperatively or perioperatively placed localization wires.
- Single wire localization for larger breast lesions may be more likely to result in positive margins, because the surgeon lacks landmarks to determine where the true boundaries of nonpalpable disease are located. For such scenarios, multiple bracketing wires may assist the surgeon in achieving complete excision at the initial intervention (**FIG 1**).

Positioning

- Before the procedure, consideration should be given to marking skin landmarks with the patient in the upright sitting position.
- Relevant landmarks to be identified include the inframammary crease, the anterior axillary fold at the pectoralis major muscle, the posterior axillary fold of the latissimus dorsi muscle, the sternal border of the breast, and the periareolar circle. Identifying these structures with the patient in the sitting position is very important to the final cosmetic outcome, because these sites may be challenging to accurately locate once the patient is anesthetized and lying supine on the operating room (OR) table.

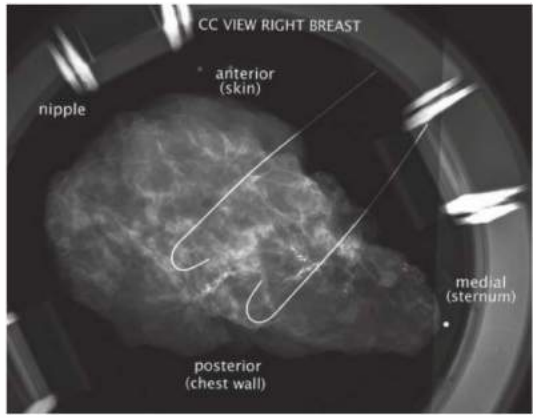

FIG 1 • Multiple bracketing wires used to perform a wire localized excision of a larger lesion.

Approach

- The patient should be supine on the OR table with the arms abducted.
- It is preferable to have both breasts prepped and draped into the field so that visual comparison with the patient in a beach chair position is possible as the wound is closed. Such an approach allows the surgeon to identify areas of unsightly tugging or dimpling inadvertently created during closure so that they can be addressed at that time.
- Multicolored inking can help orient the specimen and is best performed by the operating surgeon (**FIG 2**).

FIG 2 • Multiple ink colors are used to orient the lumpectomy specimen.

TECHNIQUES

PARALLELOGRAM MASTOPEXY LUMPECTOMY

- The most basic of the oncoplastic techniques, this involves removal of the skin island located directly superficial to the known disease and is most commonly used for superior pole or lateral cancers.[11]
- For upper inner quadrant lesions, the skin island excisions should be small or performed using a simple reapproximation of breast tissue and skin without removal of any skin island.[12]
- Removal of the overlying parallelogram of skin avoids excessive, redundant skin from being left behind after excision and helps prevent declivity.
- Be cautious when designing the skin ellipse, because removal of too broad of an island can cause substantial shifting of the NAC.
- A rounded parallelogram with two equal length lines is drawn, thus marking the skin island to be excised in conjunction with the underlying target lesion and surrounding tissues (**FIG 3**). For lesions in the upper breast, incisions should be curvilinear, whereas lesions

FIG 3 ● The rounded parallelogram, with two equal line lengths, to excise a skin island en bloc with the tumor.

FIG 5 ● The lumpectomy specimen is lifted off the pectoralis muscle.

located within the lower breast, including the 3 o'clock and 9 o'clock positions, should have a radially placed parallelogram.

- The proposed skin incision is made to breast parenchyma (FIG 4).
- After excision of the skin island, short-distance mastectomy-type skin flaps are raised along both sides of the wound.
- Dissection is carried down to the chest wall, the breast gland is lifted off the pectoralis muscle (FIG 5), and a standard tumor resection is performed.
- Four to six marking clips are typically placed at the base of the defect within the surrounding fibroglandular tissue.
- Once resection is complete and hemostasis obtained, the fibroglandular tissue at the level of the pectoralis fascia is undermined so that breast tissue advancement can be performed over the muscle (FIG 6).
- The margins of the residual cavity are then shifted together by the advancement of breast tissue over muscle and the defect is sutured at the deepest edges using 3-0 absorbable suture. The direction of tissue advancement can be adjusted depending on the location of the fibroglandular defect and the excess tissue that can be shifted to close it. The goal of the mastopexy is to perform as complete of a closure over the pectoralis muscle as possible to discourage communication between the anterior skin and the deeper tissues (FIG 7).
- The superficial tissue layer is closed with interrupted subdermal absorbable sutures (we use 3-0 sutures), whereas the skin is closed by absorbable subcuticular sutures (we use 4-0 sutures) in routine fashion (FIG 8).

FIG 4 ● The skin of the rounded parallelogram is divided with a scalpel down to the breast parenchyma.

FIG 6 ● The fibroglandular tissue is elevated off the pectoralis fascia in order to advance it over the muscle.

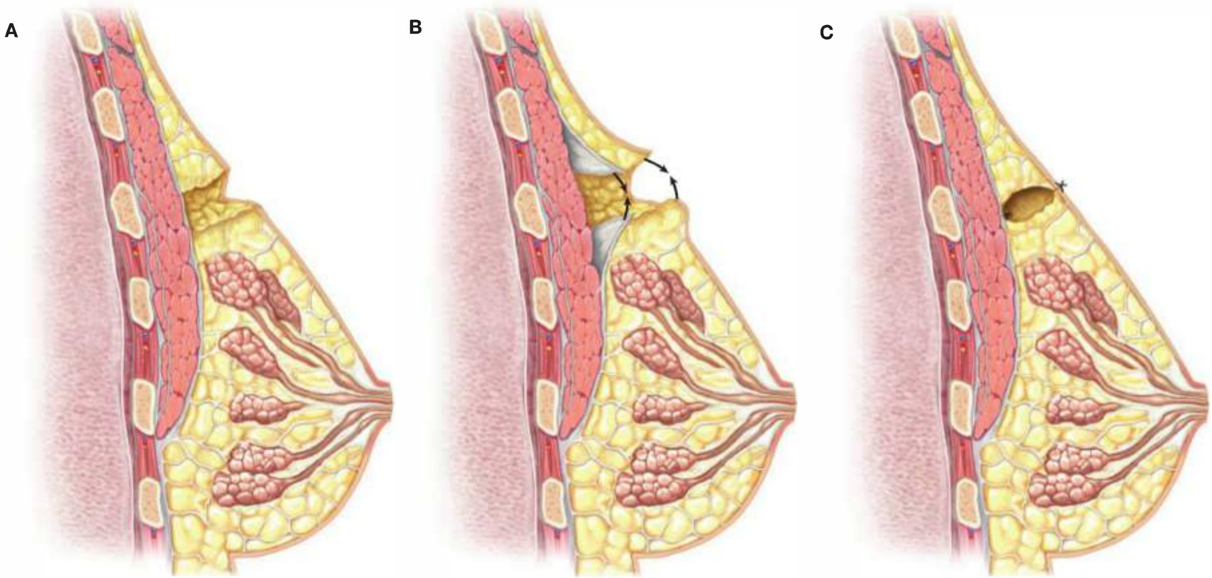

FIG 7 ● **A–C.** The fibroglandular tissue is advanced over the pectoralis muscle to separate the deeper tissues from the overlying skin.

FIG 8 ● Closure of the rounded parallelogram.

BATWING MASTOPEXY LUMPECTOMY

- For cancers adjacent to or deep to the NAC, but without direct involvement of the nipple, lumpectomy can be performed without sacrifice of the nipple itself.
- The batwing approach simultaneously preserves NAC viability as well as the breast mound by using mastopexy closure to close the resulting fibroglandular defect of the full-thickness resection.
- Two similar semicircle incisions are made with angled "wings" on each side of the areola (**FIG 9**). The two half circles are positioned to allow them to be reapproximated to each other at wound closure.
- Removal of these skin wings allows the semicircles to be shifted together without creating redundant skin folds at closure (**FIG 10**).
- Fibroglandular tissue dissection is carried down deep to the known cancer. In most situations, this dissection is carried down to the chest wall, with the breast gland lifted off the pectoralis muscle in a fashion similar to that for the parallelogram lumpectomy (**FIG 11**).
- Following full-thickness resection of the targeted lesion, some mobilization of the fibroglandular tissue for

FIG 9 ● Planned incision for a batwing mastopexy. Two semicircular incisions with angled wings on each side of the areola.

FIG 10 ● The skin is incised for a batwing mastopexy.

mastopexy closure may be required. The breast tissue is elevated off of the chest wall at the plane between the pectoralis muscle and breast gland and the remaining fibroglandular tissue is then advanced to close the resulting defect.

- We typically secure the fibroglandular tissue to itself but do not place anchoring stitches into the chest wall, thereby allowing the reapproximated breast tissues to move on the chest wall and adjust to find its most natural way to settle in for final healing. It is important to remember that what looks perfect on the chest wall when the patient is supine on the OR table may not sit as well when she sits upright and the breast becomes pendulous.
- The superficial layer is closed in the same fashion as the parallelogram mastopexy lumpectomy (**FIG 12**).
- As this procedure can cause some lifting of the nipple, it may create asymmetry when compared to the contralateral breast. If desired, a contralateral lift can be performed. Although this can be performed concurrently at the time of lumpectomy, it may be preferable after adjuvant radiation has finished and the treated breast has "declared" its new size and shape.

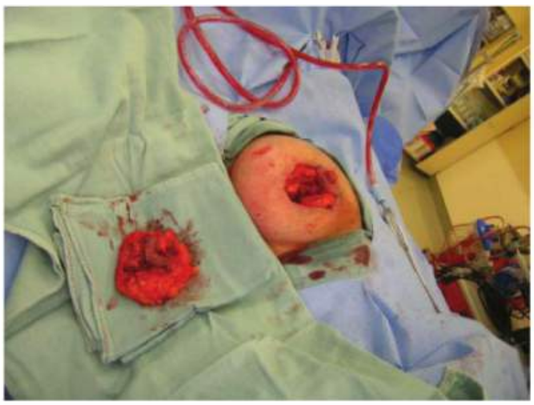

FIG 11 ● The excision is carried down to the chest wall and excised off of the underlying pectoralis muscle.

FIG 12 ● The semicircles are shifted together without creating redundant skin folds at closure.

LATERAL SEGMENTECTOMY

- A variation of the parallelogram lumpectomy, the lateral segmentectomy is especially useful for lesions located within the lower breast, including the 3 o'clock and 9 o'clock positions.
- The skin parallelogram is placed radially and, at the corner of the parallelogram which comes closest to the nipple, the design should be positioned such that the closed incision after resection will approach the NAC tangential to the periareolar line (**FIG 13**). This reduces deviation

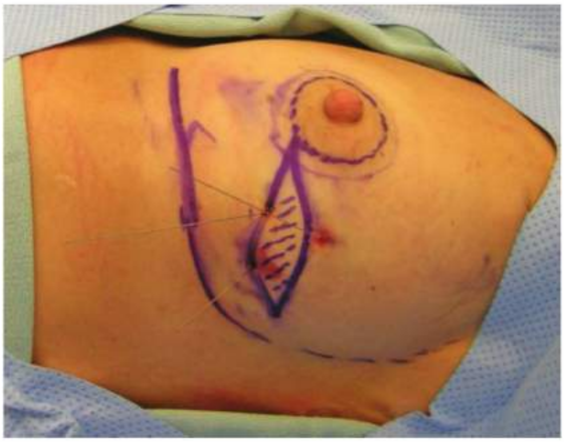

FIG 13 ● A parallelogram for a lateral segmentectomy, placed radially so that when closed, the incision will approach the NAC tangential to the periareolar line.

A

B

FIG 14 ● **A,B.** The entire specimen down to the chest wall is excised off of the pectoralis muscle.

of the NAC toward the lesion, a condition that can result from scar contraction.

- This radial approach gives more projection to the nipple, avoiding the downward displacement, which can be caused by a purely horizontal scar in the lower pole of the breast.
- The proposed skin incision is made to breast parenchyma.
- After excision of the skin island, short-distance mastectomy-type skin flaps are raised along both sides of the wound.
- Dissection is carried down to the chest wall, the breast gland is lifted off the pectoralis muscle, and a standard tumor resection is performed (**FIG 14**).
- Four to six marking clips are typically placed at the base of the defect within the surrounding fibroglandular tissue.
- Once resection is complete and hemostasis obtained, the fibroglandular tissue at the level of the pectoralis fascia is undermined so that breast tissue advancement can be performed over the muscle.
- The margins of the residual cavity are then shifted together by the advancement of breast tissue over muscle and the defect is sutured at the deepest edges using 3-0 absorbable suture.
- The superficial tissue layer is closed with interrupted subdermal absorbable sutures (we use 3-0 sutures), whereas the skin is closed by absorbable subcuticular sutures (we use 4-0 sutures) in routine fashion (**FIG 15**).

FIG 15 ● The lateral segmentectomy incision after closure.

CENTRAL LUMPECTOMY

- The cosmetic impact of nipple removal, which is an unfortunate necessity when cancer involves the NAC, likely accounts for the common use of mastectomy among these individuals despite the existence of the alternative option of central lumpectomy.
- Although central lumpectomy removes the NAC and underlying central tissues, it typically leaves behind a significant breast mound.
- The cosmetic outcome with central lumpectomy can range from good to outstanding, depending on the woman's body habitus, and may be better tolerated than mastectomy and subsequent reconstruction, particularly in women with large breasts where total mastectomy may create prominent asymmetry.
- In central lumpectomy, the incision can be made in the pattern of a large parallelogram, which encompasses the entire NAC. Angling the incision along the lay of the breast when the patient is upright may lead to a more natural position of the scar.
- After excision of the skin island, short-distance mastectomy-type skin flaps are raised along both sides of the wound.

FIG 16 ● The central segmentectomy cavity after excision of the tumor down to the underying pectoralis muscle.

- Dissection is carried down to the chest wall, the breast gland is lifted off the pectoralis muscle, and a standard tumor resection is performed (FIG 16).
- Four to six marking clips are typically placed at the base of the defect within the surrounding fibroglandular tissue.
- Once resection is complete and hemostasis obtained, the fibroglandular tissue at the level of the pectoralis fascia is undermined so that breast tissue advancement can be performed over the muscle.
- The margins of the residual cavity are then shifted together by the advancement of breast tissue over muscle and the defect is sutured at the deepest edges using 3-0 absorbable suture. The superficial tissue layer is closed with interrupted subdermal absorbable sutures (we use 3-0 sutures), whereas the skin is closed by absorbable subcuticular sutures (we use 4-0 sutures) in routine fashion (FIG 17).

FIG 17 ● The breast tissue is advanced over the muscle and the skin closed in routine fashion.

REDUCTION MASTOPEXY LUMPECTOMY

- For cancers in the lower pole of the breast, traditional lumpectomy using circumareolar incision may result in unacceptable downturning of the nipple due to scar contracture after radiotherapy.
- This unpleasant cosmetic outcome can be prevented by using the technique of reduction mastopexy lumpectomy, especially for resection of lesions in the lower hemisphere of the breast between the 4 o'clock and 8 o'clock positions.
- A reduction mammoplasty keyhole pattern incision is made (FIG 18A,B) and the skin above the areola is de-epithelialized in preparation for skin closure.
- A superior pedicle flap is created by inframammary incision and undermining of the breast tissue off the pectoral fascia to mobilize the NAC and underlying tissues (FIG 19).
- For cancers located in the inferolateral or inferomedial quadrants, the keyhole pattern can be rotated slightly to allow for a more lateral or medial excision while at the

A

B

FIG 18 ● **A,B.** Planned incision for a reduction mastopexy, including a keyhole pattern inferiorly and de-epithelialization above the areola.

FIG 19 ● Through the inframammary incision the breast tissue is elevated off the pectoralis fascia to mobilize the NAC and underlying tissues.

FIG 20 ● The resultant cavity after a full-thickness excision of the tumor.

FIG 21 ● A,B. The NAC is recentralized and the medial and lateral flaps are undermined and re-approximated, resulting in the classic inverted T scar.

same time, the NAC is moved in a direction opposite to that of the surgical defect.[12]

- Commencing inferiorly and proceeding superiorly beneath the tumor, full-thickness excision of the lesion is accomplished, with at least a 1-cm macroscopic margin of normal tissue, and the skin overlying the lesion is removed (FIG 20).
- Recentralization of the NAC is performed to recreate a harmonious breast size and shape. The medial and lateral breast flaps are undermined and sutured together to fill the excision defect, leaving a typical inverted T scar (FIG 21A,B).
- Uplifting of the NAC by virtue of removal of the superior skin island helps restore a youthful appearance to the breast but can create mild asymmetry in comparison to the contralateral breast (FIG 22).
- For patients with macromastia, consistent positioning of the breast for radiotherapy may be difficult, resulting in dosing inhomogeneity and suboptimal treatment.[13] These patients can benefit from reduction mastopexy lumpectomy using a unilateral or bilateral approach.

FIG 22 ● The reduction mastopexy can result in asymmetry compared to the contralateral breast that may require a contralateral reduction in the future.

DONUT MASTOPEXY LUMPECTOMY

- The donut mastopexy lumpectomy is best used for segmentally distributed cancers located in the upper or lateral breast to achieve resection of long, narrow segments of breast tissue.
- This technique avoids a visible long radial scar placed against Kraissl's or Langer's lines while allowing for adequate margin resection.
- Two concentric lines are placed around the areola and a periareolar "donut" skin island is excised, with only a periareolar scar visible after this operation (FIG 23).
- De-epithelialization by separating this skin island from the underlying tissues is performed, taking care to avoid full devascularization of the areolar skin.

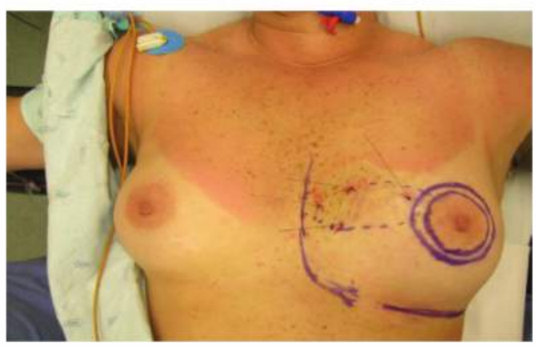

FIG 23 ● Two concentric circles are drawn around the areola, with approximately 1 cm between them.

FIG 24 ● The donut mastopexy incision.

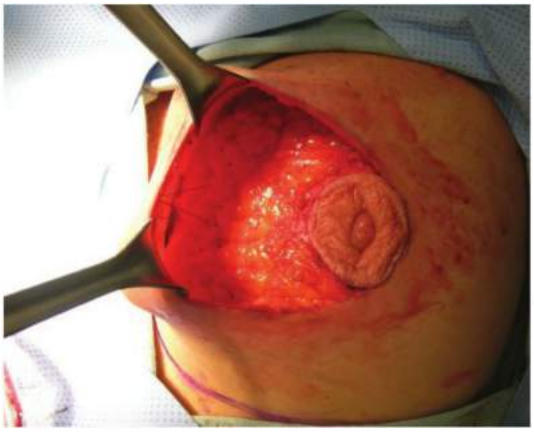

FIG 25 ● A skin flap is developed off of the tumor-bearing quadrant.

- The width of the donut skin island should be approximately 1 cm but is somewhat dependent on the size of areola and expected extent of excision (FIG 24).
- Removal of this tissue ring is required to allow for both adequate access and exposure to the breast tissue and closure of the skin envelope around the remaining fibroglandular tissue that will reduce tissue volume overall.
- A skin envelope is created in all directions around the NAC.
- The quadrant of breast tissue containing the target lesion is fully exposed using the same dissection used for a skin-sparing mastectomy (FIG 25).
- The full-thickness breast gland is then separated from the underlying pectoralis muscle and delivered through the circumareolar incision.
- The tumor-bearing segment of breast tissue is resected in a wedge-shaped fashion (FIG 26), with the width of tissue excision balanced against the difficulty that will be created by virtue of an oversized segmental defect.
- The remaining fibroglandular tissue is returned to the skin envelope; the peripheral apical corners of the fibroglandular tissue are secured to each other and then anchored to chest wall (FIG 27). This anchoring maintains proper orientation of the mobilized fibroglandular tissue within the skin envelope during the initial phases of healing.
- A purse string using absorbable 3-0 suture is placed around the areola opening at a size that reapproximates the original NAC.
- Interrupted inverted 3-0 absorbable sutures are placed subdermally around the NAC, at which time the purse-string suture is tied and then 4-0 subcuticular sutures are used to close the wound (FIG 28).
- Uplifting of the NAC may create mild asymmetry in comparison to the untreated breast, so if desired, a contralateral lift can be performed to achieve symmetry (FIG 29).

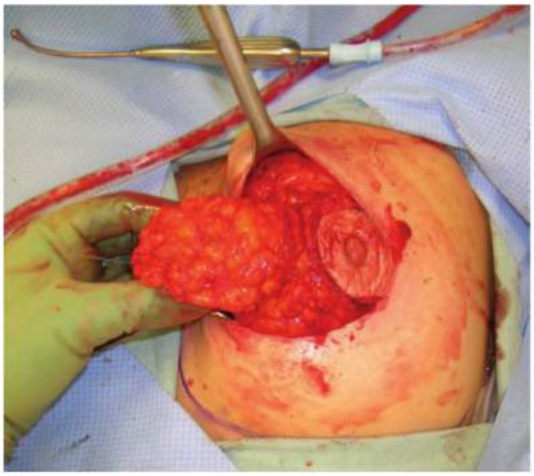

FIG 26 ● A wedge-shaped excision of the tumor-bearing tissue is performed down to the underlying pectoralis muscle.

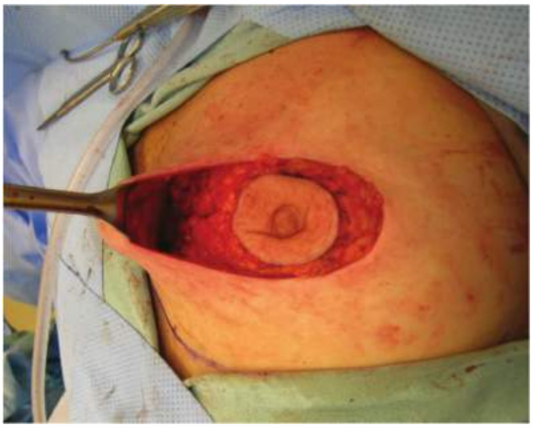

FIG 27 ● The fibroglandular tissue is reapproximated to fill the defect and anchored to the chest wall.

FIG 28 ● The circimareolar incision is closed in standard fashion.

FIG 29 ● As with the reduction mastopexy, the donut mastopexy will result in asymmetry that may require a contralateral lift and/or reduction.

PEARLS AND PITFALLS

Indications	▪ The same contraindications exist as with traditional lumpectomy: ▪ Multicentric disease ▪ Radiation contraindication ▪ Inability to obtain negative surgical margins
Nipple areolar uplifting and asymmetry	▪ May occur with some techniques, namely the batwing, reduction, and donut mastopexy lumpectomies ▪ Contralateral reduction and/or lift may be necessary.
Seroma formation	▪ More common with larger volume resections ▪ Consider small drain placement for a short time period.
Inadequate margins	▪ Will need to be addressed again surgically ▪ With limited involvement, reexcision likely is feasible. ▪ Multiple involved margins may require mastectomy to clear.
Long-term outcomes	▪ Appear to have superior cosmetic results with similar local recurrence rates

POSTOPERATIVE CARE

- Drains are rarely required in standard partial mastectomy cases, as any seroma will generally be reabsorbed.
- With more extensive dissections, such as the donut mastopexy lumpectomy, fluid accumulation can become more pronounced and may require postoperative aspiration on occasion. A 15-Fr round Blake drain left overnight will help avoid excessive fluid accumulation in the dissected breast that might distort the oncoplastic closure.
- Drains are typically removed either prior to discharge if kept overnight or on postoperative day 1 in the clinic.

OUTCOMES

- As with traditional lumpectomy, the main goal of all the oncoplastic approaches remains negative surgical margin resection.
- Excision of calcified lesions, masses, and the intended targeted lesion should be confirmed with specimen radiography during surgery.
- Additional oriented margins can be resected prior to mastopexy closure when the radiograph suggests inadequate resection may have occurred, hopefully eliminating the need for a delayed reexcision.
- Some centers use intraoperative analysis with frozen section or cytology to aid in decisions regarding the resection of additional segments of tissue.
- If subsequent reexcision is needed for inadequate surgical margins following the initial resection, use of the same incision is preferred.
- When the positive margin involves a minority of the specimen, the entire biopsy cavity does not need to be reexcised with only the involved margins of the previous biopsy cavity taken.
- When all the margins of resection are involved, mastectomy may be needed to attain satisfactory surgical clearance. In this instance, it may be technically challenging to include both the initial oncoplastic incision and the NAC in a subsequent total mastectomy and consultation with the plastic surgeon in the event that immediate postmastectomy reconstruction is mandatory.

- Although there are few large volume studies of long-term outcomes specifically addressing oncoplastic approaches in breast conservation, the results that are available are promising. One investigation from Europe followed 148 women for a median of 74 months (range 10 to 108 months) and only 2 were lost to follow-up. Among the remaining 146 individuals, there were only 5 (3%) women who suffered an ipsilateral in-breast cancer recurrence after 5 years and all had either T2 or T3 tumors at presentation.[14]
- Although additional studies are needed, it seems reasonable to presume that oncoplastic approaches, which often results in wider margins of resection than the traditional segmental mastectomy, will continue to be a sound option for breast conservation therapy.

COMPLICATIONS

- When using oncoplastic approaches, surgeons without formal training must determine which procedures they are comfortable performing without plastic surgery consultation or intraoperative collaboration.[3]
- In addition to standard potential postsurgical complications, wound infection, fat necrosis, and delayed healing in the more advanced reduction mastopexy lumpectomy have all been reported with oncoplastic resections.[15]
- The blood supply of the external nipple arises from underlying fibroglandular tissue using major lactiferous sinuses rather than the collateral circulation from surrounding areolar skin, so nipple necrosis may occur if dissection extends high up behind the nipple.[3]

Chapter 7

Brachytherapy Catheter Insertion for Breast Cancer

Peter D. Beitsch

DEFINITION

- Breast conservation therapy (BCT) requires postlumpectomy radiation.
- Radiation can be given to the entire breast as whole breast irradiation (WBI) or to the area at the highest risk of recurrence—the breast tissue surrounding the lumpectomy cavity—by accelerated partial breast irradiation (APBI).
- APBI can be delivered from an external source (3-D conformal) or an internal source (brachytherapy).

DIFFERENTIAL DIAGNOSIS

- Brachytherapy can be delivered via multiple inserted catheters (interstitial multicatheter; **FIG 1**) or via a single insertion/multiple catheter device (**FIGS 2–4**) (see videos 1 and 2 in the accompanying eBook).

FIG 1 ● Multiple catheter interstitial brachytherapy.

FIG 2 ● Strut-adjusted volume implant (SAVI)—single insertion multicatheter strut-based device. ©Cianna Medical, Inc.

FIG 3 ● MammoSite ML—single insertion multicatheter balloon device.

FIG 4 ● Contura—single insertion multicatheter balloon device.

- Radiation oncologists usually perform the multiple catheter insertions and surgeons insert the single insertion/multiple catheter devices (which is the focus of this chapter).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient selection for APBI is critically important (not everyone is a candidate).
- The American Society of Breast Surgeons[1] and the American Brachytherapy Society[2] have published guidelines for patient selection (Table 1).
- The American Society of Radiation Oncology (ASTRO) has published a consensus statement on patient selection for APBI (Table 2).[3]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Controversy exists whether all patients undergoing APBI should get preoperative advanced breast imaging (magnetic resonance imaging [MRI] or positron emission mammography); however, most surgeons only do so selectively.
- Ultrasound skills by the surgeon are helpful for insertion but are not mandatory.

Table 1: Patient Selection Guidelines for Accelerated Partial Breast Irradiation

Criteria	American Brachytherapy Society	American Society of Breast Surgeons
Age	≥50	≥45
Histology	IDC	IDC, DCIS
Tumor size	≤3 cm	≤3 cm
Node status	N0	N0
Margins	Negative	Negative

IDC, invasive ductal carcinoma; DCIS, ductal carcinoma in situ.

Table 2: American Society of Radiation Oncology Consensus Statement on Patient Selection for Accelerated Partial Breast Irradiation

	"Suitable"	"Cautionary"	"Unsuitable"
Definition	*Off clinical trial*	*Limited clinical data*	*Only on trial*
Age	≥60 y	50–59 y	<50 y
T size	≤2 cm	2–3 cm	>3 cm
Nodes	Neg	—	Pos
Histology	IDC	ILC or DCIS	—
Margins	Neg (>2 mm)	Close (<2 mm)	Pos
Path features	No EIC or LVI	EIC or focal LVI	>3 cm EIC/DCIS
Grade	Any	—	—
Multicentricity	Unifocal	—	—
ER status	Pos	Neg	—

IDC, invasive ductal carcinoma; ILC, invasive lobular carcinoma; DCIS, ductal carcinoma in situ; EIC, extensive intraductal component; LVI, lymphovascular invasion; ER, estrogen receptor.

SURGICAL MANAGEMENT

- Brachytherapy devices are routinely placed in the surgeon's office.
- Cavity evaluation devices (CEDs) (**FIG 5**) can be inserted at the time of the lumpectomy as a "space holder" until exchanged in the office for the brachytherapy device.

Preoperative Planning

- Preoperative consultation with the radiation oncologist will be helpful in facilitating postoperative treatment scheduling.
- Postlumpectomy placement in the office begins with the preoperative plan for the lumpectomy including
  - Location of incisions (do not perform sentinel lymph node biopsy through the lumpectomy incision)
  - Use of oncoplastic techniques (minimal flap rearrangement is okay but major flap movement with obliteration of the lumpectomy cavity negates the use of APBI)
  - Thicker wound closure if possible (more tissue between skin and cavity may require skin resection and multilayer closure)

Positioning

- Operative: No changes needed for CED placement.
- Office: Generally, brachytherapy devices are placed from lateral to medial to minimize the nontherapeutic radiation that other parts of the body receive as the brachytherapy seed travels into and out of each of the catheters.

FIG 5 ● Cavity evaluation device.

OPERATIVE PLACEMENT OF A CAVITY EVALUATION DEVICE

First Step

- After lumpectomy but before closure, a small skin nick is made laterally or inferiorly and the CED is tunneled from the skin nick into the lumpectomy cavity (**FIG 6**).

Second Step

- Inflate the balloon with enough saline to fill the cavity (**FIG 7**).

Third Step

- Deflate the balloon and close the lumpectomy wound.

Fourth Step

- Reinflate the balloon and note the volume used. This will assist in choosing the correct size of brachytherapy device to be placed in the office.
  - There is no need to suture the CED to the skin as the inflated balloon will hold it in place.

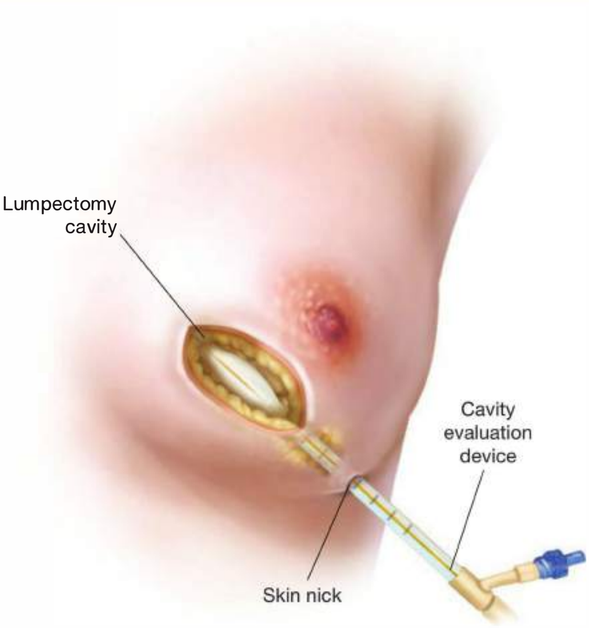

FIG 6 ● Operative placement of CED.

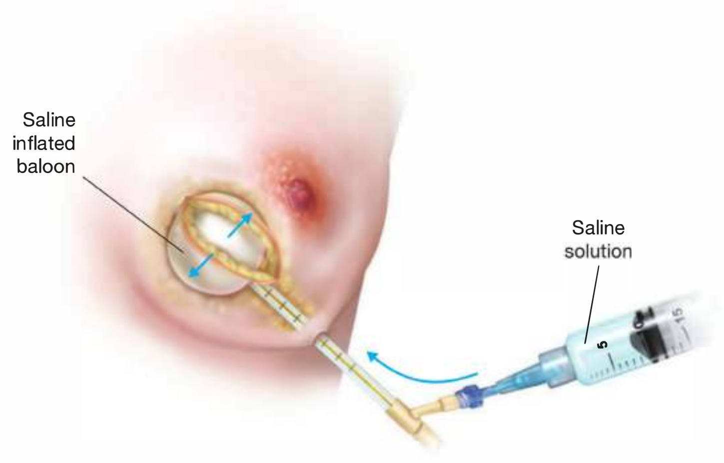

FIG 7 ● Inflating the CED.

OFFICE EXCHANGE OF CAVITY EVALUATION DEVICE FOR BRACHYTHERAPY DEVICE

First Step

- Review the pathology to ensure negative margins and negative sentinel node(s) and confirm with the radiation oncologist that the patient is a candidate for APBI.

Second Step

- Prep and drape the CED and the surrounding breast tissue with Betadine or chlorhexidine and sterile drape or towels (FIG 8).
  - Inject local anesthetic around the skin nick.

Third Step

- Deflate the CED (noting the volume used) and remove it, immediately placing the brachytherapy device through the same track into the lumpectomy cavity (FIG 9).

Fourth Step

- Inflate the balloon with the same amount of saline or expand the struts until they engage the cavity walls.

Fifth Step

- Sterilely dress the entrance site of the device.

FIG 8 ● Prep and drape the CED and surrounding breast.

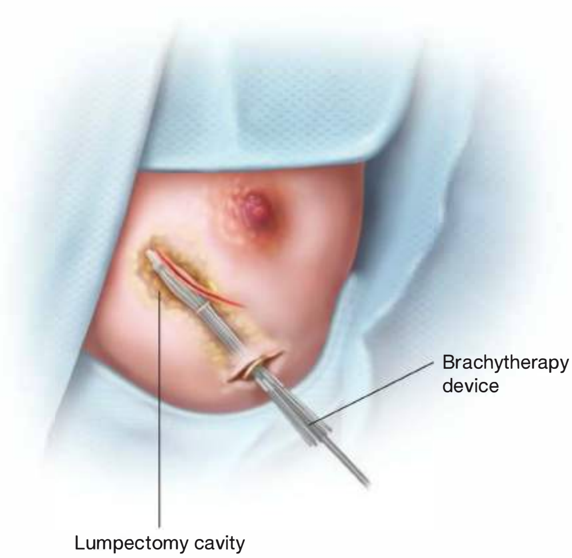

FIG 9 ● Exchange of brachytherapy device for CED through same track without need for ultrasound.

OFFICE PLACEMENT OF BRACHYTHERAPY DEVICE WITH ULTRASOUND GUIDANCE

First Step

- Review the pathology to ensure negative margins and negative sentinel node(s) and confirm with the radiation oncologist that the patient is candidate for APBI.

Second Step

- Examine the lumpectomy cavity with ultrasound to determine the best size of brachytherapy device and the best approach to place the device (**FIG 10**).
  - The approach is particularly important for the strut-based device because it is elliptical and should be placed along the long axis of the lumpectomy cavity (balloon devices will expand and make the lumpectomy cavity conform to the balloon).
  - Plan incision ~2 cm from the edge of the cavity.

Third Step

- Inject local anesthetic into the skin nick site and the track that leads to the lumpectomy cavity (**FIG 11**).

Fourth Step

- Sterilely prep and drape the site and place the ultrasound transducer into a sterile drape onto the field.
  - If a sterile transducer cover is not available, you can clean the transducer with alcohol swab and use sterile gel, but the hand using the ultrasound will no longer be sterile and therefore that hand cannot touch any of the instruments or brachytherapy device.

Fifth Step

- Use a no. 11 blade and make an approximately 12-mm incision (**FIG 12**).

Sixth Step

- The trocar is inserted into the cavity under ultrasound guidance (the lumpectomy seroma may partially evacuate at this time) (**FIG 13A,B**).

FIG 10 ● Ultrasound examination of the lumpectomy cavity.

FIG 11 ● Local anesthetic at the insertion site.

Seventh Step

- Insert the brachytherapy device through the trocar track into the lumpectomy cavity (**FIG 14**).

Eighth Step

- Inflate the balloon until you meet resistance or deploy the struts until they engage the cavity walls (**FIG 15**).

Ninth Step

- Examine the device placement with ultrasound (**FIG 16**).

Tenth Step

- Remove the center stiffener rod and replace with a catheter cap to keep fluid out of the catheter (**FIG 17**).

Eleventh Step

- Sterilely dress the device entrance site (**FIG 18**).

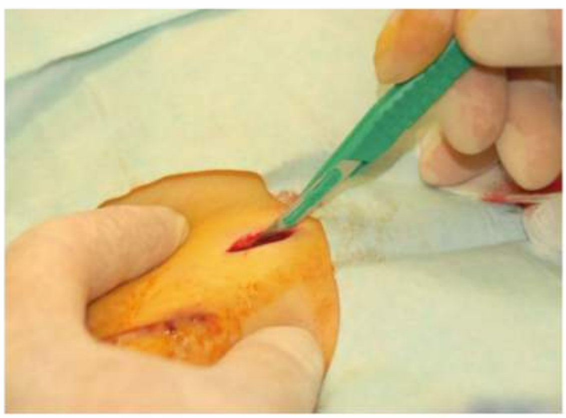

FIG 12 ● Skin incision at insertion site.

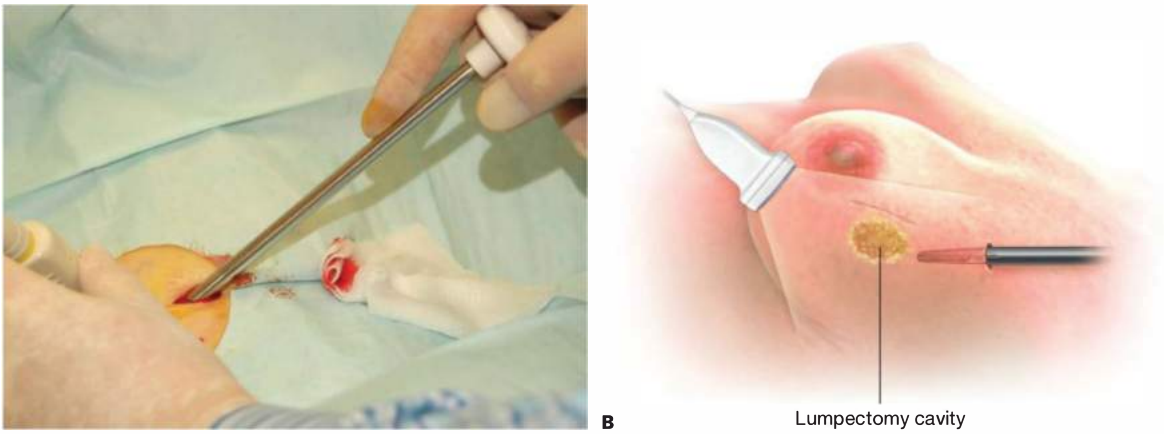

FIG 13 ● **A,B.** Trocar insertion into lumpectomy cavity under ultrasound guidance.

FIG 14 ● Brachytherapy device placement into cavity under ultrasound guidance.

FIG 15 ● Inflating the brachytherapy device balloon.

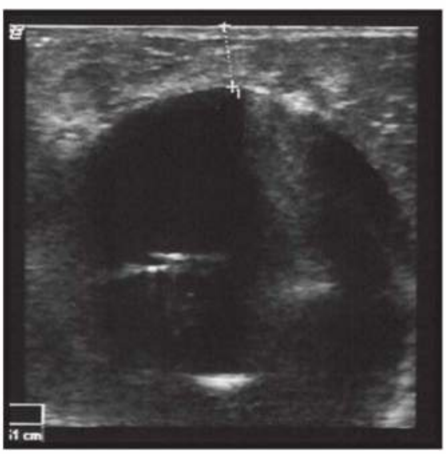

FIG 16 ● Ultrasound examination of the brachytherapy device placement.

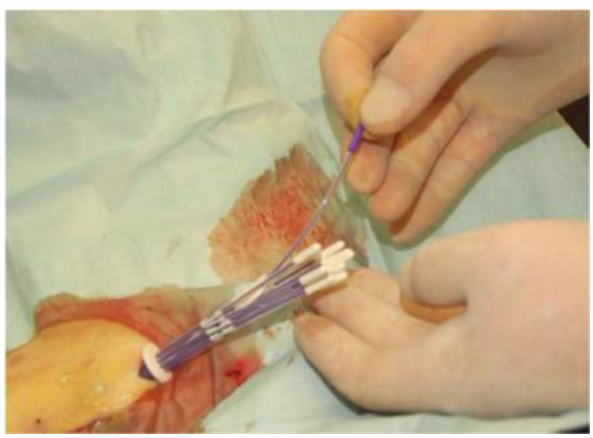

FIG 17 ● Replacing the center catheter cap.

FIG 18 ● Sterile dressing around the brachytherapy device.

PEARLS AND PITFALLS

Poor conformance of balloon device to cavity wall	■ If there is a pocket of fluid or air between the balloon and lumpectomy cavity wall (as seen by ultrasound), gently massage the breast to evacuate the fluid/air.
Drainage through track	■ There is often fluid that will drain out through the track of the CED or device. Warning your patient about this will often save a phone call at bedtime (usually occurs when patient lays down for bed).
Delay in device placement after lumpectomy	■ As the lumpectomy wound heals, the cavity will become fibrotic and eventually obliterates. This can vary between patients, but it is generally best to place the device within 4 weeks of the lumpectomy.
Avoiding radiation recall	■ If the patient is going to be receiving chemotherapy, it is best to wait a minimum of 3 weeks after the last APBI treatment to prevent radiation recall (poorly understood phenomena of noninfectious erythema overlying the lumpectomy cavity).
Minimizing skin radiation	■ Although the newer devices have multiple catheters that allow much better tailoring of the radiation to minimize radiation to normal structures (skin, lungs, ribs, heart, pectoral muscle), it is still best to create as much distance between the skin and the brachytherapy device as possible, so you may need to excise skin overlying the breast cancer and close the cavity in multiple layers.

POSTOPERATIVE CARE

- Postinsertion care includes daily dressing changes, no showering (sponge baths only until device removed).
- Most surgeons place the patient on antibiotics while the device is in.
  - Cephalexin, Bactrim DS, and ciprofloxacin are commonly used.
- Typically, the radiation oncologist will remove the device after the last treatment and Steri-Strip the opening.

OUTCOMES

- APBI has local recurrence rates of 2% to 5% at 5 years—similar to WBI.[4–7]
- Overall survival and breast cancer–specific survival are also equivalent to similarly staged patients who receive WBI.
- True recurrences (tumor bed) are usually treated with mastectomy, but elsewhere, recurrences (presumably new primaries) may be treated with lumpectomy and APBI.

COMPLICATIONS

- Early complications[4]
  - Infections—~9% (no catheter explant due to infection)
  - Seromas—~30%
    - Painful seromas—~13%
- Late complications
  - Cosmesis—excellent/good, 90%; and fair/poor, 10%
  - Fat necrosis—~2%

Chapter 8

Sentinel Lymph Node Biopsy for Breast Cancer

Anees B. Chagpar

DEFINITION

- Sentinel node biopsy is a minimally invasive means to accurately stage the axilla in breast cancer patients.

PATIENT HISTORY AND PHYSICAL FINDINGS

- As always, a complete history and physical exam is warranted. If the patient has obvious clinically enlarged axillary lymph nodes on physical exam, ultrasound, and/or fine needle aspiration (FNA) or core needle biopsy may provide diagnostic information. If the biopsied node is positive, one could proceed to neoadjuvant chemotherapy and/or axillary dissection if primary surgery is planned. Alternatively, if the biopsied node is negative, sentinel node biopsy is still indicated for definitive evaluation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Lymphoscintigraphy is commonly performed in conjunction with sentinel lymph node (SLN) biopsy for breast cancer, although it is not absolutely necessary.[1] Depending on how the radionucleotide tracer is injected, lymphoscintigraphy may show drainage to the internal mammary nodes (see Part 5, Chapter 9). If patients have had previous sentinel node biopsy and/or axillary node dissection, repeat sentinel node biopsy may be considered for staging ipsilateral recurrent or new primary disease. In this circumstance, alternative drainage patterns are possible, and therefore, preoperative lymphoscintigraphy may be useful.[2]

SURGICAL MANAGEMENT

- Sentinel node biopsy is indicated for staging of patients with invasive breast cancer or those with ductal carcinoma in situ undergoing mastectomy.

Preoperative Planning

- Timing of sentinel node biopsy vis-à-vis neoadjuvant chemotherapy is controversial; some opt to perform this procedure prior to initiation of neoadjuvant chemotherapy so as to most accurately stage the axilla, whereas others will do a sentinel node biopsy after completion of neoadjuvant chemotherapy so as to potentially spare patients who have had a pathologic complete response to the morbidity of a complete axillary dissection.

Positioning

- Patients are positioned supine. A roll may be placed under the ipsilateral shoulder so as to elevate the latissimus dorsi muscle. Care should be exercised to ensure that the arm is supported on folded sheets so as to avoid a brachial plexus stretch injury (**FIG 1**).
- Intravenous lines, pulse oximeter devices, and blood pressure cuffs should be placed on other extremities if possible.

FIG 1 • Patient positioned with roll under ipsilateral latissimus and folded sheets to support arm.

TECHNIQUES

INJECTION OF RADIOACTIVE TRACER AND/OR BLUE DYE

- Use of dual tracer has been shown to be associated with higher identification and lower false-negative rates[3]; however, particularly in patients undergoing skin-sparing mastectomy, surgeons may wish to forego blue dye, as the dye may discolor the skin and make it more difficult to evaluate for skin ischemia or necrosis.
  - In general, the radioactive tracer used is technetium Tc 99m sulfur colloid. For patients not undergoing lymphoscintigraphy, the tracer can be injected in the preoperative holding area. However, injection of this material is painful, and adequate counts can often be obtained with intradermal injection after induction of anesthesia. The radiotracer can be injected peritumoral, intradermal (in the skin over the location of the cancer), or periareolar (four intradermal injections around the areola). If injection is done on the same day as the operative procedure, a dose of 0.5 mCi is adequate. If injection is done the day prior to surgery, 2.5 mCi should be used.
- Both isosulfan and methylene blue dye have been used for SLN biopsy; they vary in their color, complication profile, and cost. Isosulfan blue is a more azure blue (which is easier to distinguish from venous structures) but is associated with less than 1% risk of anaphylaxis[4] and is significantly more costly than methylene blue. Methylene blue is darker, associated with a higher rate of skin necrosis, but is far cheaper.[5]

In general, 5 mL of these tracers are used; if methylene blue is chosen, it should be diluted 1:2 with saline.

- Blue dye may be injected peritumoral or using a subareolar approach. The latter allows for lymphatic mapping of multiple tumors and those which are not easily identifiable[6] (**FIG 2**). For patients undergoing breast conservation, the subareolar approach may leave the patient with a "blue breast" for some time.

FIG 2 ● Subareolar injection of blue dye.

PREPPING AND DRAPING

- The arm is prepped circumferentially along with the breast. The arm is draped into the field and kept free such that the surgeon may move the arm in a sterile fashion during the case (**FIG 3**).

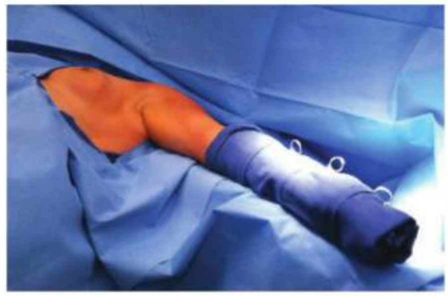

FIG 3 ● Patient draped with breast and axilla in the field; the ipsilateral arm is draped in the sterile field.

INCISION

- Identification of the area of maximal radioactivity in the axilla using a handheld gamma probe allows one to position the incision over the sentinel node.
- Landmarks of the pectoralis and latissimus dorsi muscle are used to fashion an incision for an axillary dissection of which the sentinel node incision would be a segment (**FIG 4**). A lazy S incision will allow for optimal cosmesis and will allow for extension superiorly and inferiorly if needed for maximal visualization. Alternatively, if a conventional mastectomy is planned, the sentinel node biopsy can often be performed through the lateral aspect of the same incision.
- Local anaesthetic may be used for preemptive analgesia. The incision is taken down through skin, subcutaneous tissue, and clavipectoral fascia.

FIG 4 ● Incision planning. The pectoralis and latissimus dorsi muscle borders are identified. An "X" marks the area of maximal radioactivity. A lazy S incision is fashioned for a potential axillary dissection going through the X. A smaller segment (marked by the crosshatch lines) delineates the incision for the sentinel node biopsy.

IDENTIFICATION OF SENTINEL NODES

- Care is taken to remove the hottest node, and any node with radioactive counts greater than 10% of the ex vivo counts of the hottest node. In addition, all blue nodes and those at the end of a blue lymphatic channel are also removed (**FIG 5**).
- Palpation is critical to identify any clinically suspicious lymph nodes; these should also be removed regardless of whether they are blue or hot, as tracers may not have travelled to positive lymph nodes if lymphatics are obstructed with tumor.
- Although some have argued that the procedure can be terminated after three SLNs have been removed,[7] others have argued that all nodes that fit the earlier mentioned criteria be removed.[8] On average, however, two sentinel nodes are identified.

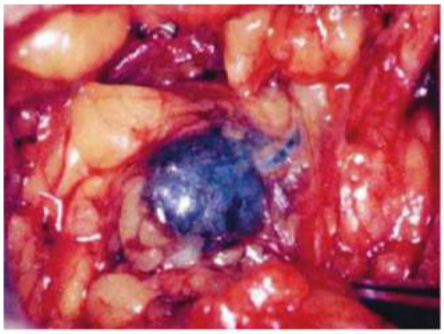

FIG 5 ● Blue SLN at the end of a blue lymphatic channel.

INTRAOPERATIVE EVALUATION

- Intraoperative evaluation with either touch preparation cytology or frozen section has been found to have a high specificity and fairly high sensitivity (**FIG 6**).
- Some surgeons may opt to forego intraoperative evaluation if they do not intend to complete the axillary node dissection at the same operative setting given the findings of the sentinel node biopsy. For patients who fit the American College of Surgeons Oncology Group Z0011 criteria, completion axillary node dissection may be avoided if only one to two sentinel nodes are positive and whole breast irradiation after partial mastectomy is planned.[9]

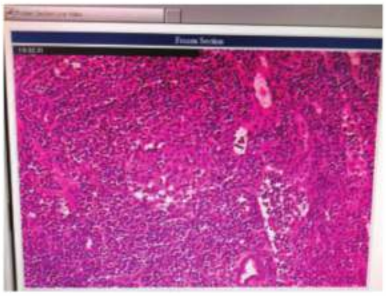

FIG 6 ● Intraoperative frozen section results.

CLOSURE

- In general, if axillary node dissection is not performed, no drains are required. The incision is closed in standard fashion with subdermal and subcuticular sutures followed by Steri-Strips. If, however, an axillary dissection is indicated, the incision can be extended (as planned in the earlier discussion).

POSTOPERATIVE CARE

- After sentinel node biopsy alone (i.e., without axillary dissection), patients can go back to usual activities. No special exercises are required nor is there any need for lymphedema compression garments.

OUTCOMES

- Outcomes after sentinel node biopsy alone are outstanding, with no detriment in survival or local recurrence. Morbidity is low, especially compared to axillary dissection.

COMPLICATIONS

- Bleeding/hematoma
- Infection
- Seroma
- Numbness/paresthesia
- Lymphedema
- Allergic reaction to isosulfan blue dye
- "Blue breast" from blue dye injection
- Skin or fat necrosis from methylene blue dye

Chapter 9

Internal Mammary Sentinel Node Biopsy

A. Marilyn Leitch

DEFINITION

- Internal mammary node dissection is performed for both diagnostic and therapeutic purposes. This surgery is generally performed in conjunction with breast cancer surgery as part of nodal staging. In modern times, this usually involves removal of lymph nodes from one or two parasternal interspaces as part of a sentinel node staging procedure. In the first descriptions of internal mammary node dissection, the entire internal mammary nodal chain was resected including the adjacent ribs.[1] With the advent of sentinel lymph node mapping, it is possible to perform a more minimally invasive procedure to resect in a directed fashion internal mammary nodes that are demonstrated to have lymphatic drainage from the breast. Internal mammary sentinel node drainage is identified on lymphoscintigraphy in 10% to 22% of mapping studies. Internal mammary drainage is more likely to be identified if the radionucleotide is injected in the peritumoral region rather than subareolar. The technique described here to retrieve sentinel nodes can also be used to surgically biopsy small suspicious internal mammary nodes identified on preoperative imaging with computed tomography (CT) scan or breast magnetic resonance imaging (MRI).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The breast cancer patient should have a careful evaluation with a complete history and physical examination as well as appropriate imaging studies. The patient's history should focus on specific breast complaints including how long the patient has been aware of the cancer in her breast, associated symptoms and signs, and focal chest wall pain. It is important to ascertain the patient's medical history to assess the patient's risk for surgery related to intercurrent medical conditions. Prior surgery such as sternotomy, coronary artery bypass graft, thoracotomy, and breast augmentation should be noted, as these may complicate the performance of internal mammary node dissection. Past history should include annotations about prior radiation to the chest wall such as mantle radiation for Hodgkin's disease. The patient should be queried about prior trauma to the anterior chest wall.
- Physical examination includes the full examination of the breast to document any palpable mass lesion, including the size and location with respect to the quadrant of the breast and its distance from the nipple. The nodal basin should be carefully examined including the cervical, supraclavicular, axillary basins, as well as the palpation of the parasternal region. If there are any evident abnormal nodes, these should be further evaluated with imaging including mammography and ultrasound. Needle biopsy of suspicious nodes can be undertaken preoperatively in order to plan the therapeutic intervention.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The standard imaging workup for a newly diagnosed breast cancer patient would include mammography and ultrasound of the breasts. Many patients will have an MRI performed as well. This study permits visualization of the internal mammary nodal chain. If an abnormal lymph node is identified, it can be biopsied with a needle or targeted for excision at the time of surgery (**FIG 1A,B**).
- CT scanning of the chest is not routine for the workup of that early-stage breast cancer. However, if a CT scan of the chest or positron emission tomography (PET)-CT is performed for other indications, internal mammary node enlargement may be identified (**FIG 2A,B**). If the patient has palpable fullness in the parasternal region, a CT scan should be ordered to evaluate for internal mammary nodal metastases.
- In order to identify the internal mammary nodal drainage in the sentinel node procedure, it is critical to inject a radiolabeled tracer for mapping of the pathways to the internal mammary nodes. To maximize the chance of identifying internal mammary lymphatic drainage, it is important to perform the injections of technetium sulfur colloid in the peritumoral region rather than performing a subareolar injection only. Lymphoscintigraphy can be performed to have a visual representation of the location of the internal mammary drainage (**FIG 3A–D**). The area of radioactivity in the parasternal region can be marked on the skin by the nuclear medicine technician at the time of scanning (**FIG 4A,B**). This increases the efficiency of identifying the appropriate interspace for exploration for the sentinel node. Most commonly, there will be one interspace that demonstrates a hot spot. However, more than one interspace may demonstrate a radioactive focus. The most common areas of drainage are the 2nd and 3rd interspaces.

SURGICAL MANAGEMENT

Preoperative Planning

- The lymphoscintigraphy should be reviewed prior to going into the operating room. It is important to consent the patient specifically for the internal mammary exploration. Knowing from the lymphoscintigraphy that there is internal mammary lymphatic drainage, the surgeon can convey to the patient that this pathway can be pursued if the patient is agreeable. If it is the practice of the surgeon not to perform lymphoscintigraphy prior to surgery, then the interspaces can be examined intraoperatively with the gamma probe to identify foci of increased radioactivity in the parasternal interspaces. It remains important to consent the patient for the possibility of an internal mammary exploration with its potential complications.

Positioning

- The patient is positioned supine with the arms abducted to 90 degrees on padded arm boards. The skin prep of the chest wall should cross to the contralateral breast so that the sternum and parasternal regions are draped into the field of operation.

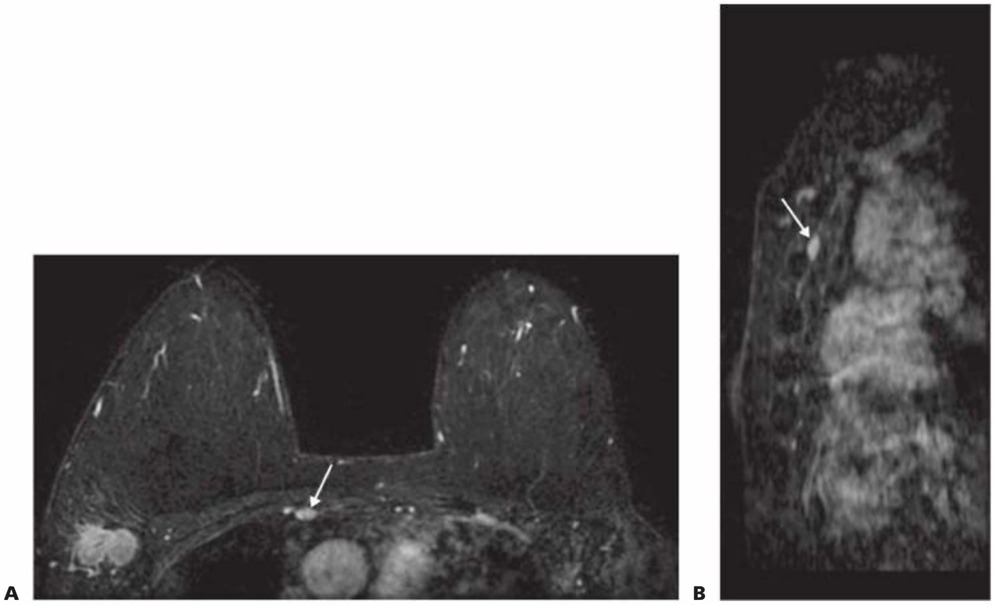

FIG 1 ● **A.** Abnormal right internal mammary lymph node and right axillary lymphadenopathy seen on breast MRI axial T1 postcontrast subtraction series. **B.** Breast MRI. Sagittal T1 reconstruction demonstrating the abnormal internal mammary node. (Courtesy of Stephen Seiler, MD, University of Texas Southwestern Medical Center.)

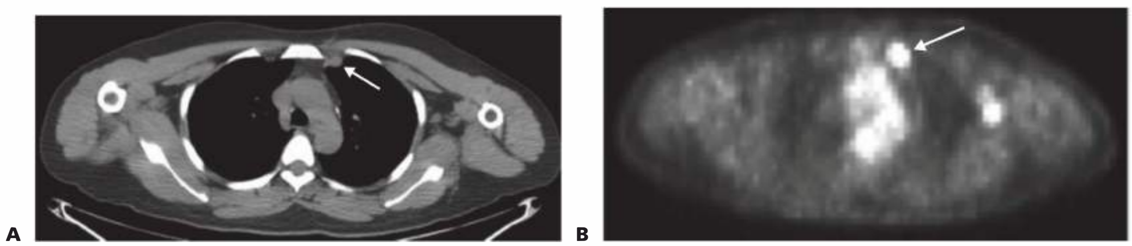

FIG 2 ● **A.** Chest CT scan demonstrating enlarged left internal mammary node. **B.** PET scan image shows fluorodeoxyglucose (FDG) uptake in the left internal mammary node. (Courtesy of Stephen Seiler, MD, University of Texas Southwestern Medical Center.)

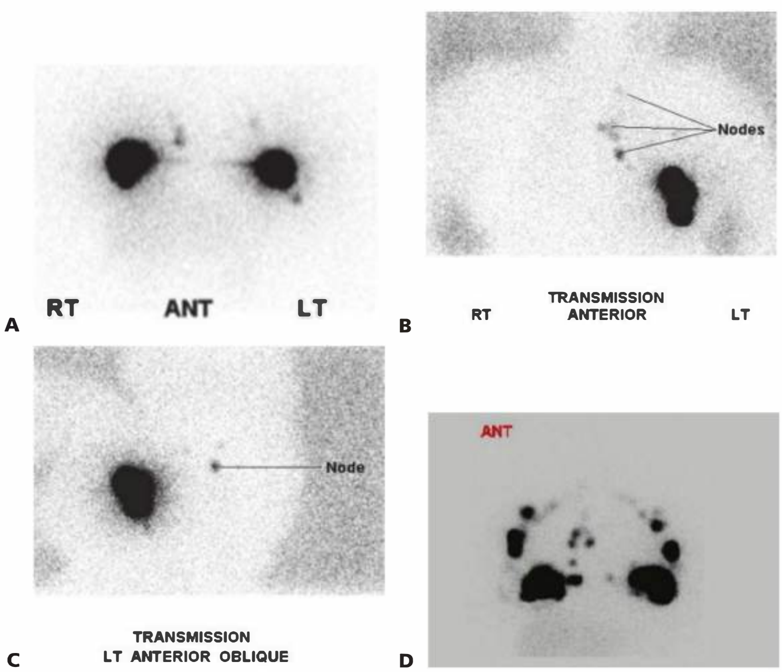

FIG 3 ● **A.** Lymphoscintigraphy of bilateral breasts demonstrating internal mammary nodal drainage on the right in the anterior projection. **B.** Anterior projection of lymphoscintigraphy showing radioactive uptake in two interspaces with faint uptake base of neck. In this view, the axillary node is faint. **C.** Left anterior oblique projection shows the axillary uptake more intensely. **D.** Lymphoscintigraphy (anterior projections) with lymphatic drainage to multiple internal mammary nodes.

TECHNIQUES

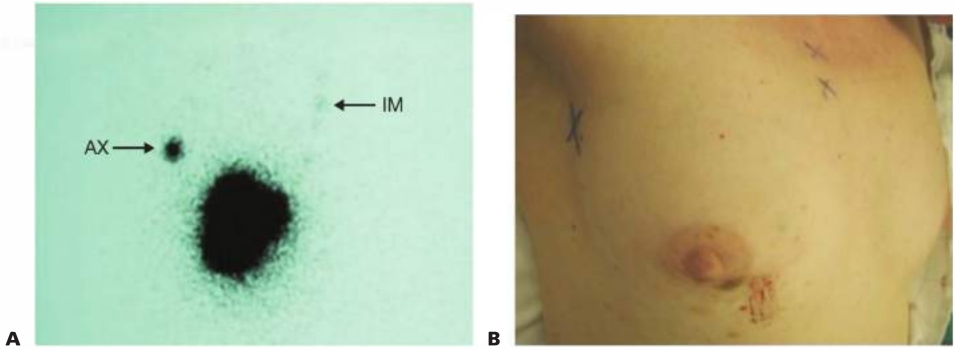

FIG 4 ● **A.** Lymphoscintigraphy demonstrating intense radioactivity in the right axillary node basin and very faint radioactivity in the internal mammary basin. **B.** Note "X" marks placed by the nuclear medicine technician to guide gamma probe examination.

INCISION AND INITIAL IDENTIFICATION OF AREA OF INTERNAL MAMMARY SENTINEL NODE

- Placement of the incision is governed by the procedure planned for resection of the breast tumor. For patients having breast-conserving surgery, the incision for the primary tumor is placed overlying the primary lesion. If the primary lesion is near to the area of internal mammary drainage, then it may be feasible to explore the interspaces via the partial mastectomy incision. However, if the primary lesion is distant from the parasternal region, then the incision for exploration of the interspace is placed overlying the area of focal radioactivity.
- If the patient is undergoing a mastectomy, the standard mastectomy incision is used for accessing the parasternal interspaces (FIG 5). When reconstruction is planned, the mastectomy incision is generally more limited with the skin-sparing technique. However, the parasternal region can be generally accessed via these incisions with retraction of skin flaps, unless there is nipple preservation with the incision placed in the inframammary line. In this circumstance, the incision location would be determined in a similar fashion as patients having breast-conserving surgery.
- It is much easier to identify the area of focal radioactivity in the interspaces after the breast is removed or after the partial mastectomy is completed. This reduces the amount of background radioactivity, which increases the ease of identifying radioactivity in an internal mammary node. In order to find an internal mammary sentinel node, it is imperative to have a strong signal that can be picked up by the gamma probe to direct the incision placement.
- Lymphazurin blue, which is often injected for identification of the sentinel nodes in the axilla, should be injected prior to beginning any resective procedure in the operating room. Lymphazurin blue alone will not be successful in identifying the internal mammary sentinel nodes. However, once the area of radioactivity is identified and exploration is begun, blue lymphatics or staining of the sentinel nodes may be identified but not with the frequency that it is seen in the axillary nodes. As with the radioactive tracer, the blue dye is more likely to be identified in the internal mammary nodes if the injection is peritumoral.
- After the blue dye is injected, the axillary sentinel node exploration is then begun. (Refer to Part 5, Chapter 8 for more information on sentinel node dissection.) In most cases, there will be an axillary sentinel node identified in those patients who also have internal mammary drainage.
- The mastectomy or partial mastectomy is then performed.

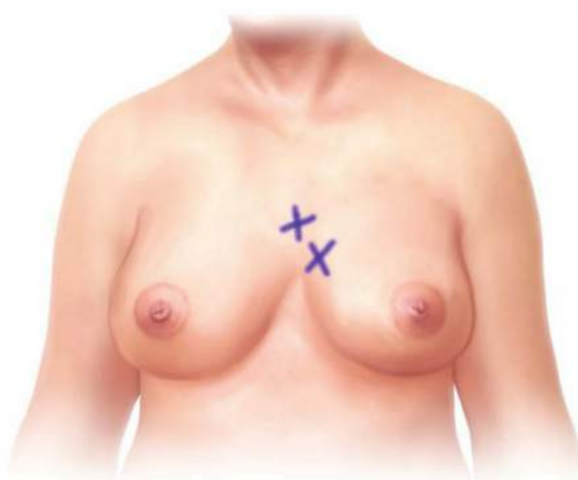

FIG 5 ● Skin sparing mastectomy incision with edge retracted to expose parasternal interspace.

EXPLORATION OF THE PARASTERNAL INTERSPACES

- Using the gamma probe, the **parasternal interspaces** are examined in sequence from superior to inferior. In patients having a standard or skin-sparing mastectomy incision, the skin edges can be retracted with a Richardson retractor or with Lone Star hooks, which can obviate the need for an assistant to retract. With the pectoralis muscle exposed, the gamma probe is then placed directly on the muscle after palpating the interspace. When an area of focal radioactivity is identified, counts are taken for 10 seconds, two or three times with a background taken a centimeter away to confirm that it is a focal hot spot. Counts are taken at each interspace.
- For the partial mastectomy patients, the initial examination with a gamma probe may have to be done through the skin overlying the interspaces if the partial mastectomy incision is away from this area. Because the skin surface is farther from the node, it can be more technically difficult to identify the hot spot. Each interspace is examined and counts taken as described for the mastectomy. When the focal hot spot is identified, the incision is made overlying the interspace along the axis of the ribs (**FIG 6**). The incision is carried through the skin, the subcutaneous tissue, and any underlying breast tissue down to the pectoralis muscle. A self-retaining retractor is placed to expose the pectoralis muscle widely. Lone Star hook retractors may be used if the thickness of the tissue in this portion of the breast is thin.

A B

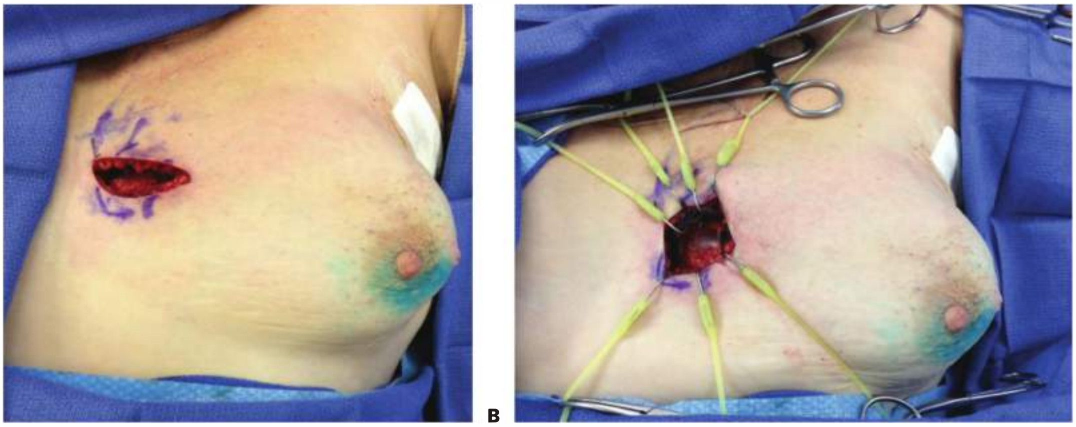

FIG 6 ● **A.** Parasternal incision in conserved breast with exposure of pectoralis muscle. **B.** Lone Star hook retractors placed to retract skin to expose muscle.

DISSECTION THROUGH THE CHEST WALL

- Once the pectoralis major muscle is exposed overlying the radioactive interspace, the fibers of the pectoralis muscle are split along their axis. A small self-retaining retractor or Lone Star hooks are placed to hold the fibers apart (**FIG 7**). Examination is performed again with the gamma probe to confirm that the radioactivity is persistent deep to the pectoralis muscle (**FIG 8**). If there is persistent radioactivity, then the intercostal muscles are incised with electrocautery over a 3- to 4-cm length extending from the sternal edge laterally (**FIG 9A**).

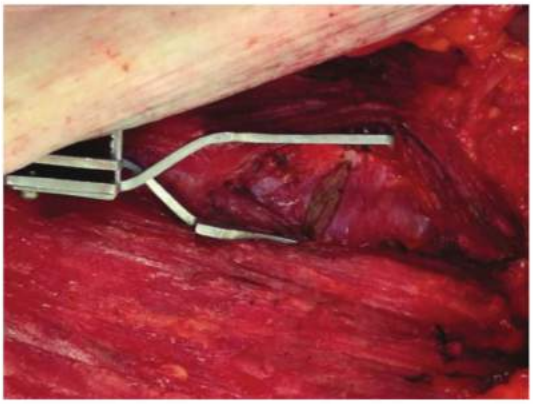

FIG 7 ● Pectoralis muscle fibers split and retracted to expose intercostal muscle.

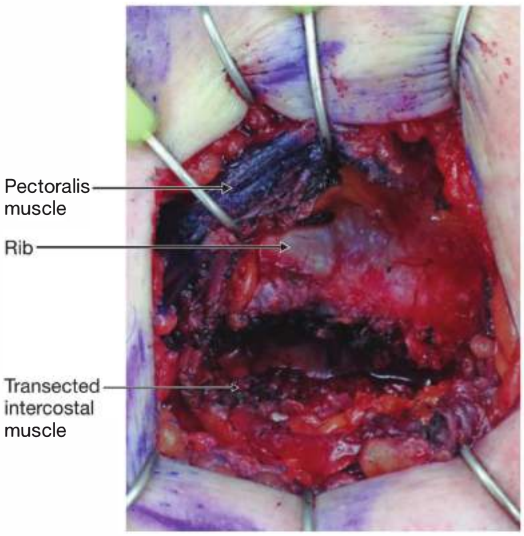
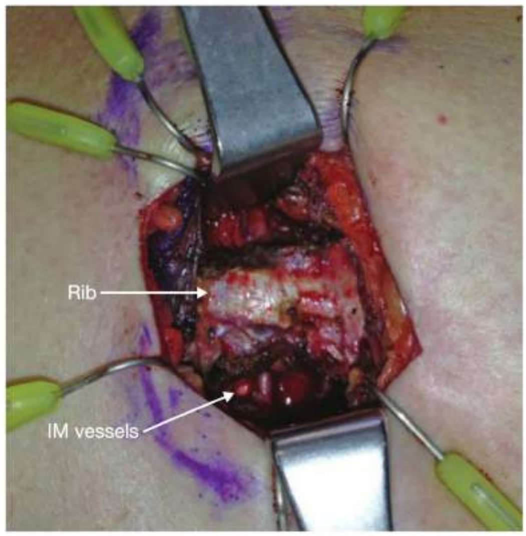
FIG 8 ● Examination is performed again with the gamma probe to confirm that the radioactivity is persistent deep to the pectoralis muscle.



A



B

FIG 9 ● Exposure of intercostal space in breast conserving surgery with intercostal muscle divided **(A)**. Two interspaces exposed by dividing intercostal muscle above and below the rib via this limited incision. The internal mammary vessels are medially located in the interspace **(B)**.

DISSECTING IN THE INTERSPACE TO RETRIEVE THE SENTINEL NODE

- A thin, filmy fascia is incised deep to the intercostal muscles to expose a thin plaque of fatty tissue that lies just anterior to the pleura. Again, the gamma probe is used to localize the node that will be in fatty tissue deep to the intercostal muscles. The internal mammary vessels are most medial in the interspace (FIG 10)
- The sentinel nodes are often quite small and are yellow to yellow tan in color. Thus, their identification may be somewhat tedious. Frequent use of the gamma probe helps to direct the dissection. Fine instruments are used to tease out the fat around the nodal tissue. A small Kittner may be used to gently tease away the fatty tissue to expose the nodes. Small titanium clips can be used to ligate fine capillaries. It is critical to avoid any bleeding, which can obscure the small operative field. The lymph nodes may be intimately related with the internal mammary vessels, so any branches must be securely ligated in dissecting the node away from these vessels. The pleura will be exposed as the fatty tissue is teased away with the movement of the lung visible through the thin pleura (FIG 11).
- When the node is removed, gamma counts are taken of the node to confirm its radioactivity (FIG 12). The interspace is again examined with the gamma probe to confirm there is no residual radioactivity. If there is residual activity, further exploration is done to identify any other sentinel nodes in the interspace.

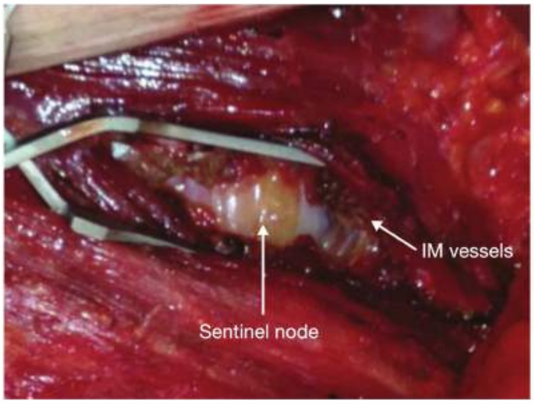


FIG 10 ● Right mastectomy procedure with exposure of interspace showing internal mammary vessels medially and yellow sentinel node lateral to vessels.

FIG 11 ● Mastectomy site with pectoralis muscle retracted and pleura visible after removal of sentinel node.

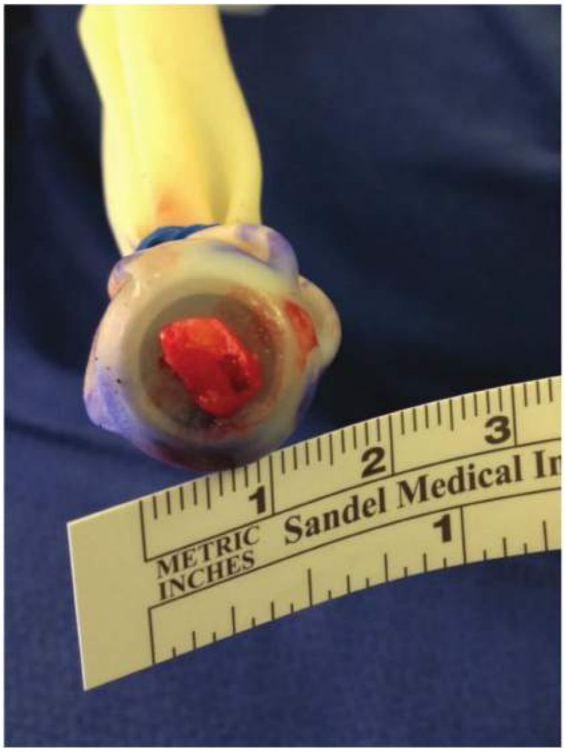

FIG 12 ● Internal mammary node ex vivo on gamma probe to confirm radioactivity in resected specimen.

EXAMINATION OF THE INTERSPACE FOR A PLEURAL TEAR

- The wound is irrigated to clear all blood and loose fat tissue that may obscure the field. Then, irrigation fluid is instilled and left to pool in the interspace. The anesthesiologist can then deliver a sustained breath into the endotracheal tube. The interspace is observed for air bubbles. If air bubbles are seen, a pleural tear can be assumed.
- One can aspirate the fluid and look for the tear. If the tear can be identified, it can be repaired with a 5-0 suture. This is more important if the tear is large. A small red rubber catheter can be put in the opening with repair performed up to it. Prior to tying the suture, the tube can be aspirated with the anesthesiologist giving a sustained breath to the patient to inflate the lung. The tube is removed and the suture tied down.
- If the tear if quite small, attempting repair may enlarge the hole. Fluid can be placed in the interspace and wound closure begun with the anesthesiologist maintaining lung inflation.

WOUND CLOSURE

- The intercostal muscles cannot be reliably closed, as the sutures tear through the muscle.
- Close the posterior fascia of the pectoralis muscle in a running fashion with 3-0 Vicryl suture.
- Then, close the anterior pectoralis muscle or muscle fascia, if present, with a running 3-0 suture (**FIG 13**).
- With mastectomy, a drain is placed overlying the chest wall in the usual fashion. Closed suction bulb is attached. Skin closure is then performed. The dermis is closed with interrupted 3-0 or 4-0 absorbable suture. The skin is closed with a running monofilament absorbable suture.
- Wound closure in the partial mastectomy circumstance should include closure of the divided breast tissue anterior to the interspace to avoid a soft tissue defect over the interspace. This is performed with either a running or an interrupted 3-0 absorbable suture. The dermis and subcutaneous tissue is closed with interrupted 3-0 or 4-0 absorbable suture. The skin is closed with a running monofilament absorbable suture.

FIG 13 ● Closure of the anterior pectoralis muscle or muscle fascia, if present, with a running 3-0 suture.

PEARLS AND PITFALLS

Preoperative planning	■ The injections of the radionuclide for lymphatic mapping should be performed in the peritumoral region rather than subareolar alone in order to identify the lymphatic pathways to the internal mammary nodes.
Placement of incision and exposure	■ Making exposure easier—If free flap breast reconstruction is being done with anastomosis of vessels to the internal mammary vessels, wait to remove the internal mammary sentinel node until the vessel exposure is done with removal of the costochondral cartilage which gives much wider exposure (**FIG 14**). If the patient has breast implants, prepectoral, or subpectoral, be certain that the implant is well retracted from the interspace to permit adequate exposure but also to avoid implant injury. There will be a fibrous capsule to be dissected through to get to the intercostal muscle.  **FIG 14** ● Removal of the costochondral cartilage.
Exploration of the parasternal interspaces	■ Performing examination with the gamma probe after the breast or breast lesion is removed will make identification of the area of radioactivity in the internal mammary nodal chain easier, because of reduction of background radioactivity.
Dissection through the chest wall	■ Reexamine with the gamma probe at each layer through the chest wall to be certain there is persistent radioactivity in the next layer. There can be an intramammary node medially that picks up radioactivity or background radioactivity may have complicated the exam.
Dissecting in the interspace	■ Avoid excessive bleeding. Dissection must be careful and deliberate with securing of even very small vessels. An obscured field will increase chance of pleural tears or more major vasculature injury. When biopsy is being performed for an abnormal internal mammary node identified on preoperative imaging, it may be necessary to remove the costochondral cartilage to expose and successfully remove the enlarged node.
Closure	■ Know when to stop. When performing the surgery for staging, do not risk major vasculature injury if you are not able to find the node with usual maneuvers. Place a titanium clip to mark the area of increased radioactivity, which can inform radiation planning.

POSTOPERATIVE CARE

- In the recovery room, a chest x-ray should be performed if a pleural tear occurred to be certain there is no significant pneumothorax.
- If the surgeon is early in experience, a chest x-ray may be done as routine postoperatively.
- A small pneumothorax will generally not require therapy, as there is no intrinsic lung injury with ongoing air leak.
- If there is a large pneumothorax causing symptoms, then a chest tube can be placed, which can usually be removed in 1 to 2 days.
- Usual postoperative pain management is acceptable for these patients. They generally do not complain of focal pain in the area of the internal mammary node resection.
- Patients having breast-conserving surgery can be discharged home on the same day if there is no pneumothorax.

OUTCOMES

- Success in identification of the internal mammary sentinel node at surgery varies from 70% to 100%.[2]
- Complications from internal mammary node biopsy are rare, ranging from 0% to 5%. Even when a pleural injury occurs, chest tube drainage is rarely required.
- Recovery from this procedure is similar to that of the mastectomy or breast-conserving surgery performed at the same time.
- Patients who undergo lymphoscintigraphy and biopsy of internal mammary nodes that demonstrate lymphatic drainage have more accurate staging of their breast cancer, which can result in treatment changes. The rate of internal mammary sentinel node positivity ranges from 10% to 24%. Among five series of internal mammary sentinel node biopsy, in approximately 37% of cases, the internal mammary sentinel node was positive when the axillary sentinel node was negative.[3–7]
- The 10-year survival for patients who are internal mammary node positive and axillary node negative is similar to those who are axillary node positive alone as reported by Veronesi and colleagues.[8] In this study, patients with either axillary or internal mammary node metastasis only had a 10-year survival of approximately 54% compared to 30% if both internal mammary and axillary nodes were positive.[8] This indicates the equivalent significance of knowing the internal mammary nodal status as well as the axillary, if there is lymphatic drainage to the internal mammary nodal basin. In a modern series, patients with internal mammary nodal metastases had an overall survival of 97% at 5 years with multimodality therapy.[9]

COMPLICATIONS

- Pleural injury with or without pneumothorax
- Bleeding from injury to internal mammary vessels

Chapter 10 Simple Mastectomy

Michael S. Sabel   Lisa Newman

DEFINITION

- A simple mastectomy, also commonly referred to as a total mastectomy, is the surgical removal of all breast tissue, including the nipple–areolar complex and enough overlying skin to allow closure. A simple mastectomy does not include removal of the axillary contents; when the breast tissue and axillary lymph nodes are removed en bloc, this is referred to as a modified radical mastectomy (MRM) (see Part 5, Chapter 12). Variations of the simple mastectomy, typically performed in concert with immediate reconstruction include the "skin-sparing mastectomy," where the nipple–areolar complex is removed but the overlying skin is preserved; and the "nipple–areolar sparing mastectomy," where the native skin and nipple–areolar complex are preserved. These are described in Part 5, Chapter 11.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In clinically early-stage breast cancer, survival is largely driven by risk of distant organ micrometastatic disease and ability to control/eliminate this aspect of the cancer with adjuvant systemic therapy. Locoregional manifestations of disease in the breast and axilla can usually be controlled with surgery and radiation. Multiple prospective, randomized clinical trials have therefore documented survival equivalence between breast-conserving and mastectomy surgery for invasive breast cancer as well as for ductal carcinoma in situ (DCIS). Lumpectomy for a diagnosis of breast cancer is usually followed by breast radiation to sterilize microscopic/occult foci of disease in the remaining breast tissue, thereby reducing the incidence of ipsilateral breast tumor recurrence. Many women will nonetheless undergo total mastectomy as the primary breast surgical option either because of personal preference, medical contraindication to breast radiation, or because of disease features suggesting inability to achieve a margin-negative lumpectomy with a cosmetically acceptable result (e.g., diffuse suspicious-appearing microcalcifications on mammogram, multiple breast tumors not amenable to resection within a single lumpectomy, unfavorable tumor-to-breast size ratio). It is important for the clinician to remember that aesthetic acceptability must be defined by the patient. Total mastectomy is also the conventionally accepted surgical approach for breast cancer prophylaxis in high-risk women such as those with hereditary susceptibility.
- A detailed history and physical examination is imperative on the first consultation with these patients. In addition to the details of their breast cancer diagnosis, the history should cover medical comorbidities, medications, surgeries, allergies, and also any musculoskeletal issues, which could affect operative positioning and/or radiation treatment planning. Prior chest wall irradiation (such as for Hodgkin's lymphoma or as part of breast-conserving treatment for a past ipsilateral breast cancer) is a contraindication to reirradiation and breast conservation for a new or recurrent breast cancer. Connective tissue disorders such as Sjögren's syndrome or scleroderma can result in severe radiation-related toxicity and patients with these medical conditions will typically require mastectomy for management of breast cancer, even if the tumor is detected at a small size that would otherwise have been amenable to breast-conserving surgery. Patients that are unable to raise the arm above shoulder level may have difficulty tolerating the breast radiation tangents.
- All breast cancer patients should have a detailed family cancer history, focusing on both the maternal and paternal sides of the family. Patients with a strong family history, particularly of breast and ovarian cancer, should receive genetic counseling. These patients may want to consider bilateral mastectomies for prevention of second cancers.
- A bilateral breast and lymph node examination, including the axillary, cervical and supraclavicular lymph nodes, is critical. Any patient with clinically evident lymph nodes should undergo further evaluation, including axillary ultrasound and fine needle aspiration (FNA) biopsy.
- Breast examination should focus on the size and location of the tumor, fixation to the underlying musculature or overlying skin, and skin changes, particularly those consistent with inflammatory breast cancer (erythema, swelling, peau d'orange) or locally advanced disease (bulky tumors, tumors with secondary inflammatory changes, or cancers associated with matted nodal disease). These patients may require neoadjuvant chemotherapy in order to downstage the cancer and to improve resectability. A coordinated multidisciplinary approach, including input from medical and radiation oncology specialists promptly following the breast cancer diagnosis, is important for efficient management planning and is vital to the successful treatment of these patients.
- Early-stage breast cancer patients with a clinically negative axillary exam undergoing total mastectomy require axillary staging, which can usually be performed as lymphatic mapping and sentinel lymph node (SLN) biopsy. Mastectomy patients with axillary metastases documented by either needle biopsy or SLN dissection require standard levels 1 and 2 axillary lymph node dissection (ALND) or MRM, and postmastectomy locoregional radiation needs are then determined by the full pathologic extent of disease identified in the breast and axillary contents.
- All patients planning mastectomy should be presented the option of immediate reconstruction and a consultation with a plastic surgeon. Patients who opt for immediate reconstruction may be candidates for a skin-sparing or nipple–areolar sparing mastectomy. If postmastectomy radiation is being considered, this might impact the patient's options and eligibility for immediate reconstruction. Because the axillary nodal status is a strong predictor of postmastectomy radiation benefit, it may therefore be helpful to perform the SLN biopsy prior to the mastectomy surgery in cases where immediate breast reconstruction is planned.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Breast imaging plays a vital role in the screening and diagnostic workup for breast cancer. Imaging can define the extent of the disease and help assess for any abnormalities in the contralateral breast. Bilateral mammography is essential for any patient with breast cancer. Any suspicious contralateral lesions should be worked up before making the final surgical decision.
- Axillary ultrasound can be performed in many patients with a biopsy-proven invasive cancer to identify suspicious nodes suggestive of regional involvement. Suspicious nodes on axillary ultrasound should undergo an FNA biopsy with ultrasound guidance.
- It should not be assumed that any axillary node that is palpable or suspicious on ultrasound is malignant, as often they may be reactive. They should always be interrogated with FNA biopsy; and if the FNA is negative, then definitive axillary staging should be performed by SLN biopsy. At the time of lymphatic mapping and sentinel node dissection, it is important to excise any palpable/suspicious node, regardless of whether or not the node has any appreciable radiocolloid or blue dye uptake. If local resources permit, intraoperative evaluation of the sentinel node(s) with frozen section analysis can also be useful so that the patient can proceed onto immediate completion of the ALND if metastatic nodal disease in confirmed. When frozen section analyses are available and planned, the patient must be consented preoperatively for possible conversion from total mastectomy to MRM.
- The use of magnetic resonance imaging (MRI) is controversial. For patients undergoing mastectomy, MRI may detect contralateral cancers that were not visualized on mammography. For patients that hope to pursue breast-conserving surgery, a preoperative breast MRI may detect suspicious foci of disease in the breast such that mastectomy may be recommended. MRI usage has therefore been associated with increased rates of bilateral mastectomies. However, MRIs are sensitive but not specific and may lead to false-positive findings that necessitate additional biopsies. Furthermore, the natural history of MRI-detected multifocal/multicentric lesions in the cancerous breast is unclear, as these areas of otherwise occult disease would typically be radiated following lumpectomy for the known cancer. Retrospective and prospective studies of outcome following breast-conserving surgery in patients whose breast-conserving surgery eligibility was planned with versus without breast MRI have failed to demonstrate any significant differences in cancer-related outcomes.[1–3] We do not recommend routine MRI but rather its use should be on a patient by patient basis.
- In the absence of locally advanced disease (skin or muscle involvement, multiple matted nodes), routine staging tests, such as computed tomography (CT) scan of the chest, abdomen and pelvis, or bone scan, are not indicated.

SURGICAL MANAGEMENT

Preoperative Planning

- In the preoperative area, the breast to be removed should be clearly marked and confirmed with the patient.
- Prophylactic antibiotics have been shown to reduce postoperative infections and are indicated.[4] Sequential compression devices should be placed prior to initiation of general anesthesia for venous thromboembolism (VTE) prevention.

Positioning

- The patient should be positioned supine with the arm out laterally, taking care not to abduct the arm greater than 90 degrees as this may cause an injury to the brachial plexus. For a simple mastectomy, it is not necessary to prep and drape the ipsilateral arm into the field. However, if an SLN biopsy with frozen section and possible ALND is planned, it may be reasonable to include the arm using a sterile stockinette and Kerlix wrap. The endotracheal tube should be positioned toward the contralateral side of the mouth from the side of the mastectomy.
- Position the table and lights to allow enough room above the arm for an assistant to stand.
- If an SLN biopsy is to be performed and blue dye is to be injected, this can be done at this time. Either isosulfan blue dye or dilute methylene blue dye can be injected subareolar, periareolar, or peritumoral, according to surgeon preference.
- The chest wall, axilla, and upper arm are prepped into the field. Be sure to prep widely, extending across the midline and onto the abdomen and neck.

CHOICE OF INCISION

- The standard incision for a simple mastectomy is the classic Stewart incision, an ellipse oriented medial to lateral, encompassing the nipple–areolar complex and any prior biopsy scar (**FIG 1**). Alternatively, the modified Stewart incision is angled toward the axilla. It has been suggested that the modified Stewart incision, by excising more of the dermal lymphatics running toward the axilla, may provide better local control.
- In addition to the Stewart and modified Stewart, there are alternate options for a simple mastectomy. The placement and orientation of the incision must be based on the location of the biopsy scar and/or the location of the tumor. For a palpable tumor, particularly one close to the skin, the skin over the tumor should be included in the excised skin. Planning of the skin incision in conjunction with the plastic surgeon can be quite helpful in patients undergoing skin-sparing mastectomy and immediate reconstruction. If the patient has a surgical cancer biopsy incision, this scar should be resected with the underlying mastectomy specimen. Incisions located in proximity to the nipple–areolar complex can be resected within the central skin ellipse that is being sacrificed. Incisions that are located remote from the central nipple–areolar skin can sometimes be resected as a separate ellipse of sacrificed skin, as long as the remaining skin bridge is wide enough to remain viable. The original surgical cancer biopsy scars should not be left intact in the mastectomy skin flaps because of the oncologic concern that this skin

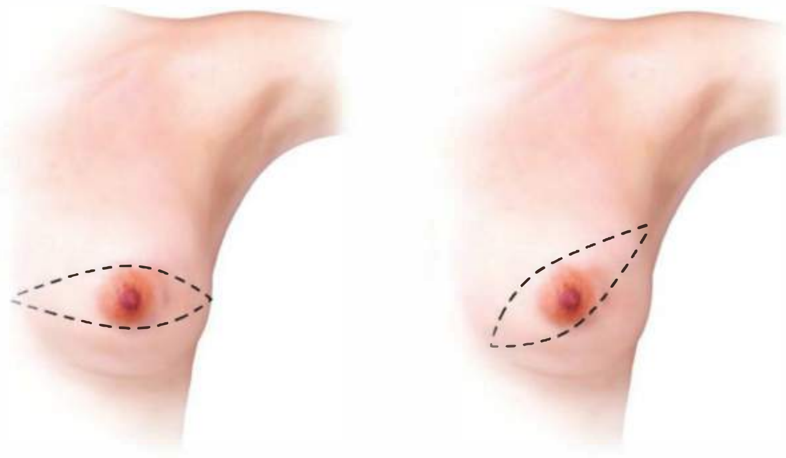

FIG 1 ● Standard incisions for a simple mastectomy. The Stewart incision **(left)** involves a horizontal ellipse that encompasses the nipple–areolar complex and adequate skin to allow a flat closure. The modified Stewart incision is angled toward the ipsilateral axilla.

may potentially harbor cancer cells (and the mastectomy skin is usually not being radiated, as is the case following lumpectomy); and from a wound healing perspective, the subcutaneous fat deep to the traumatized incisional skin will be less healthy and more likely to necrose. Old surgical biopsy scars that are unrelated to the cancer diagnosis can be left in place. Also, percutaneous needle biopsy scars can be left intact on the skin flaps, as these have not been shown to contribute to risk of local recurrence.

- It is important to remove enough skin so that there is no redundancy but not so much that there is undue tension on the incision. A useful method to determine the placement of the superior and inferior incisions is to hold a marking pen in the air over the nipple and retract the breast inferiorly. Mark this site on the skin and then retract the breast superiorly to mark the inferior extent (FIG 2A,B).
- When designing the ellipse, closure will be facilitated by making sure the superior and inferior incisions are of equal length (FIG 3). This can easily be assessed using a 3-0 silk suture.

A

B

FIG 2 ● With a marking pen held over the nipple, the breast is retracted inferiorly **(A)** and the extent of the superior flap is marked. The breast is then retracted superiorly **(B)** and the inferior extent is marked. This allows the surgeon to estimate how much skin should be excised to eliminate redundancy without undue tension.

FIG 3 ● Confirming the superior and inferior incisions are of equal length will facilitate closure.

- Before making the incision, mark the boundaries of the breast tissue. Although the breast is an obvious external feature of the human anatomy, its boundaries deep to the skin are less well defined. Lacking any clear-cut capsule to delineate breast tissue from surrounding fat and subcutaneous tissue, the surgeon must identify anatomic landmarks that serve as reasonable and relatively constant structures, beyond which it is unlikely to find significant amounts of breast tissue. These radial boundaries for the skin flaps essentially serve as a picture frame; and once these flaps are completed, the breast is dissected off the pectoralis major muscle en bloc with the pectoralis fascia. The conventionally accepted peripheral mastectomy flap boundaries are as follows: superior margin—clavicle or 2nd rib (identified by palpation); inferior margin—inframammary fold (IMF); medial margin—lateral border of the sternum (identified by palpation); lateral margin—the lateral extent of the breast tissue can be marked externally on the skin surface and the edge of the latissimus dorsi muscle is a useful vertical boundary that can be visually identified from within the mastectomy surgical field (**FIG 4**).

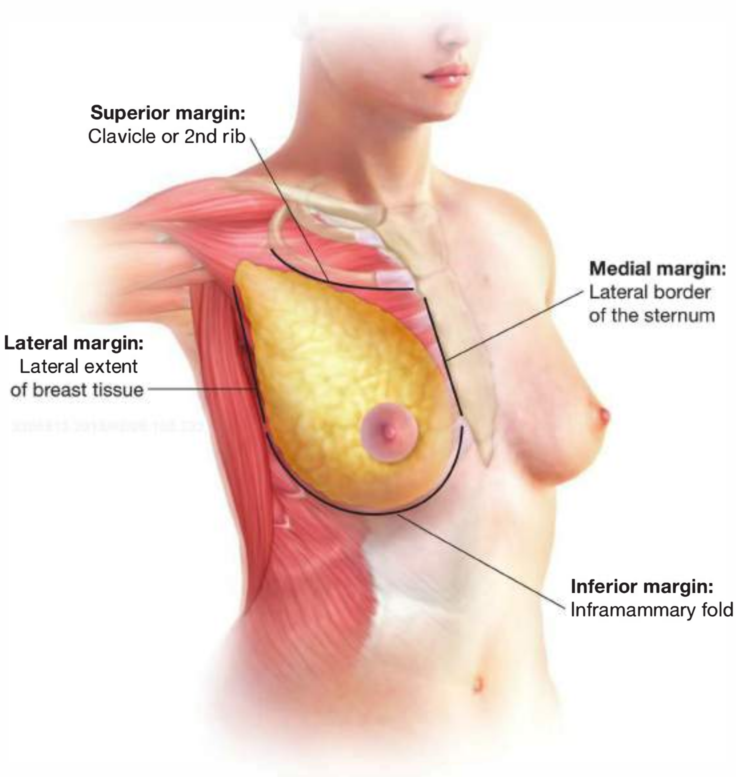

FIG 4 ● To assure removal of all breast tissue, the dissection is performed to the clavicle or 2nd rib superiorly, the IMF inferiorly, the lateral border of the sternum medially, and the lateral extent of the breast tissue or edge of the latissimus dorsi muscle laterally.

SKIN INCISION AND CREATION OF FLAPS

- Once the skin incision has been mapped out on the breast, a scalpel is used to cut through the skin and dermis. Cautery is used to then obtain hemostasis. It is important to get into the right plane to raise flaps at the start. The initial incision should extend through full-thickness skin, just barely exposing the subcutaneous fat, and no further. Incising through deeper layers of subcutaneous fat will result in a splaying out of those fatty planes, and these deeper tissues will spuriously appear as anterior margin surfaces when analyzed and inked in the pathology laboratory. The actual anterior margin of the mastectomy specimen (beyond the central ellipse of sacrificed nipple–areolar skin) should be defined by the surgeon via dissection of the appropriate-thickness skin flaps. Failing to leave a small amount of tissue beneath the dermis can lead to ischemia and wound complications, and this can be particularly concerning in cases involving immediate reconstruction. Conversely, an excessively thick skin flap leaves the patient at risk for residual breast tissue on the chest wall, thereby increasing risk of local recurrence.

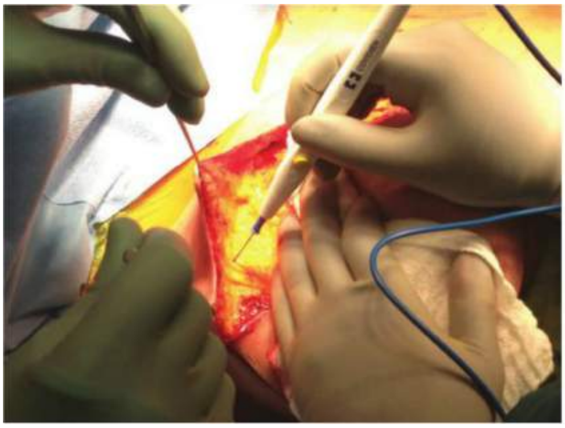

FIG 5 ● The surgeon's opposite hand is used to provide adequate tension on the breast tissue to allow elevation of the superior flap in the correct plane.

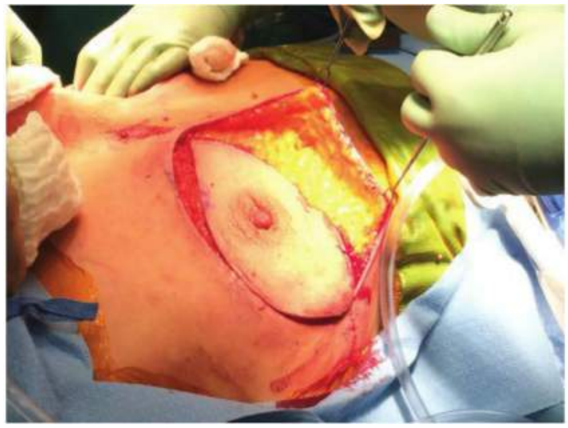

FIG 7 ● If done correctly, there will be a small amount of subcutaneous fat beneath the dermis so that the blood supply is preserved.

- Starting with the superior flap, skin hooks are used to elevate the skin and provide appropriate tension for elevation of the flap (**FIG 5**). The key to elevating an appropriate flap is the tension on the breast tissue. Initially, a forceps can be used to get into the right plane; but once that plane is identified, traction with the contralateral hand of the surgeon using a laparotomy pad on the breast tissue will be critical. As the flap elevation proceeds, it is important to reposition the contralateral hand accordingly.
- It is imperative that the assistant holding the skin hooks maintain retraction straight up (**FIG 6**). Often, a resident will retract toward themselves so they have a better view of the dissection. However, this can lead to exposing the dermis and possibly a buttonhole injury to the skin.

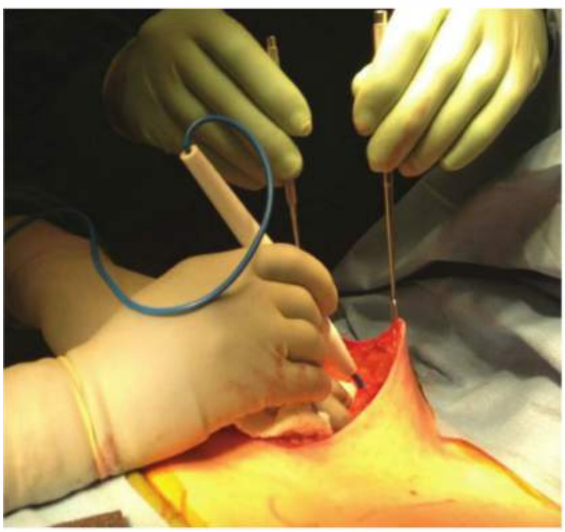

FIG 6 ● It is important that the assistant retract straight up while the flap is raised; otherwise, exposure of the dermis or injury of the flap is more likely.

- The correct plane will leave a small amount of subcutaneous fat beneath the dermis so that the blood supply is preserved while not leaving any breast tissue. This plane is often avascular (**FIG 7**). Intermittently inspecting and palpating the flap will assure the correct thickness. Older women (where much of the breast is fatty-replaced) and heavier patients often have a thicker flap of subcutaneous fat separating the skin from the underlying breast parenchyma. In contrast, younger and thin patients may have breast tissue closely abutting the dermis, allowing for a very narrow margin of error while raising the flap.
- Flaps can be elevated using cautery, scissors, or a scalpel. Cautery will help provide hemostasis during the procedure. If sharp dissection is used, pressure on the breast with a laparotomy sponge will help maintain hemostasis.
- The superior flap is complete when you reach the level of the clavicle. At this point, the pectoralis muscle should be identified and the pectoralis fascia divided (scored) along the length of the flap (**FIG 8**).
- At this point, if an SLN biopsy is to be performed, this can usually be performed through this incision. Performing the SLN at this time point allows adequate time for intraoperative analysis if conversion to an MRM is being considered. The lateral edge of the pectoralis muscle is identified and the clavipectoral fascia is identified and divided. This allows access to the fibrofatty tissue of the axilla. The sentinel nodes can now be identified by using the gamma probe or by following any blue-stained lymphatics.
- The medial margin should extend to the lateral edge of the sternum. Going too far medially can lead to excessive dog-earing, which will need excision and thus lengthen the incision. In the case of bilateral mastectomies, going too far medially can accidently connect the two incisions,

FIG 8 ● At the superior extent (clavicle or 2nd rib), the pectoralis fascia is divided along its length.

FIG 9 ● Visualization of the edge of the latissimus dorsi muscle assures the completeness of the lateral flap.

potentially contaminating the prophylactic side and complicating reconstruction.

- The inferior flap is then elevated in an identical manner to the level of the IMF. It is important to mark this, as it can easily be lost while elevating the flap. The assistant can provide feedback to the surgeon as the IMF is approached. Elevating past the IMF is not only unnecessary but can also complicate reconstruction, necessitating the plastic surgeon to recreate it to assure symmetry.
- Finally, the lateral margin is developed. As this is not an MRM, it is not necessary to thoroughly mobilize the latissimus dorsi muscle but identifying the edge of these fibers can enhance the completeness of the lateral flap (**FIG 9**). Avoiding an unnecessary mobilization of the latissimus dorsi muscle in total mastectomy patients undergoing immediate reconstruction is especially important, as creating extra dissection flaps in this lateral tissue can compromise the plastic surgery aesthetics. It is important that the lateral extent of the breast tissue is removed. This includes the axillary tail of Spence, which extends around the superior aspect of the pectoralis muscle to the clavipectoral fascia.

REMOVAL OF THE BREAST TISSUE

- Once the flaps have been completed circumferentially to the appropriate landmarks, it is time to excise the breast tissue and the pectoralis fascia off the pectoralis major muscle. It is important to remove the fascia with the specimen to assure negative margins. Failure to excise the fascia with the specimen may lead to a positive deep margin, increase chest wall recurrence, and prompt the use of postmastectomy radiation.[5] It can be useful to resect a tiny sample of pectoralis muscle fibers (labeled as sample of additional posterior margin) to serve as pathologic documentation that the mastectomy specimen included the pectoralis fascia. Some patients can have diffuse DCIS extending throughout the breast to its posterior surface, but by definition, the noninvasive nature of this disease is such that documenting resection of the pectoralis fascia is consistent with an adequate resection and further local therapy in the form of postmastectomy radiation is unnecessary. Patients with palpable breast tumors abutting the chest wall surface should have a wedge of underlying pectoralis muscle at the site of the tumor resected en bloc with the mastectomy specimen.
- The breast tissue is retracted inferiorly. This is typically done with the contralateral hand but grasping the fascia with a right-angle clamp can facilitate this. The fascia is elevated off the muscle using cautery, moving the cautery back and forth in the direction of the fibers of the muscle (**FIG 10**). This technique minimizes the damage to the pectoralis muscle.
- Small perforators extending from the pectoralis to the breast should be grasped with a hemostat or forceps and cauterized. There are slightly larger perforators medially. It is best to preserve these if possible. If not, these should be grasped and cauterized or suture

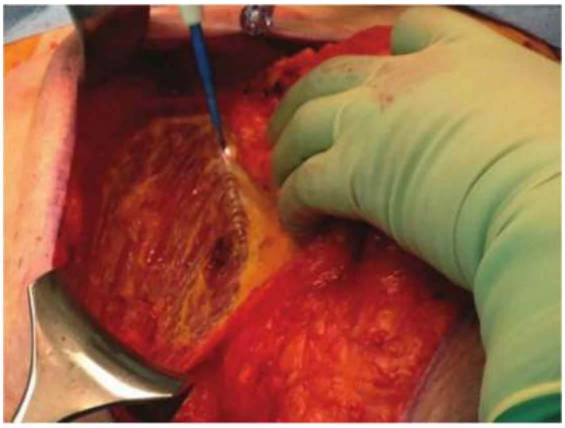

FIG 10 ● Retracting the breast inferiorly, the breast tissue and pectoralis fascia are taken off the pectoralis major. The cautery is moved back and forth in the direction of the fibers of the muscle.

FIG 12 ● As opposed to the pectoralis fascia, which is taken with the breast tissue, the fascia over the serratus anterior is left intact.

ligated (**FIG 11**). If these are accidentally divided, they often retract into the muscle and can be difficult to control. Some patients (especially older and/or less fit patients) will have a weakened, attenuated, and fatty-replaced pectoralis musculature. Caution should be exercised during the lateral retraction of the breast in these cases, as overly aggressive tugging on the breast can result in the muscle being inadvertently avulsed from its costochondral and sternal attachments.

- Dissection of the breast off the pectoralis muscle continues inferiorly toward the IMF and then out laterally. Resecting the pectoralis fascia has oncologic significance; however, fascia overlying the serratus anterior muscle can be left intact (**FIG 12**). Dissecting deep to this fascia and exposing the serratus muscle bed results in unnecessary bleeding and can place the long thoracic nerve at risk for injury, because this important motor nerve is not routinely identified through visual exposure unless the patient is undergoing an ALND.
- Intercostal nerve block: Many mastectomy patients will benefit from intraoperative injection of approximately 5 mL of 0.5% ropivacaine into 2 or 3 intercostal spaces along the surgical field lateral to the pectoralis muscle. The surgeon should notify the anesthesia staff who will then give the patient a few extra deep breaths. At maximal end expiration, the patient is taken off the ventilator while the surgeon injects the long-acting anesthetic just at the inferior edge of the selected rib to block the associated intercostal nerves. Ventilator-assisted respirations then resume. If intercostal nerve blocks as well as incisional long-acting anesthetic injection is planned, then the maximum volume of safe anesthetic delivery (based on body weight of the patient) should be calculated.

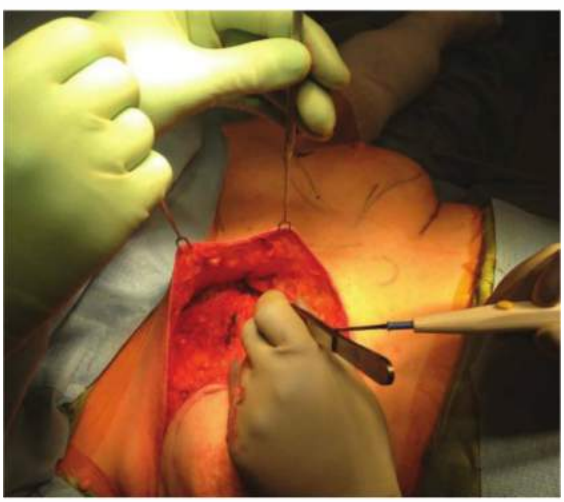

FIG 11 ● Medial perforators are grasped and cauterized.

DRAIN PLACEMENT

- A closed suction drain is placed over the pectoralis major muscle through a separate stab incision and sutured in place with a monofilament suture (**FIG 13**). When inserting the drain through the skin flap, it is useful to be mindful of the location of the latissimus dorsi muscle. Inadvertent insertion of the drain through this muscle can result in excessive bleeding from the tract. In cases where the drain tract does bleed excessively, the best remedy is to simply remove the drain, apply pressure, and replace the drain through a different tract.

FIG 13 ● A flat channel drain is placed over the pectoralis major muscle through a separate stab incision prior to closing.

CLOSURE

- Although excess tension on the incision can lead to wound complications, excess skin will lead to redundant flaps, which can be uncomfortable for the patient; they can be difficult to monitor for recurrence and can interfere with wearing a prosthesis. In cases where postmastectomy radiation and delayed reconstruction is planned, it may be helpful to leave the skin flaps a little looser, but a floppy anterior skin flap will be unsightly and serves as a site for recurrent seroma accumulation. Excess skin can be excised, so that the incision approximates flat on the chest wall. Remember that the patient is lying flat back, but once awake will slouch forward slightly, so a small amount of tension will be released.
- Commonly, the medial and lateral aspects of the incision will "dog ear." Often, these can be easily excised as an ellipse. There are times, particularly in older, heavier women, where excising the lateral dog ear simply moves the dog ear more posteriorly. In these cases, a fish-tail plasty (**FIG 14A–C**) can be useful.[6]
- The dermal layer should be closed with interrupted deep dermal absorbable sutures. Because the Jackson-Pratt (JP) drain will evacuate the postoperative seroma formation, the mastectomy skin flap closure should be subject to minimal tension. A reasonable closure alternative can therefore rely on a few interrupted sutures to line up the appropriate skin closure, followed by a running, continuous absorbable deep dermal suture. The skin can be approximated with an absorbable 4-0 monofilament suture in a running subcuticular closure or a surgical adhesive.

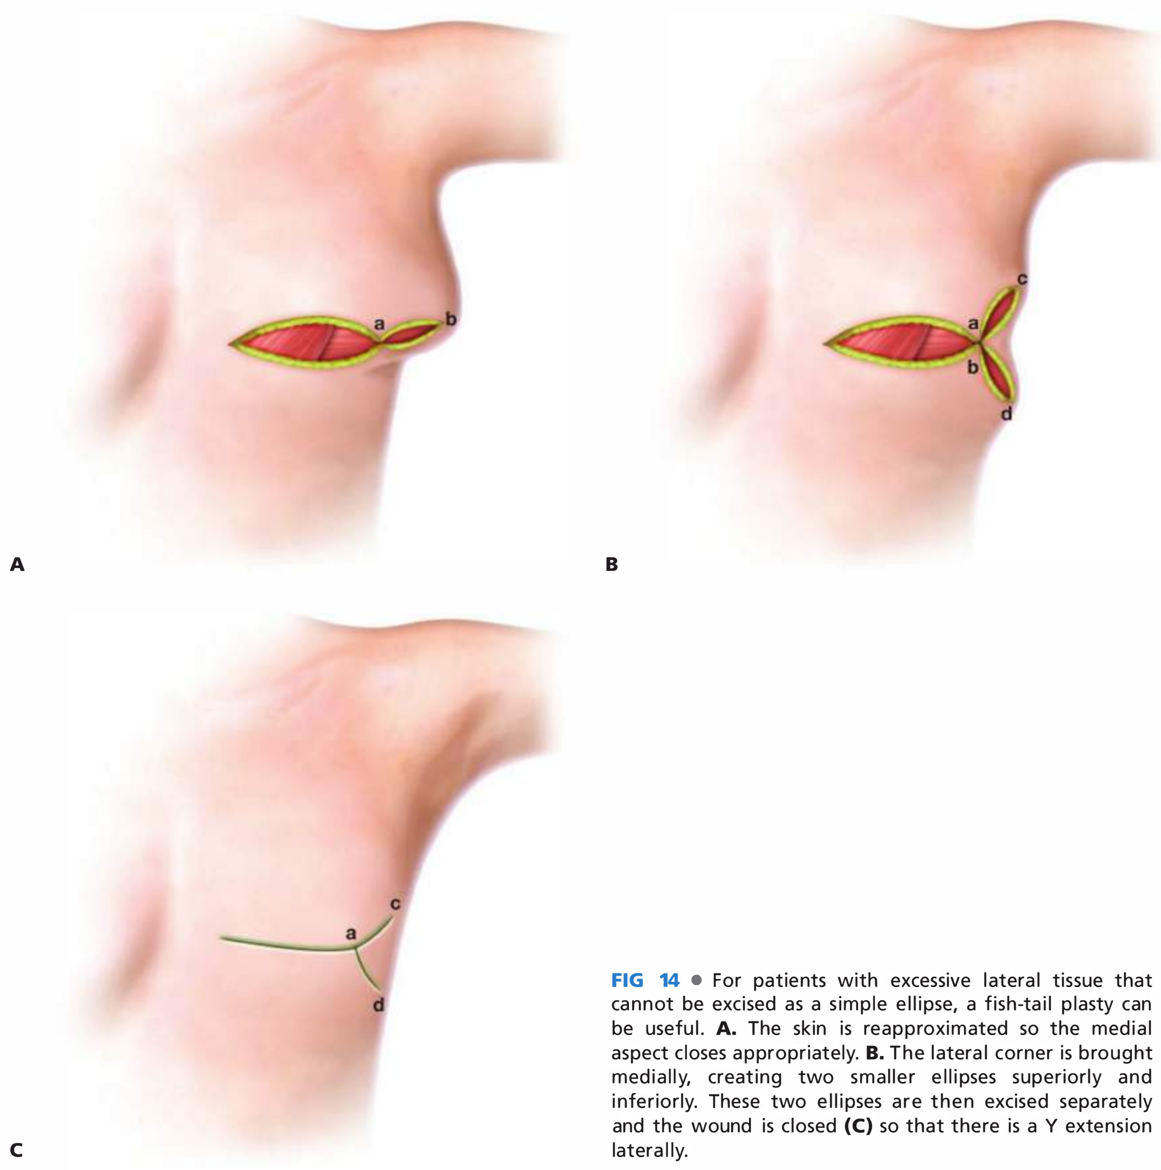

FIG 14 ● For patients with excessive lateral tissue that cannot be excised as a simple ellipse, a fish-tail plasty can be useful. **A.** The skin is reapproximated so the medial aspect closes appropriately. **B.** The lateral corner is brought medially, creating two smaller ellipses superiorly and inferiorly. These two ellipses are then excised separately and the wound is closed **(C)** so that there is a Y extension laterally.

PEARLS AND PITFALLS

Patient expectations	■ Patients who are candidates for breast conservation therapy (BCT) should understand there is no improvement in survival with a mastectomy. ■ All patients undergoing mastectomy should be offered consultation with a plastic surgeon to discuss reconstruction options. ■ Patients may have concerns regarding cosmesis and sexual identity after mastectomy that should be addressed preoperatively. ■ Patients should also understand the potential for redundancy or dog ears after mastectomy and how these can be addressed.

Planning the incision	■ Include the excisional biopsy scar in the ellipse. For palpable tumors, include an adequate amount of skin over the tumor. ■ Plan the ellipse so that it will lie flat, without excess laxity, yet not too tight. ■ Measure the superior and inferior incisions to confirm they are roughly the same length.
Raising the flaps	■ Make sure to start in the right plane with the initial incision and not go too far into the subcutaneous fat. ■ The assistant should hold the skin hooks straight up. Bending the skin backward can inadvertently lead to exposing dermis or "buttonholing." ■ Countertension with the opposite hand is the key to being in the right plane. As you progress, reposition the hand accordingly. ■ Be careful not to pass the IMF while raising the inferior flap.
Removing the breast	■ Retract the breast inferiorly and move the cautery medial to lateral, parallel to the pectoralis major muscle fibers. ■ Remove the fascia of the pectoralis with the specimen. ■ Grasp perforators with a forceps or clamp and coagulate rather than try to directly cauterize. ■ Do not retract the breast laterally with excess force, this will avulse the muscle from the sternum.
Closure	■ Excise excess skin so that the flaps close flat against the chest wall. ■ Medial and lateral dog ears should be excised, but do not keep repositioning a lateral dog ear more posteriorly. A plasty can eradicate a dog ear but can make reconstruction more difficult. A dog ear can always be corrected at a later date under local anesthetic.

POSTOPERATIVE CARE

- A nonadherent dressing can be placed over the incision. Patients can be placed in a breast binder with Kerlix fluffs in order to apply even compression. This will help prevent hematoma but should not be excessively tight.
- Patients do not need to be admitted to the hospital overnight, they may be safely discharged to home. Arranging for a visiting nurse can be helpful for drain management and wound checks.
- The drain can be removed when the output is less than 30 mL/24 hours for 2 days in a row.

OUTCOMES

- Overall, local (chest wall) recurrence after mastectomy is low, ranging from 0.6% to 9.5%, increasing with increasing stage, the presence of nodal metastases, and positive margins after mastectomy. However, local recurrence rates also appear to be decreasing as systemic therapies improve.[7] Local recurrence is also related to the histologic subtype, with luminal subtype tumors (ER/PR positive) less likely to recur than *HER2/neu* overexpressing or triple negative tumors after mastectomy.[8]
- Because local recurrence rates remain higher among patients with node-positive disease or positive margins, postmastectomy radiation therapy (PMRT) should be considered in these situations. PMRT is strongly indicated for patients with positive margins or more than four positive lymph nodes. It should also be considered for patients with one to three positive lymph nodes, particularly, if they have other risk factors for chest wall recurrence.

COMPLICATIONS

- Seroma
- Wound infection
- Hematoma
- Wound dehiscence
- Flap necrosis
- Positive margins

Chapter 11

Skin-Sparing and Nipple/Areolar-Sparing Mastectomy

Eleni Tousimis   Rache Simmons

DEFINITION

- Skin-sparing mastectomy is defined as removal of the breast tissue while preserving the natural skin envelope for immediate breast reconstruction. This is an effective treatment option for patients with operable breast cancer without skin involvement. By preserving the patient's skin envelope with a smaller incision, it markedly improves the aesthetics of the breast reconstruction. To further enhance cosmesis, the nipple and areola can be preserved at the time of mastectomy in select patients. This is called nipple-sparing mastectomy.

ANATOMY

- As with all types of mastectomy, a thorough understanding of the anatomy of the breast, chest wall, and axilla is necessary. The goal of mastectomy is to remove the breast tissue while maintaining the viability of the skin envelope.
- The breast tissue is encapsulated by the superficial fascia that adheres to the subcutaneous tissue in a lobulated fashion (**FIG 1**). This makes it difficult to remove all of the breast tissue during mastectomy and maintain skin viability.
- The boundaries of the breast (**FIG 2**) are defined by the clavicle superiorly, the sternum medially, the 6th rib inferiorly, and the latissimus dorsi muscle laterally.
- The axillary tail of the breast extends toward the low axilla and is called the axillary tail of Spence. Posteriorly, the breast adheres to the pectoralis major muscle and is separated by the deep fascia of the breast (see **FIG 1**).
- A skin-sparing mastectomy involves preserving the skin envelope while removing the nipple–areolar complex and underlying breast via a small incision (**FIG 3**). Nipple-sparing mastectomy is a total skin-sparing mastectomy with preservation of the nipple–areolar complex.
- When performing a skin-sparing mastectomy, it is important to remove as much breast tissue as possible while maintaining the viability of the skin. This is a balancing act from the oncologic standpoint to remove the majority of the breast tissue but not make the skin flaps so thin, resulting in skin necrosis and flap loss. The anatomic plane that divides the

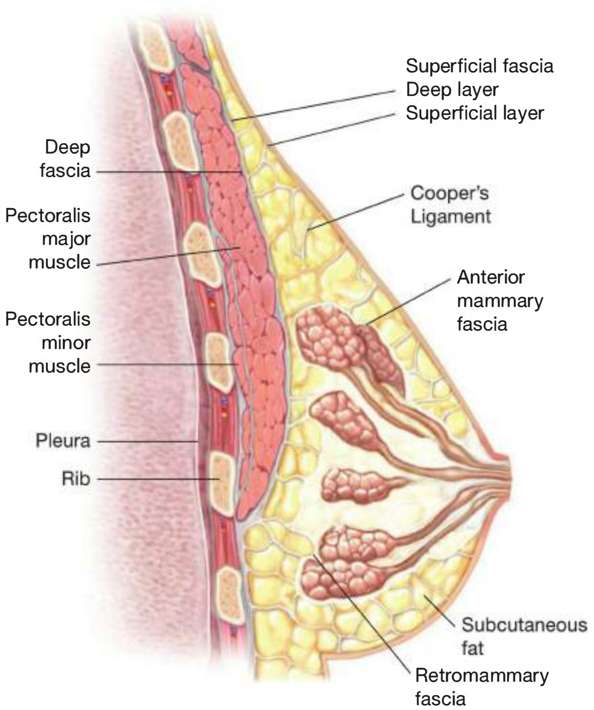

FIG 1 ● Cross-section of the breast demonstrating the superficial fascia, including both the superficial and deep layers.

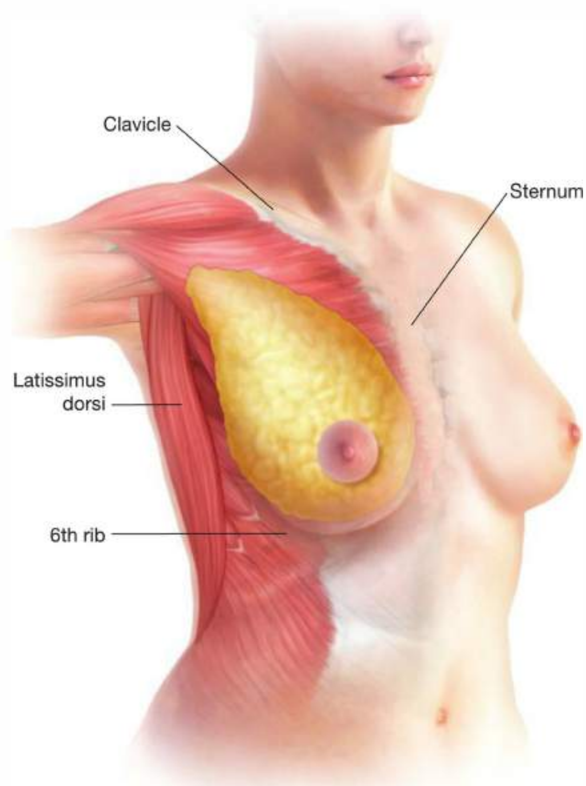

FIG 2 ● Anatomic boundaries of the breast.

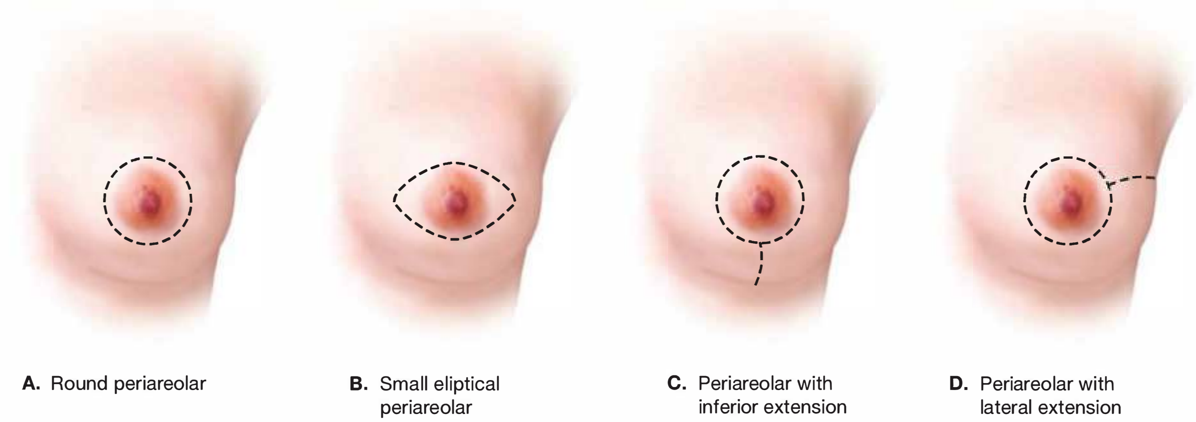

FIG 3 ● **A–D.** Surgical incisions used for a skin-sparing mastectomy.

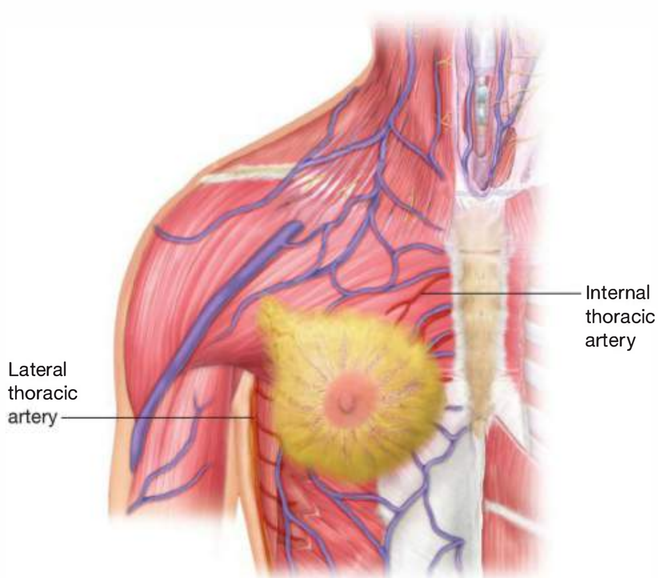
subcutaneous tissue and the underlying breast parenchyma is formed by the superficial fascia of the breast. This is an ill-defined thin layer visualized by a faint white fascial line (see **FIG 1**). The dissection is carefully performed in this plane. The remaining tissue on the skin envelope usually ranges between 2 and 5 mm in thickness depending on the patient's anatomy.

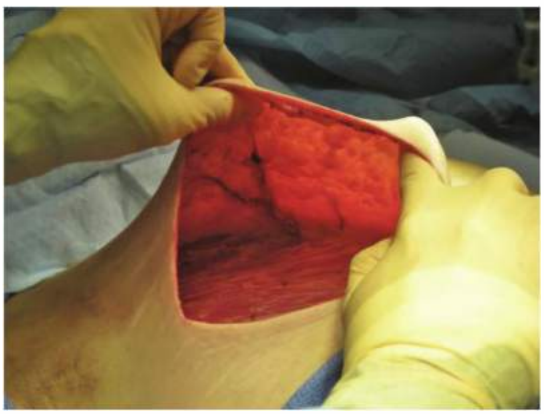
- It is crucial to flap viability to preserve both the subcutaneous venous plexus under the skin as well as the branches of the 2nd intercostal perforator in the upper medial flap as it exits the ribs. This is the largest blood supply to the skin flap (**FIG 4A,B**).
- Once the flaps are created to the clavicle superiorly including the axillary tail of Spence, medially to the sternum, laterally to the latissimus dorsi muscle, and inferiorly to the 6th rib, the breast is then removed posteriorly from the pectoralis major muscle including the underlying deep fascia overlying the muscle. It is important when creating the flap medially not to extend to the contralateral breast.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with operable breast cancer are candidates for either breast conservation therapy (BCT) or skin-sparing mastectomy with or without reconstruction. It is important for patients to understand that the survival between BCT and mastectomy is equal. However, mastectomy does carry a slightly lower locoregional recurrence rate of about 2% versus 5% in 10 years after BCT.[1]
- Another important difference between the two surgical treatment options is that mastectomy usually does not require postoperative radiation therapy. Postmastectomy radiation is recommended for patients with tumors greater than 5 cm in size, patients with positive margins after mastectomy, or select patients with axillary lymph node involvement for locoregional control and to improve survival.[2]



A



B

FIG 4 ● **A.** The blood supply to the breast comes primarily from the lateral (mammary) thoracic artery, the internal (mammary) thoracic artery, and the intercostal arteries. It is crucial to preserve the branches of the 2nd intercostal artery in the upper medial flap to ensure viability. **B.** The subcutaneous venous plexus and branch off the 2nd intercostal artery are seen preserved with the flap.

Table 1: Methods for Examining the Breast and Pathognomonic Signs

Examination	Technique	Grading	Significance
Breast exam	Upright Supine	Symmetry Skin changes Palpable masses Adenopathy Nipple discharge	Cancer causing enlargement Peau d'orange, associated with inflammatory breast cancer, or an underlying tumor pulling on Cooper's ligaments Cancer, benign mass or cyst Lymph node metastasis or reactive lymph nodes Bloody or clear spontaneous unilateral discharge associated with carcinoma risk

- Prior to determining whether a patient will be a candidate for mastectomy or BCT, a thorough history and physical examination should be performed.
- The medical history should focus on the patient's family history of breast cancer in first-degree relatives and ovarian cancer in the family. Patients with a strong family history of breast or ovarian cancer, premenopausal breast cancer, patients with bilateral breast cancer, male family members with breast cancer, or those of Ashkenazi Jewish descent should be recommended for genetic counseling and testing for the BRCA 1 and 2 gene mutations. Also included in the medical history, the surgeon should ask about personal risk factors for developing breast cancer such as early menses, late menopause, a personal history of an atypical breast biopsy, lobular carcinoma in situ (LCIS), a history of previous chest wall radiation for Hodgkin's lymphoma, or use of hormone replacement therapy. Many of these high-risk patients who decide to undergo mastectomy also opt for contralateral mastectomy at the time of mastectomy to decrease their risk of a future breast cancer. Another reason for the recent increased incidence of contralateral prophylactic mastectomy is because of patient's anxiety, fear, and desire to reduce future risk of recurrence and cosmetic symmetry.[3]
- After obtaining a thorough medical history, a detailed physical examination would include examination of the patient in both the upright and supine positions (Table 1). While placing the patient's hands on her hips in the upright position, the patient is visually examined for symmetry, evidence of skin changes, or dimpling. The cervical and axillary areas are palpated for adenopathy and the breasts are examined. The patient is then placed supine with both arms over her head. The breasts are examined again for palpable masses and nipple discharge, and the axillae are palpated again while lowering the arms to the side. The abdomen is then examined for hepatosplenomegaly.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The purpose of preoperative imaging is to clinically stage the patient, determine operability, assist with surgical decision making, and assess the need for preoperative chemotherapy for downstaging. All patients prior to mastectomy require a recent bilateral mammogram including craniocaudal and medial lateral views. On mammogram, one should look for spiculated masses, tumor size and location, additional tumors, skin involvement, and associated calcifications (**FIG 5**).
- For patients with dense breast tissue or young age, a breast sonogram may be a helpful addition to assess the presence of additional lesions in dense breast tissue and the extent and depth of the tumor.
- Ultrasonography is also helpful to assess the axilla radiographically. Suspicious nodes have a very characteristic appearance with an obliterated hilum and nondistinct borders. An ultrasound-guided fine needle aspiration (FNA) can be performed preoperatively for suspicious nodes (**FIG 6**).

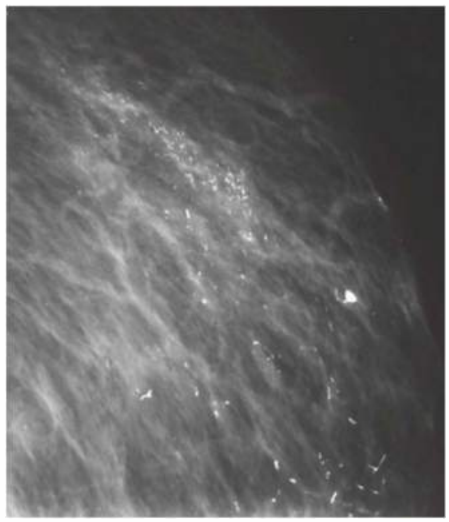


FIG 5 • Magnification mammogram showing pleomorphic calcifications suspicious for carcinoma.

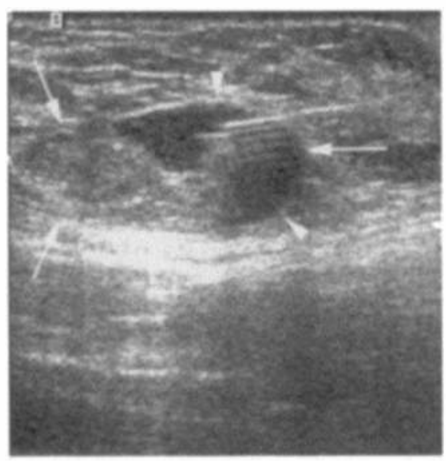

FIG 6 • Ultrasound-guided FNA biopsy of axillary lymph node metastases.

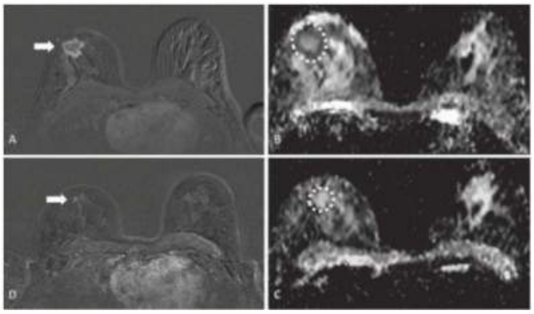

FIG 7 ● MRI showing response to chemotherapy before treatment **(A)** and after treatment **(B)**.

- Magnetic resonance imaging (MRI) of the breast is used selectively for patients who are having mastectomy. One indication is for patients with invasive lobular cancer because of a higher incidence of contralateral disease.[4]
- MRI may also be used preoperatively for high-risk patients such as those with the BRCA 1 or 2 mutation, a strong family history, dense breast tissue, difficult breast examinations, large tumors with questionable skin involvement, or those undergoing neoadjuvant chemotherapy. In patients undergoing preoperative chemotherapy, MRI helps to monitor the response to treatment. An MRI is performed before treatment begins and then repeated again after systemic treatment is completed for comparison. The MRI shows a nice relationship of the tumor location to skin distance for treatment planning and choice of surgical incision (**FIG 7**).
- Staging tests to rule out metastatic disease, such as positron emission tomography–computed tomography (PET/CT) or a computed tomography (CT) scan of the chest, abdomen, and pelvis and bone scan should be considered in patients with lymph node involvement and large tumors or those patients with signs or symptoms suggestive of metastases (Table 2).

SURGICAL MANAGEMENT

- Indications for skin-sparing mastectomy include patients who choose mastectomy to reduce their risk of a future local recurrence and patients with the *BRCA* gene mutation, other high-risk patients that have a strong family history of breast cancer, or young age at diagnosis. The patient must have operable breast cancer and not have extensive skin involvement or fungating, ulcerating lesions.
- Indications for nipple-sparing mastectomy include patients who are undergoing prophylactic surgery, *BRCA* gene mutation carriers, and have operable cancers not located close to the nipple. Patients who should not undergo nipple-sparing mastectomy are those patients with very large, ptotic breasts, cancers located directly under the nipple, radiographic evidence of nipple involvement, or those with suspicious nipple discharge or nipple retraction. Patients must be informed that it is not possible to remove all the tissue under the nipple and that there is a reported risk of recurrence in the nipple and nipple necrosis of less than 5%.[5]

Table 2: Indications for Preoperative Positron Emission Tomography–Computed Tomography

Examination	Indications Preoperatively
PET/CT	Tumors >3 cm in size Evidence of lymph node metastasis Symptomatic disease (i.e., bone pain) Locally advanced breast cancer

PET/CT, positron emission tomography–computed tomography.

Preoperative Planning

- All preoperative radiographic studies should be studied prior to surgery to determine tumor location, size, and depth.
- The breast cancer surgeon and patient discuss the optimal type of skin-sparing mastectomy preoperatively and determine whether they are candidates for skin-sparing simple mastectomy or nipple-sparing mastectomy.
- All patients undergoing immediate reconstruction consult with a reconstructive surgeon prior to surgery for preoperative planning. After the reconstructive surgeon examines the patient and determines the optimal reconstruction depending on the patient's body habitus, breast size, and clinical stage, the reconstructive surgeon collaborates with the breast surgeon for the optimal oncologic approach with the best cosmesis.
- Patients with palpable tumors close to skin or those considering nipple-sparing mastectomy with tumors close to the areola may benefit from a preoperative breast MRI to address distance of tumor to the skin or disease below the nipple–areolar complex. This may alter treatment planning such as the use of neoadjuvant chemotherapy to achieve negative margins as well as surgical decision making.

Positioning

- The optimal operative position for all patients undergoing skin-sparing mastectomy is supine with the arms abducted approximately 45 degrees. Care is taken not to hyperextend the arms in anticipation for a long surgery. The arm boards are padded in order to protect the elbows from pressure compression causing a median nerve palsy.
- Compression boots are placed preoperatively and there is no need for additional anticoagulation unless the patient is at high risk for deep vein thrombosis (DVT), including obesity, a personal history of DVT, or cardiac valves requiring prophylaxis.
- Upon induction, if the patient is undergoing immediate breast reconstruction, they should receive a dose of intravenous (IV) antibiotics to cover gram-positive bacteria, usually a first-generation cephalosporin such as cephazolin.
- A Foley catheter is inserted after induction, if a prolonged reconstruction is anticipated.
- Prior to prepping the patient, methylene blue dye is injected subareolar for those surgeons who use both blue dye in addition to radioisotope for identification of the sentinel lymph node (**FIG 8**).
- Once prepped, the patient's arm is wrapped with a free arm dressing in anticipation of an axillary node dissection if axillary metastasis is suspected; otherwise, it is draped outside the field.

FIG 8 ● Patient positioning and preoperative injection of blue dye in a subareolar fashion.

SKIN-SPARING MASTECTOMY

- Prior to surgery, the patient is skin marked by both the reconstructive and breast cancer surgeons. The nipple–areolar complex is removed by a small elliptical skin incision. There are many options of excision depending on breast size and tumor location as well as type of reconstruction (see **FIG 3**).
- The nipple–areolar complex is incised in an elliptical fashion with a no. 15 blade scalpel into the dermis. Skin hooks are placed on the flap and pulled upward by the first assistant. Care is taken to ensure the first assistant pulls directly perpendicular to the chest wall to avoid an inadvertent buttonhole in the flap (**FIG 9**).
- By retracting the breast downward against the upward traction of the skin, the superficial fascial plane is identified. The surgeon uses cautery to create the flaps by dissecting just above the superficial fascia in order to remove as much of the breast tissue as possible. Alternatively, some surgeons may use either the knife or scissors to create the mastectomy flaps. As long as the surgeon is in the correct anatomic plane, it should be relatively avascular.
- As the surgeon progresses further posteriorly, medium-sized Richardson retractors or lighted retractors are used to assist with retraction (see **FIG 15**). Because the skin ellipse opening may be quite small, the flaps are created in a spiral fashion until the pectoralis muscle is identified.
- The surgeon's hand is then used to examine the flaps. If the surgeon is in the proper plane, the flaps will only be a couple of millimeters thick and even throughout. Care is taken to ensure that the axillary tail of the breast has been adequately dissected and removed en bloc with the specimen.
- Next, the breast is removed from the pectoralis muscle. Medium-sized or large Richardson retractors are used to retract the skin superiorly and Kelly clamps may be placed on the superior aspect of the breast to assist with downward traction.
- Electrocautery is then used to separate the breast from the pectoralis muscle by dissecting parallel to the muscle fibers from medial to lateral (**FIG 10**). All perforating vessels are carefully cauterized prior to cutting to prevent retraction into the muscle and subsequent bleeding.
- Once the breast is removed from the chest wall, a silk stitch is used to mark the axillary tail for orientation for the pathologist. The breast is passed off the field for permanent section and attention is paid to the axilla to perform either a sentinel lymph node biopsy or axillary lymph node dissection, depending on the stage of the cancer. This may be performed via the mastectomy incision if there is no tension on the wound. If the axilla is too far away, a separate axillary incision is made.

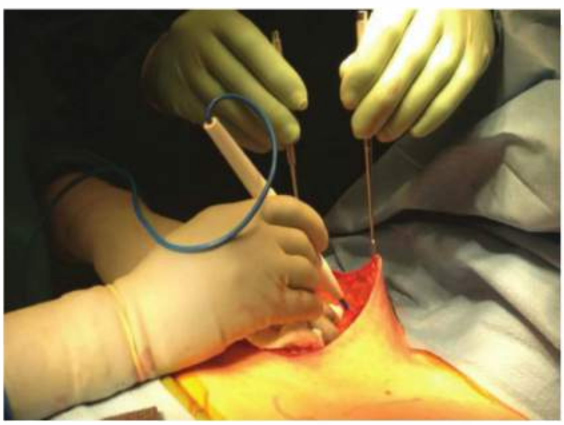

FIG 9 ● Skin hooks are placed on the flap and pulled upward by the first assistant. Care is taken to ensure the first assistant pulls directly perpendicular to the chest wall to avoid an inadvertent button hole in the flap.

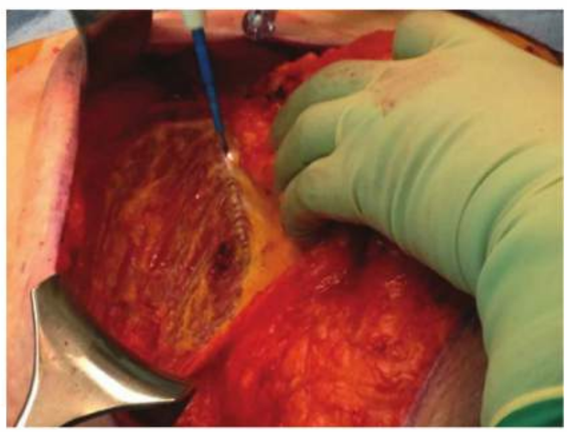

FIG 10 ● Electrocautery is used to dissect the breast and pectoralis fascia off the underlying muscle. Cautery is moved parallel to the muscle fibers from medial to lateral.

NIPPLE-SPARING MASTECTOMY

- Nipple-sparing mastectomy is performed similar to skin-sparing mastectomy (**FIG 11**); however, the nipple–areolar complex is spared.This can be done through various approaches (**FIG 12**).
- The most cosmetic approach is via an inframammary fold skin incision (**FIG 13A,B**). The entire flap is created from the inframammary fold inferiorly to the clavicle superiorly. This is a long flap and is therefore best used on women with small to medium-sized breasts. The inframammary fold incision is usually approximately 9 cm in length. It extends from just below the medial aspect of the areola in the inframammary fold to 9 cm laterally. The most challenging technical aspect of this approach is getting sufficient upward traction of the skin in order to create the flap in the appropriate plane.
- Skin hooks are used for upward traction, as in the traditional skin-sparing mastectomy. However, when approaching the nipple–areolar complex, it is best to have the first assistant gently pinch and retract the nipple upward or alternatively place a 2-0 silk stitch through the nipple in order to give upward traction and use a lighted retractor lateral to the nipple–areolar complex in order to visualize the area adequately (**FIGS 14** and **15**).
- The ductal tissue posterior to the nipple is usually more dense and lighter in color (**FIG 16**). Once through this area, the silk stitch can be removed and the lighted retractors are advanced in order to complete the superior aspect of the flaps to the clavicle. The first assistant can apply gentle traction of the skin flap by placing the palm of his or her hand on the superior aspect of the flap and pushing away from the surgeon.
- To create even flaps, it is important that both the first assistant and surgeon apply steady, even traction and avoid readjusting multiple times.
- After the breast is removed from the chest wall, attention is paid to the nipple to take an additional nipple margin.
- The surgeon's finger is placed on the outside of the nipple and the nipple is everted. An Allis clamp is then placed on the tissue inside the nipple and a no. 15 blade scalpel is used to perform a shave biopsy of any residual ductal tissue within the nipple. The tissue is then sent to pathology for frozen or permanent section.

FIG 11 ● Nipple-sparing mastectomy via inframammary skin incision versus skin sparing mastectomy on patient with left centrally located tumor. (Photo courtesy of Sherman J, MD.)

- All patients undergoing nipple-sparing mastectomy are consented preoperatively that if the nipple margin is positive for cancer, then the nipple–areolar complex will be removed. If this is recognized intraoperatively on frozen section, the nipple–areolar complex can be removed at this time. If this is deferred to permanent section, it will be removed postoperatively by the reconstructive surgeon.
- If the skin flaps and nipple–areolar complex appear well vascularized and the nipple margin is negative on

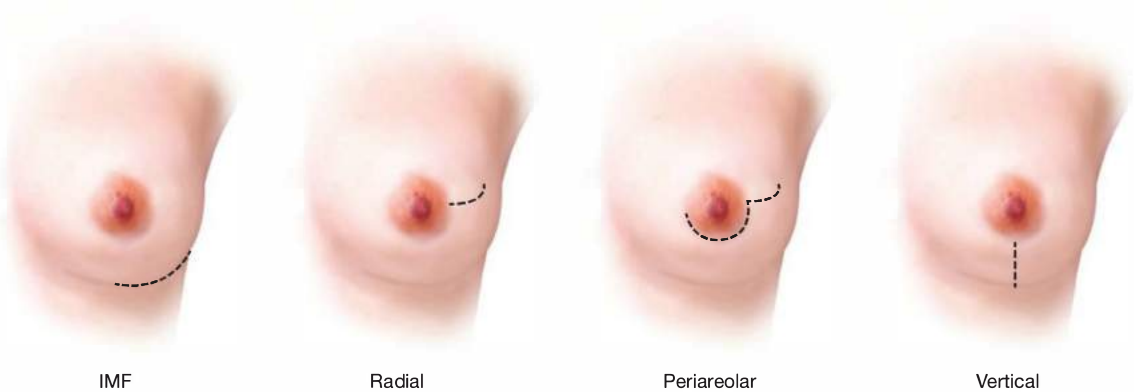

FIG 12 ● Skin incision options for nipple-sparing mastectomy.

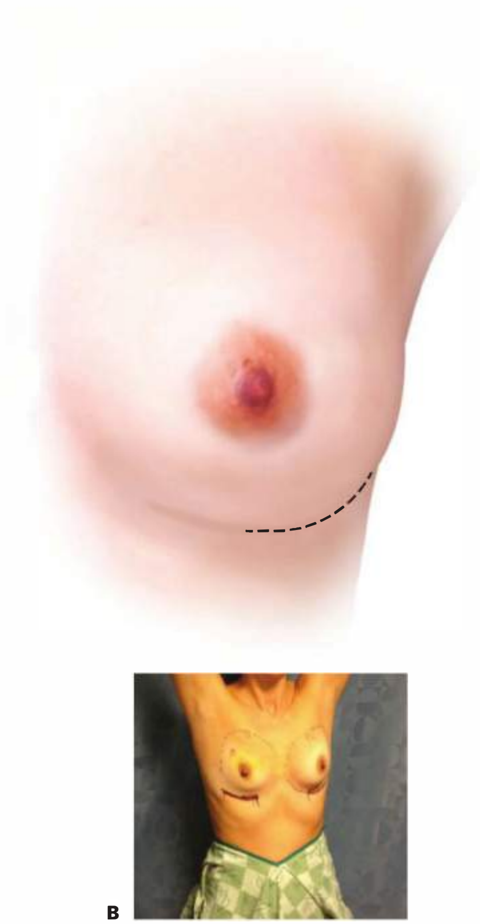

FIG 13 ● **A.** Nipple-sparing mastectomy via inframammary fold skin incision. **B.** Preoperative skin marking for inframammary skin incision. Below medial areola to 9 cm laterally in the inframammary fold.

frozen section (if obtained), the reconstructive surgeon can proceed (FIG 17).

- For patients with ptotic breasts who are not ideal candidates for nipple-sparing mastectomy, we recommend performing a superior circumareolar mastopexy incision with a lateral extension to remove excess skin and achieve a slight lift. Another option for macromastia or significant ptosis is a two-stage procedure suggested by Spear and colleagues[6] where the patient undergoes a primary mammoplasty followed by nipple-sparing mastectomy 3 weeks later (FIG 18).

Analgesia after Mastectomy

- Mastectomy is performed under general anesthesia. In addition to general anesthesia, a long acting local anesthetic may be injected into the borders of the mastectomy wound just below the cut edge of the fascia. Postoperatively, patients are given both an oral narcotic as well as vallium to relax the muscle and prevent muscle spasm and tightness.

PEARLS AND PITFALLS

Possible Pitfalls of Skin-Sparing Mastectomy	Pearls
Flap necrosis	■ Identify fascial plan below subcutaneous tissue; stay just above this line to create flap. ■ Maintain even traction/countertraction in order to create even flaps. ■ Preserve the subcutaneous venous plexus and the 2nd intercostal perforator to prevent flap necrosis. ■ Avoid denuding the skin.
Nipple necrosis	■ Do not denude the nipple. ■ Avoid too much traction on the nipple for prolonged periods of time. ■ Avoid cautery under the nipple.
Infection	■ Treat reconstructive patients with preoperative IV antibiotics and postoperative oral antibiotics until the drains are removed. ■ Irrigate thoroughly with normal saline after the mastectomy is performed. ■ Obtain careful hemostasis.

POSTOPERATIVE CARE

- Patients who undergo implant reconstruction are admitted as an inpatient overnight.
- Patients who undergo flap reconstruction are admitted longer depending on the type of flap reconstruction.
- They are maintained on oral first-generation cephalosporin until the Jackson-Pratt (JP) drains are removed.
- The patients are discharged with a surgical bra and the JP drains attached to the bra.
- They may resume showering after 48 hours and are taught how to empty and record the drain output.
- The patient returns in 1 week to have the drains removed if she is draining less than 30 cc per day from each drain and to discuss the pathology report.
- Patients are then referred to medical oncology for adjuvant treatment and a radiation oncologist if indicated.
- When the breast is removed, the sensory innervations to the skin are also removed, resulting in loss of sensation. This resulting band of numbness gets narrower over time but never completely resolves.
- Following mastectomy, patients are seen in follow-up by the breast surgeon every 6 months for 5 years to examine the skin for recurrent disease, then yearly thereafter.
- An instruction book of postmastectomy stretching exercises is given to the patient after the drains are removed to increase mobility and prevent frozen shoulder. For patients who develop decreased mobility after surgery, they are referred to a specially trained physical therapist.

OUTCOMES

- Include functional and prosthetic survivorship data, as applicable.

FIG 19 • Nipple and flap necrosis after nipple-sparing mastectomy via inframammary skin incision.

FIG 20 • Inferior flap necrosis after skin-sparing mastectomy with deep inferior epigastric perforator (DIEP) flap reconstruction.

COMPLICATIONS

- Skin flap necrosis (**FIGS 19** and **20**)
- Nipple necrosis
- Infection
- Seroma
- Hematoma

Chapter 12

Modified Radical Mastectomy

Tiffany A. Torstenson Judy C. Boughey

DEFINITION

- Modified radical mastectomy (MRM) is a surgical procedure that removes all breast tissue and lymphatic-bearing tissue in the axilla. This operation removes the nipple–areolar complex, skin envelope, and level I and II axillary nodes but spares the pectoralis major muscle. It can also be termed as a total mastectomy with an axillary lymph node dissection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- There has been a huge evolution in types of the mastectomy over the years. We have moved away from the radical mastectomy to more cosmetic pleasing procedures such as simple mastectomy, skin-sparing mastectomy, and nipple-sparing mastectomy. In mastectomy patients with node-positive disease, axillary lymph node dissection is often recommended.
- Patients undergoing an MRM usually have documented lymph node metastases diagnosed preoperatively or surgically and either elect to have a mastectomy or require a mastectomy (i.e., are not candidates for breast-conserving therapy). Patients diagnosed with inflammatory breast cancer should also undergo an MRM after induction chemotherapy according to National Comprehensive Cancer Network (NCCN) guidelines.[1]
- It is crucial to decide from the beginning if these patients are operable candidates and whether neoadjuvant therapy should be considered. A multidisciplinary approach is vital in the treatment success of these patients. Involvement of a medical oncologist and radiation oncologist early in the management of these patients helps treatment planning and to streamline patient care.
- A comprehensive history and physical examination is imperative on the first consultation with these patients. The history should be very detailed and include questions pertaining to medical conditions, medications, surgeries, allergies, and also about any musculoskeletal issues, which could affect operative positioning. It is important to evaluate for any family history of breast or ovarian cancer.
- If there is a strong family history of breast or ovarian cancer, it is essential to offer genetic counseling and possibility of genetic testing.
- Physical examination starts with an inspection of bilateral breasts both with arms at the patient's side and with the arms elevated, noting any asymmetry, nipple retraction, prior scars, or skin changes.
- Palpation of the breasts should always be done both in a sitting and supine position in a circular or vertical pattern. Palpable masses should have bidimensional measurements and should be assessed for chest wall adherence and skin proximity. Any palpable masses that do not correspond to radiologic findings require further testing and tissue biopsy.
- A thorough examination of the lymph node basins should be performed, including the axillary, cervical, supraclavicular, and infraclavicular nodes. If there is adenopathy on palpation, patients should undergo an in-office or radiologic ultrasound. Any suspicious nodes on imaging should undergo a fine needle aspiration or core needle biopsy.
- Imaging and pathologic diagnoses should be shared and explained to the patient. It is helpful to map out the incisions for the patients to see preoperatively. Explain to patients the need for either neoadjuvant or adjuvant chemotherapy as well as likely need for postmastectomy radiation in patients with node-positive disease.
- Neoadjuvant chemotherapy has been shown to be equivalent to adjuvant chemotherapy in terms of survival and can increase rates of breast-conserving therapy.
- Postmastectomy radiation in node-positive disease decreases rates of locoregional recurrence and increases disease-free and breast cancer–specific survival.
- Inquire if patients are seeking immediate reconstruction or desire to go flat chested. If postmastectomy radiation is recommended, patients may not be candidates for immediate reconstruction.
- Allocate enough time to spend with these patients in order to answer all their questions, and be empathetic to their needs during this emotional time. Keep interruptions with pagers and cell phones to a minimum.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Breast imaging plays a vital role in the screening and diagnostic workup for breast cancer. Imaging can define the extent of the disease and help assess for any abnormalities in the contralateral breast. It is also used as a monitor for local recurrence in patients postoperatively.
- Mammography is the initial imaging test in the breast cancer workup. Mammograms are very sensitive in detecting abnormalities and have been shown to decrease breast cancer mortality approximately by 30%. Screening mammograms should begin yearly in women who are 40 years of age and asymptomatic.[2]
- Diagnostic mammograms should be obtained in any patient being considered for an MRM (**FIG 1**). Spot and magnification views can help aid to focus and distinguish abnormalities. Implant displacement views (Eklund views) should be obtained in women with implants.[2,3] Request films if they were done at an outside institution. An ultrasound should also be performed to further assess the size of the tumor and the proximity of it to the skin and chest wall. Lesions that are suspicious on ultrasound or mammogram should undergo a percutaneous biopsy.
- Axillary ultrasound should be performed in patients with a biopsy-proven invasive cancer. Lymph nodes should be evaluated for their size, shape, and morphology. Suspicious nodes

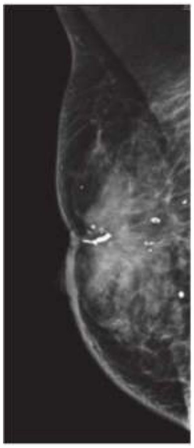

FIG 1 ● Mammogram showing a right invasive ductal carcinoma invading the skin and causing skin retraction.

on imaging or clinically palpable nodes should undergo a fine needle aspiration or core needle biopsy with ultrasound guidance (**FIG 2**). Approximately 31% of axillary metastases are diagnosed with ultrasound-guided biopsy.

- Magnetic resonance imaging (MRI) usage is still controversial but can be used as an additional imaging tool for screening, staging of known breast cancers, and evaluating the contralateral breast. MRIs are highly sensitive tests but lack specificity leading to an increased false-positive rate. Studies have also demonstrated an increased rate of mastectomies in patients undergoing MRIs. The decision to order an MRI should be based on the recommended indications and individualized.
- According to NCCN guidelines, positron emission tomography (PET) scans can be used to evaluate for distant metastasis in patients with stage IIIA breast cancer, but this is a category 2B recommendation. Systemic staging is not recommended for patients with early stage breast cancer in the absence of symptoms.[1]
- When a suspicious lesion is identified on imaging, a tissue biopsy is needed to decipher between a benign and malignant process. Percutaneous biopsy is preferred over an excisional biopsy, which can lead to unnecessary surgeries for benign entities. Core needle biopsy is preferred to evaluate histology and differentiate in situ from invasive disease. Most lesions in the breast will need to undergo a core needle biopsy using ultrasound or stereotactic guidance. MRI-guided core needle biopsy can also be performed when lesions are not detected on ultrasound or mammography but these are more technically challenging. If cancer is identified, there should be a detailed pathologic assessment, including subtype and hormone receptor status. In cases with morphologically abnormal lymph nodes on ultrasound, fine needle aspiration biopsy or core biopsy of lymph nodes should be used.

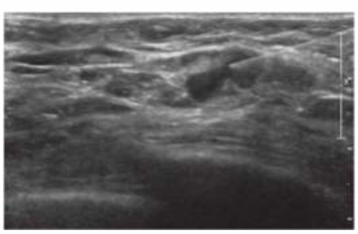

FIG 2 ● Ultrasound-guided fine needle aspiration of an axillary lymph node that revealed metastatic carcinoma in a male breast cancer patient who underwent an MRM.

- After any percutaneous biopsy, a marking clip should always be placed. This is extremely important in patients receiving neoadjuvant chemotherapy.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperatively, patients can be considered for regional anesthesia at the surgeon's and anesthesiologist's discretion. Paravertebral blocks (PVBs) are increasing in popularity for breast surgery and are more commonly favored over epidural blocks. They can be performed as single- or multiple-level injections or as a continuous catheter infusion. PVBs have been shown to shorten recovery times and length of hospital stays, decrease opiate usage, and decrease the incidence of vomiting. It is also hypothesized this type of regional anesthesia may protect the immune system and decrease metastasis.[4]
- PVBs are preferred over epidural blocks because they induce less hypotension, less urinary retention, are technically easy to learn, and have less severe side effects. Patients who are coagulopathic or who have musculoskeletal deformities such as kyphosis or scoliosis should not be considered for a PVB.[5,6]
- Potential complications associated with a PVB are pneumothorax, vascular penetrance, sepsis, and hematoma. Pneumothoraces are more common with multiple-level injections in comparison to single-level injections. Patients can either be seated with the spine in a kyphotic curve or placed in a lateral decubitus position (**FIG 3**). The local anesthetic is injected in the paravertebral space where the thoracic spinal nerves emerge.
- Ultrasound can also help guide the correct placement of the local anesthetic. Patient comfort improves when an ultrasound is used, and the pneumothorax rate decreases due to the direct visualization of the pleura.
- Before patients enter the operating theater, they should be site marked in the preoperative area to ensure the correct side is being operated on. Radiologic imaging should be thoroughly reviewed prior to the procedure to ensure the location of the tumor and the proximity of it to the skin.
- Prophylactic antibiotics have been shown to reduce postoperative infections and should be administered prior to incision.[7] Most surgeons prefer to avoid the use of paralytics during an MRM in order to aid identification of important motor nerves, but excessive handling of these nerves is discouraged to prevent axonal injury.

FIG 3 ● When performing a PVB, the patient can be seated with the spine positioned in a kyphotic curve. (Modified from Hebl JR, Lennon RL. *Mayo Clinic Atlas of Regional Anesthesia and Ultrasound-Guided Nerve Blockade*. Rochester, MN and New York, NY: Mayo Clinic Scientific Press and Oxford University Press; 2010. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

FIG 4 ● Positioning and draping of a patient for an MRM. (Modified from Donohue JH, Van Heerden J, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge, MA: Blackwell Science; 1995. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

FIG 5 ● The contralateral arm should contain the IV and blood pressure cuff.

- Prophylactic anticoagulants for prevention of venous thromboembolism (VTE), such as subcutaneous heparin, should be considered on a case-by-case basis. Sequential compression devices should be placed prior to initiation of general anesthesia for VTE prevention.

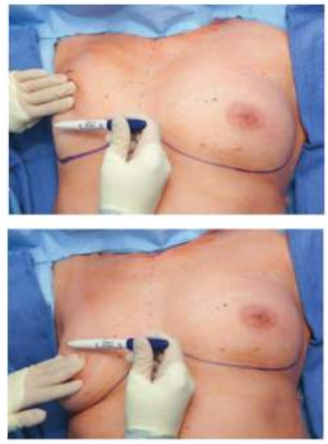
Positioning

- Correct positioning of patients undergoing an MRM is vitally important. Patients should be in a supine position with the side of the MRM close to the edge of the operating table. The endotracheal tube should be positioned toward the contralateral side of the mouth from the side of the MRM. Arms should not be abducted greater than 90 degrees to prevent injury to the brachial plexus. Arms should be placed on padded arm boards and positioned in a way that pressure points are alleviated. It is often helpful, particularly with bulky adenopathy, to prepare the ipsilateral arm into the field and wrap it with a sterile stockinette and Kerlix wrap (**FIG 4**). This allows for relaxation of the pectoralis muscles and easier access to the level II and III axillary nodes.
- The arm should be secured to the arm board. Blood pressure cuffs and intravenous (IV) lines should be placed in the contralateral upper extremity (**FIG 5**). Allow enough room between the operating table and anesthesiologist cart to allow an assistant to stand above the arm.
- Surgical preparation should include the breast and axilla and extend across the midline, inferiorly onto the abdomen, superiorly to the neck and the upper arm, and laterally to the level of the operating table. Draping should ensure preservation of a sterile field with exposure of the whole breast and axilla (**FIG 6**).

FIG 6 ● Draping should ensure preservation of a sterile field with exposure of the whole breast and axilla.

INCISION PLACEMENT

- There are many options for incisions for a total mastectomy that are based on the tumor location. In an MRM, it is important to have an incision that provides good exposure to the axilla and reduces skin redundancy. The incision should include the skin overlying the tumor in cases where the tumor is close to the skin and a 1- to 2-cm margin around the tumor and include the previous biopsy site.
- The classic Stewart incision is a transverse elliptical incision, provides access to the axilla, and is the preferred incision of many plastic surgeons for patients seeking delayed reconstruction (**FIG 7**).
- When mapping the incision, it is important to make sure there will be adequate skin for a tension-free closure without excess skin for redundancy (**FIG 8A,B**). Most of these patients will be receiving postmastectomy radiation, which can lead to incision breakdown, and this is increased when incisions are under tension. The boundaries of the breast (clavicle superiorly, inframammary fold inferiorly, sternum medially, and midaxillary line laterally) define the extent of the flap dissection.
- Measuring the length of the planned superior incision and inferior incision to ensure that these are equal in length can help guide adjustments to allow equal length skin flaps.



A

B

FIG 8 ● **A,B.** Measuring the distance from the superior to the inferior incision with a marking pen will help provide a tension-free closure and reduce skin redundancy.

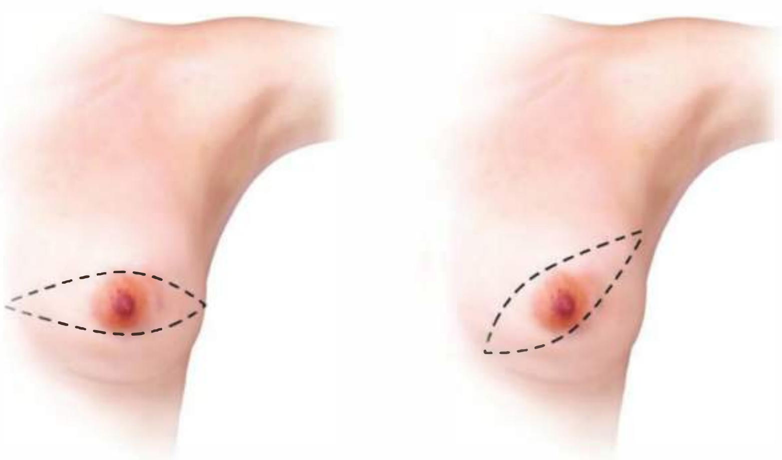


FIG 7 ● The two most common and preferred incisions for an MRM, which provide good axillary exposure. **Left:** Stewart incision. **Right:** Modified Stewart incision. (Modified from Donohue JH, Van Heerden J, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge, MA: Blackwell Science; 1995. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

SKIN INCISION AND CREATION OF FLAPS

- Once the skin incision has been mapped out on the breast, a scalpel is used to cut through the skin and dermis. A small edge of tissue is raised below the dermal layer to develop the flap (**FIG 9**). Skin hooks are used to provide traction for flap elevation, and these should be replaced with deeper retractors or lighted retractors when the dissection flaps are extended (**FIG 10**). Traction of the contralateral hand of the surgeon with a sponge also provides necessary tension for appropriate plane dissection. Flap dissection can be done sharply or with electrocautery, but electrocautery will provide better hemostasis during the dissection.
- The goal of flap elevation is to remove all the breast tissue while maintaining vascular supply to the flaps. The dissection plane should be developed between the breast tissue and subcutaneous fat. Frequently, there will be an avascular plane that can help guide in the dissection. It is important to keep traction on the breast to assist in finding the correct plane, and intermittent flap palpation should be performed to determine the correct thickness of the flaps. Flap thickness will vary among patients and is dependent on the patient's body habitus.

FIG 9 ● Raise an area of tissue under the dermis to begin the flap dissection. Using a sponge in the opposite hand can help provide traction, which will help in the flap creation.

FIG 11 ● The superior flap dissection is extended up to the clavicle where the underlying muscle can then be exposed.

- The superior flap should be extended up to the inferior border of the clavicle, and the medial flap should be dissected to the sternal border (FIG 11). When creating the medial flap, careful attention should be directed to the medial perforators. These perforators should be preserved where feasible to maintain vascular supply to the flap. When these need to be sacrificed, clips or suture ligation should be used to assure hemostasis. The lateral flap should be extended to the latissimus dorsi and the inferior flap should be dissected to the inframammary fold (FIG 12). It is important to avoid excess traction as the dissection is extended to avoid flap ischemia.

FIG 10 ● Joseph retractors or skin hooks are used at the beginning of the flap dissection. These should be switched out for deeper retractors as the dissection is extended.

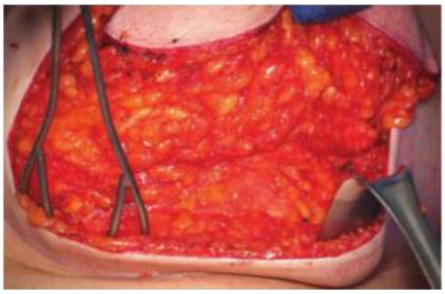

FIG 12 ● The inferior flap dissection is carried to the inframammary fold.

DISSECTION FROM THE PECTORAL MUSCLES

- When the flaps are completed to the appropriate landmarks, the breast tissue is dissected off the pectoralis muscle taking the pectoral fascia with the breast tissue using the electrocautery. The dissection should be started superiorly at the level of the clavicle. Traction should be applied with the contralateral hand to visualize the dissection plane (FIG 13).
- The dissection should continue inferiorly and in a medial to lateral fashion to follow the muscle fibers. The fascia surrounding the muscle should be dissected off with the breast in order to prevent local recurrence.[8,9] Careful attention should be provided to preserve the serratus anterior muscle fascia laterally and inferiorly and the rectus sheath fascia inferiorly. The axillary tail of the breast should remain attached in order to keep the breast and axillary contents as one pathologic specimen and also to guide the axillary dissection.

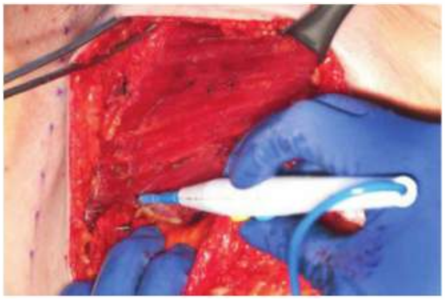

FIG 13 ● Dissection of the breast tissue off the pectoralis major muscle should be done with electrocautery in a medial to lateral fashion taking the pectoralis major muscle fascia with the specimen.

AXILLARY DISSECTION

- The axilla has a pyramidal shape and is located between the upper arm and thoracic chest wall. It is bounded superiorly by the axillary vein, anteriorly by the pectoralis muscle, medially by the serratus anterior muscle, and posterolaterally by the latissimus dorsi.
- The axilla can be reached when the breast tissue is positioned laterally and the dissection is continued under the pectoralis major muscle (**FIG 14**). The clavipectoral fascia should be incised along the edge of the pectoralis major muscle, which will free up the pectoralis major and minor muscle from the nodal tissue (**FIG 15**). Close attention should be paid to identify the medial pectoral neurovascular bundle. It sweeps laterally along the pectoralis minor, and care should be taken to preserve the bundle. The inferior border of the dissection should extend to the 4th or 5th rib to ensure that level I nodes are included in the specimen.[10]
- Once the axillary fat pad is encountered, the subcutaneous fat appears darker and is glistening. Once the axillary space is entered, it is vitally important to identify landmarks to guide your dissection and to prevent neurovascular injury. This ALND describes a lateral to medial approach to the axillary lymph node dissection. A medial to lateral approach is described in Part 5, Chapter 28.
- The first vital structure to identify is the thoracodorsal bundle, and this is facilitated by visualizing the latissimus dorsi laterally (**FIG 16**). The thoracodorsal nerve inserts approximately 4 cm inferior to the axillary vein, and the bundle can be followed superiorly to its posterior insertion on the axillary vein (**FIG 17**).
- The next step is to identify the axillary vein. Richardson retractors should be used at this time to provide exposure to the vein by retracting the pectoral muscles (**FIG 18**). The axillary vein can be easily identified using

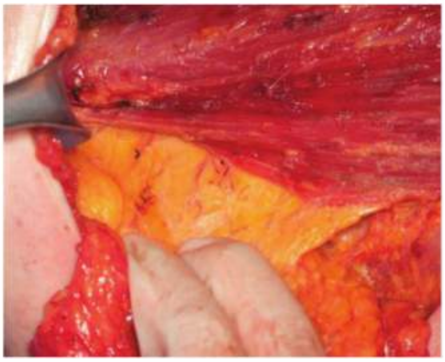

FIG 14 ● The axilla can be reached when the breast tissue is positioned laterally and the dissection is continued under the pectoralis major muscle, where the clavipectoral fascia is exposed.

FIG 15 ● The axillary fat pad is entered when the clavipectoral fascia is incised.

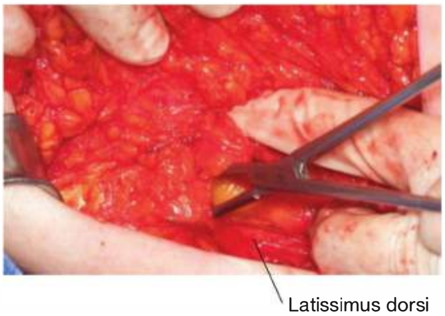

FIG 16 ● Dissect laterally to identify the latissimus dorsi muscle and enter axilla just anterior to latissimus dorsi to find the thoracodorsal bundle.

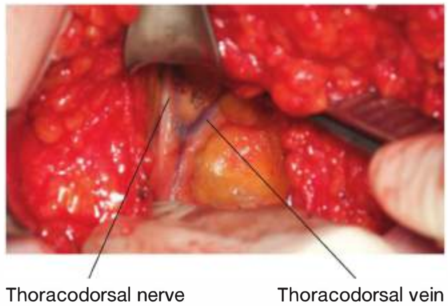

FIG 17 ● The thoracodorsal bundle.

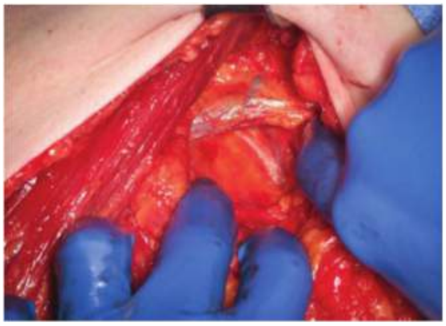

FIG 18 ● The Richardson retractor is used to expose the axillary vein by retracting the pectoral muscles. The thoracodorsal bundle is seen posterior to the axillary vein.

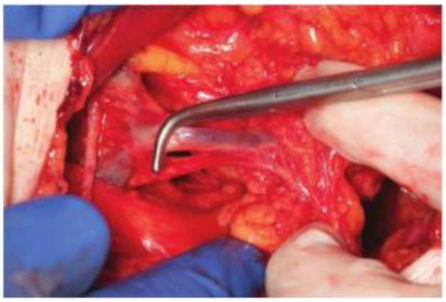

FIG 19 ● The thoracoepigastric vein is the only superficial tributary of the axillary vein and should be ligated with clips or ties.

blunt dissection of the axillary fat once the clavipectoral fascia has been divided. Once the vein is identified, the dissection should continue inferiorly to it. The nodal tissue superior to the axillary vein should be preserved to reduce lymphedema and brachial plexus injury. The thoracoepigastric vein is the only superficial tributary of the axillary vein and should be ligated with clips or ties (**FIG 19**). Before any ligation of this branch is performed, care must be taken to not mistake this vein for the thoracodorsal vein, which lies deep to it. All other lymphatic channels should be clipped and divided using scissors, and superficial branches of the axillary vein should be divided sharply between clips or sutures.

- Level II nodes are located underneath the pectoralis muscle, and level III nodes are located medial to the muscle. Level III nodes are rarely involved in most breast cancer metastasis and are not included in the traditional axillary lymph node dissection.[11] To gain access to the level II nodes, the Richardson retractor should retract the pectoral muscles medially. When placing the retractor deep under the muscles, pay careful attention to the medial pectoral bundle to prevent damage to these structures (**FIG 20A,B**). The dissection should continue to extend medially along the axillary vein, and the lymphatic tissue on the chest wall should be retracted inferolaterally. This tissue should be dissected off the chest wall with ties or clips to prevent lymphatic leaks.
- The long thoracic nerve lies along the chest wall and is superficial to the investing fascia of the serratus anterior muscle (**FIG 21**). This nerve can be difficult to identify, and palpation of this nerve can help to recognize it. The nerve feels like a string of spaghetti when running a finger along the serratus anterior muscle. Care should be taken to not retract the nerve off the chest wall with the specimen. If this nerve is inadvertently injured, it will cause patients to have a winged scapula. Dissection of the lymphatic tissue close to the nerve should be done with sharp dissection and not electrocautery.

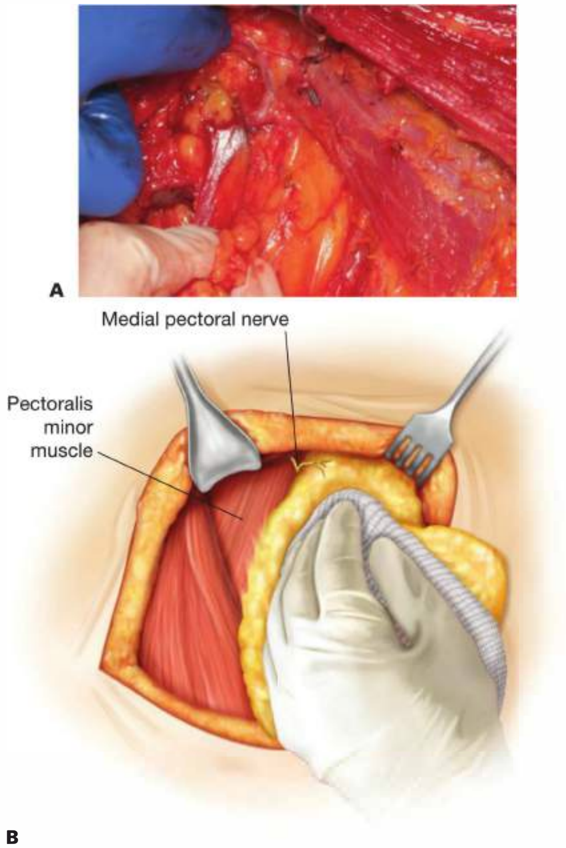

FIG 20 ● **A,B.** When placing the retractor deep under the muscles, pay careful attention to the medial pectoral bundle to prevent damage to these structures. The medial pectoral nerve wraps around the underside of the pectoralis minor muscle. (Part **B** modified from Donohue JH, Van Heerden J, Monson JRT, eds. *Atlas of Surgical Oncology*. Cambridge, MA: Blackwell Science; 1995. Used with permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

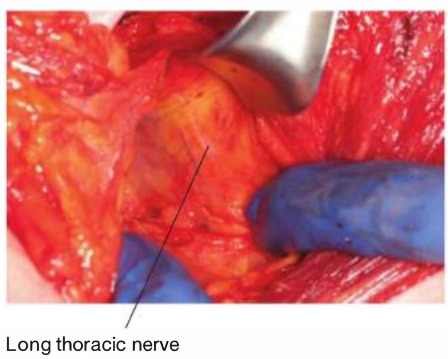

FIG 21 ● The long thoracic nerve lies along the chest wall and is superficial to the investing fascia of the serratus anterior muscle. Care should be taken to not pull the nerve laterally during the axillary dissection. The nerve can be difficult to identify and sometimes will only be felt on palpation. Running a finger along the lateral chest wall can aid in identifying the nerve.

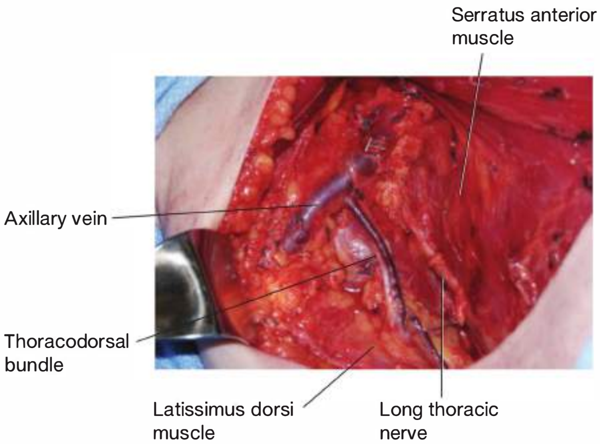

FIG 22 • The axilla after removal of level I and II lymph nodes, with thoracodorsal bundle and long thoracic nerve and axillary vein intact.

- The thoracodorsal bundle is found lateral to the long thoracic nerve. The lymphatic tissue between the two nerves should be dissected and removed. The thoracodorsal bundle should be skeletonized. Any lymphatic channels or superficial branches should be clipped or suture ligated. The branches of the thoracodorsal vein and artery entering the chest medially should be preserved where possible (**FIG 22**).
- Attempts should also be made to try to preserve the intercostobrachial nerves, but if the path of the nerve is directly through the specimen, it can be ligated (**FIG 23**). Patients should know that the intercostobrachial nerves may need to be sacrificed preoperatively, and explain to them that ligating the nerve will cause loss of sensation to their upper inner arm.
- The breast and attached nodal tissue should be excised en bloc by dividing the remaining lateral pedicle. The specimen should be sent to pathology with sutures placed for orientation (**FIG 24**).

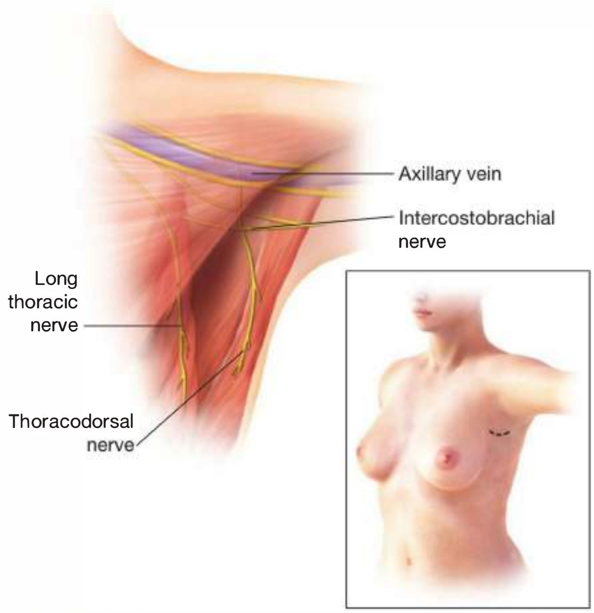

FIG 23 • Schematic drawing of the relationship of the axillary nerves to each other. The intercostobrachial nerves should be preserved if possible. (Modified from and used with permission of Mayo Foundation for Medical Education Research. All rights reserved.)

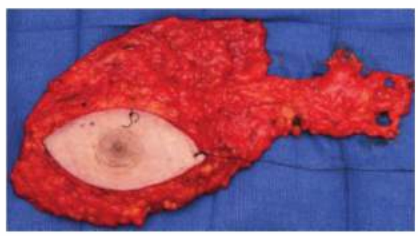

FIG 24 • Suture orientation should be done before the specimen is passed off to pathology. A short stitch should be placed superiorly and a long stitch laterally.

DRAIN PLACEMENT

- Two closed suction drains should be placed to prevent seroma formation. Studies have shown two drains are superior in comparison to one drain placed.[12] One drain should be placed over the pectoralis major muscle and the other drain should be placed in the axillary space (**FIG 25A,B**). The drains should be sutured in place with a monofilament suture and dressed appropriately based on surgical preference.

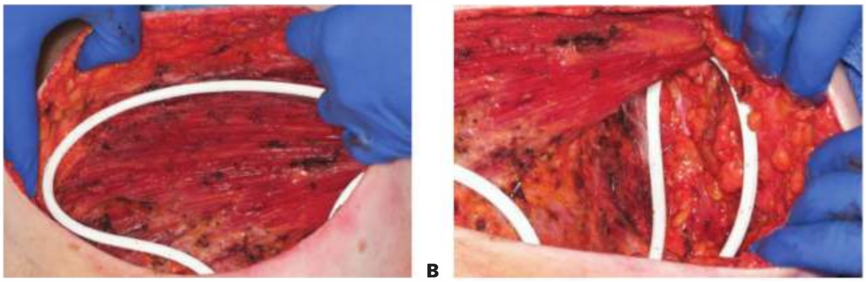

FIG 25 ● **A.** One drain should be placed over the pectoralis major muscle, **(B)** and the other should be placed in the axillary space. The drains should be secured to the skin.

CLOSURE

- A cosmetically pleasing closure is important for psychologic reasons. The goal is to provide a closure that will cause the chest to have a very flat appearance without excess skin redundancy.
- If the skin edges are traumatized, they should be excised with scissors or scalpel. Many times, dog ears appear at the medial and lateral edges of the incision. These should be excised to make the incision have a smoother and flatter appearance. The dermal layer should be closed with an inverted interrupted closure using absorbable suture. INSORB, an absorbable suture stapler, can also be used to close the dermal layer and is a faster alternative to traditional suture closure. The skin should be approximated with an absorbable 4-0 monofilament suture in a running subcuticular closure (**FIG 26**).

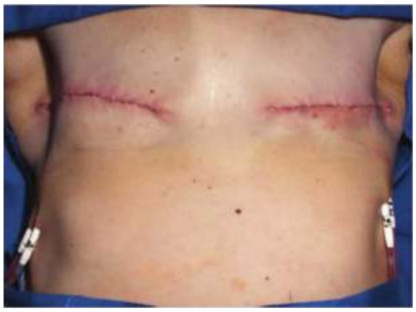

FIG 26 ● A cosmetic closure with a flat-appearing chest wall without skin redundancy is the goal.

PEARLS AND PITFALLS

Indications	■ A comprehensive history and physical examination should be undertaken, as well as review of the radiographic images of the breast and axilla and pathology from all biopsies. Patients with node-positive disease either not amenable to breast conservation or electing mastectomy are candidates for modified radical mastectomy, which encompasses a simple mastectomy together with an axillary lymph node dissection. ■ Once a cancer diagnosis is made, multidisciplinary coordination is essential for successful treatment planning.
Incision placement	■ When choosing an incision for a modified radical mastectomy, the goal is to provide great exposure to the axilla and a good cosmetic outcome. ■ The incision should include a 1- to 2-cm margin around the tumor (if close to the skin) and include the previous biopsy site. ■ The classic Stewart incision is the preferred incision for a modified radical mastectomy providing the necessary exposure and cosmetic outcome.
Flap dissection	■ Flaps should be extended to the borders of the breast tissue. Careful attention needs to be paid to ensure all the breast tissue is resected and the vascular supply to the remaining skin flaps is preserved to avoid flap ischemia.
Axillary lymph node dissection	■ Careful identification of vital structures and the axillary borders will define the dissection. ■ Close attention needs to be paid to the preservation of the axillary vein, thoracodorsal bundle, and long thoracic nerve during the dissection.

Closure	■ The goal is to reduce skin redundancy and create a smooth flat incision. Avoid medial and lateral dog ears. Two closed suction drains should be placed to avoid seroma.
Rehabilitation	■ Patients should have access to counseling or therapy to help in coping with issues of body image. Patients who do not desire reconstruction should also be set up to be fitted for a breast prosthesis. ■ All patients should meet with a lymphedema specialist to coordinate an exercise plan and be provided with compression garments if needed.

POSTOPERATIVE CARE

- Patients after an MRM should be placed in a breast binder or an Ace wrap following their surgery (**FIG 27**). This will provide good compression to prevent development of any hematoma. Steri-Strips or Xeroform dressing can be placed directly over the incisions. Fluffs or Kerlix gauze can be placed over the incision to act as a barrier between the incision and binder.
- Patients who have undergone an MRM will face a variety of rehabilitation issues pertaining to lymphedema, body image, and sexual dysfunction. It is important to have all these concerns addressed preoperatively, during their hospital stay, or at follow-up appointments. The most dreaded complication of having an axillary lymph node dissection is lymphedema. All patients should be scheduled to meet with a lymphedema therapist approximately 2 weeks from their surgery or after drain removal. The therapists can help educate patients on lymphedema and how to prevent the complication and provide them with exercises to avoid restricted shoulder range of motion.
- Patients who have undergone MRM without reconstruction should be referred to be fitted for a breast prosthesis after the drains are removed and the swelling has gone down.

OUTCOMES

- Patients who undergo an MRM are at risk for developing secondary lymphedema. This is one of the most dreaded fears of many breast cancer survivors, and many women are not educated on this complication preoperatively.
- Many patients undergoing an MRM will require postmastectomy radiation. The addition of radiation after a nodal dissection can substantially increase the risk of development of lymphedema to over 40%. Successful diagnosis and treatment of patients suffering from lymphedema should focus on risk-reducing therapies and lifelong self-directed care.[13,14]
- Survival outcomes in patients undergoing MRM are not based solely on the operative procedure but dependent on the tumor stage, nodal stage, and tumor biology. Studies have shown in node-positive patients that the number of positive lymph nodes, patient age, tumor grade, and race are significant variables to affect survival.[15]

FIG 27 ● Patients should be wrapped in an Ace binder or a breast binder to provide compression. The drains should be in view to monitor output and consistency.

COMPLICATIONS

- Seroma
- Wound infection
- Hematoma
- Wound dehiscence
- Flap necrosis
- Positive margins
- Brachial plexus injury
- Nerve injury
- Winged scapula
- Axillary vein thrombosis
- Lymphedema

Chapter 13

Techniques for Correcting Lumpectomy Defects

Julie E. Park Jonathan Bank David H. Song

DEFINITION

- Breast conservation therapy (BCT), the combination of lumpectomy and breast radiation, allows women with breast cancer to avoid mastectomy without compromising outcome. Although the majority of women will have an excellent cosmetic outcome, some women will develop asymmetry from volume loss and postradiation contour deformity and nipple–areolar complex (NAC) deviation. Several techniques exist for correcting lumpectomy defects to allow for oncologically sound and aesthetically acceptable BCT.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In some situations, the plastic surgeon is asked to evaluate the patient prior to lumpectomy in order to plan for an immediate correction. In other situations, the patient is referred to plastic surgery after radiation therapy for correction of postradiation contour deformity and NAC deviation.
- It is important to discuss with the patient her expectations; specifically, whether she would accept a smaller breast.
- Does the patient have symptomatic macromastia and would she benefit from, or be interested in, breast reduction?
- Does the patient smoke? This might impact nipple perfusion.
- A thorough breast examination should take note of the breast size and any preexisting asymmetry. Any previous scars or contour deformities should be noted, especially in women who have already completed BCT.
- It is also important to document the position of the nipple, including any ptosis, and the distance from the sternal notch.
- For patients anticipated to have a significant deformity from BCT, a multidisciplinary approach is critical to achieving the optimal cosmetic outcome. Communication with the surgical oncologist is critical to both identifying appropriate patients, planning the site and expected volume of resection, and coordinating schedules. It is important to identify with the radiation oncologist if the patient will require a "boost," as this will limit how much tissue can be rearranged. In cases of wire-localized lumpectomy, marks should be placed prior to wire placement and this should be coordinated with the breast radiologist.

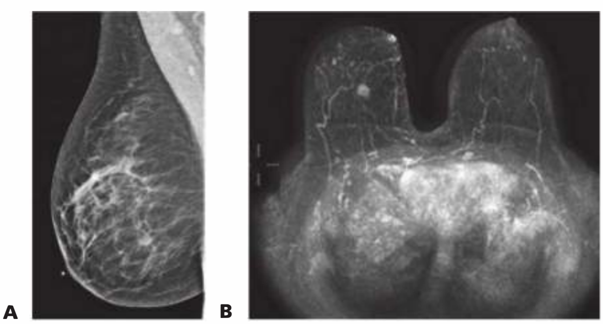

FIG 1 ● Mammogram **(A)** and MRI **(B)** of patient with 1.1 × 1.0 × 0.8 cm right-sided breast cancer at 5 o'clock position.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Almost all patients who have undergone BCT should have had bilateral mammography as part of the workup (**FIG 1A**), and some women may have had magnetic resonance imaging (MRI) (**FIG 1B**).

SURGICAL MANAGEMENT

Preoperative Planning

- The goals of correcting lumpectomy defects include obliterating any dead space, supporting the NAC and maintaining adequate perfusion, and resecting any excess skin.
- There are two main options for reconstructing a lumpectomy defect. ***Volume displacement*** techniques use parenchymal remodeling (volume shrinkage). ***Volume replacement*** techniques use both local and distant tissue to preserve volume.
- After reviewing the preoperative imaging and discussing with the surgical oncologist, the next question is whether given the size and location of the tumor, will there be sufficient tissue in the breast to rearrange and obliterate dead space without losing too much volume?
  - Yes—volume displacement: reduction, mastopexy, or intrinsic breast flaps
  - No—volume replacement: local rotational flaps
    - Thoracodorsal artery perforator (TAP) or muscle-sparing latissimus dorsi (MSLD) flap
    - Lateral intercostal artery perforator (LICAP) flap

Positioning

- The patient is positioned supine with the arms secured to the arm boards at the side to allow for sitting the patient up during the surgery (**FIG 2**). The arms should be place on padded arm boards and positioned in a way that pressure points are alleviated.

FIG 2 ● Positioning of a patient with both arms abducted, padded, and secured, enabling seating the patient during surgery to assess for symmetry of reconstruction.

FREESTYLE INTRINSIC BREAST FLAPS

- For some defects, dermatoglandular flaps can be created to fill small defects. Depending on the location, even small defects can lead to unfavorable cosmetic results, particularly a significant concavity at the site of the lumpectomy after radiation. This can occur when there is minimal tissue between the skin and underlying muscle.
- The principle of intrinsic breast flaps is to focus on perfusion and support to the NAC and to obliterate the dead space.
- The lumpectomy cavity is examined to evaluate how much dead space there is and the remainder of the breast is assessed for where there is extra tissue (**FIG 4A**). An intrinsic breast flap is created by dissecting between the skin and breast parenchyma and between the breast parenchyma and pectoralis (**FIG 4B**). The flaps are based either on axial blood supply from perforators originating from the internal mammary artery or from the intercostal vessels. As these vessels are not typically identified in the dissection, the flaps should be created as random pattern flaps, adhering to the principles of creating broad-based flaps that are not too lengthy as to put the distal tip of the flap at risk of ischemia. The flap is then advanced and secured to fill the lumpectomy cavity and to maintain support to NAC (**FIG 4C**).
- Any excess skin is resected and the wound is closed.

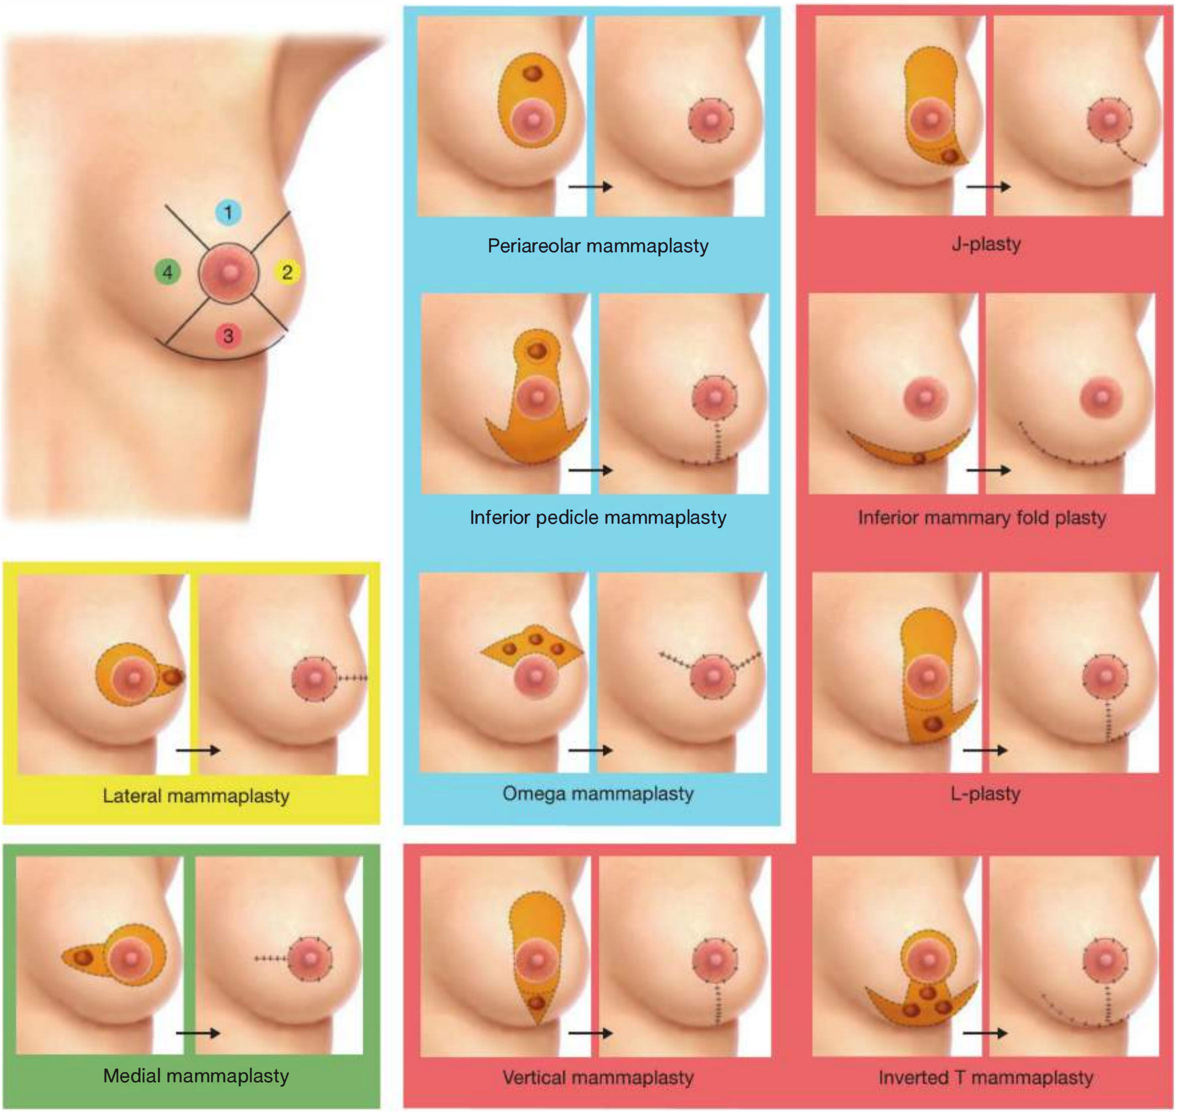

FIG 3 ● There are multiple options for skin incisions for resections depending on the location of the defect, size of the defect, and size of the breast.

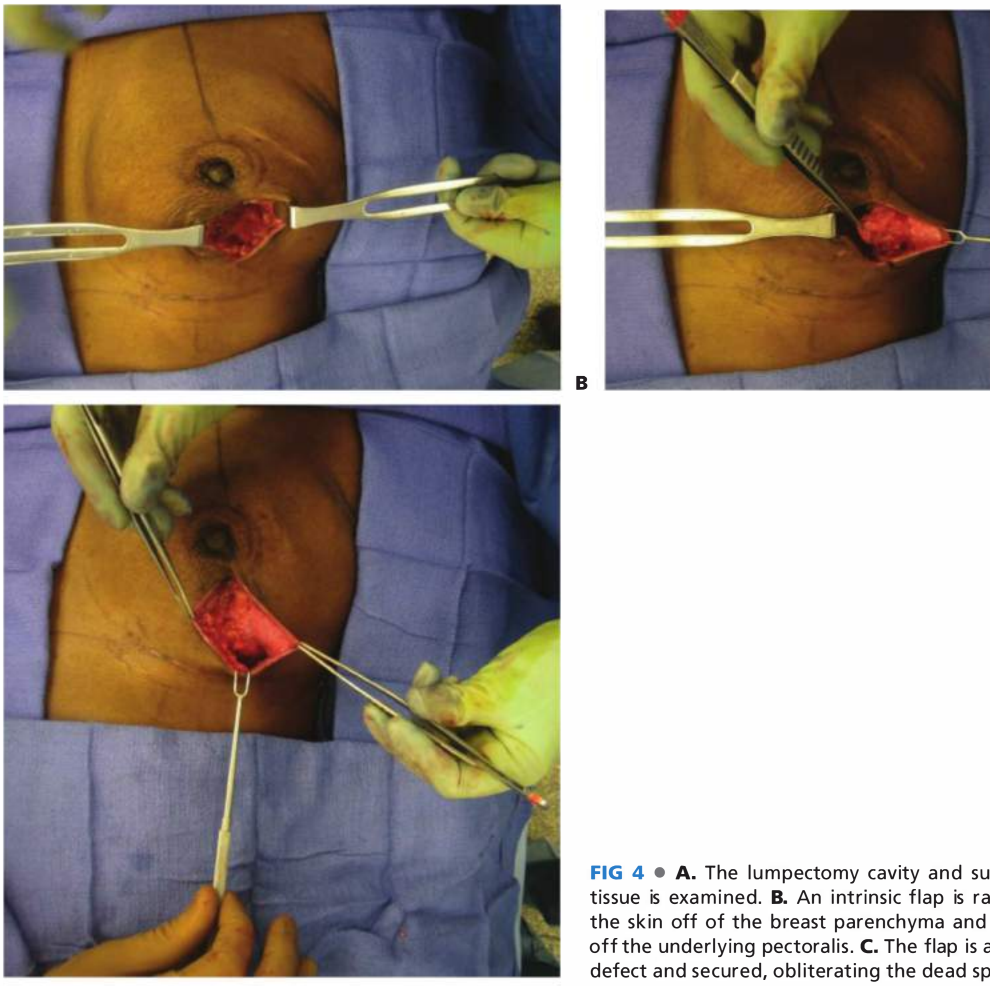

FIG 4 ● **A.** The lumpectomy cavity and surrounding breast tissue is examined. **B.** An intrinsic flap is raised by elevating the skin off of the breast parenchyma and the breast tissue off the underlying pectoralis. **C.** The flap is advanced into the defect and secured, obliterating the dead space.

INFERIOR POLE LUMPECTOMY DEFECTS—THE VERTICAL MAMMAPLASTY TECHNIQUE

Preoperative Marking

- This approach is an option for patients with lumpectomy defects from approximately 4 o'clock to 8 o'clock positions.
- For patients with appropriately sized breasts, a vertical reduction pattern is marked out on the breast (**FIG 5**). Alternatively, an inverted T pattern can be used.
- With the patient in the upright position, landmarks are drawn—sternal notch, midline, and breast meridians. The new position of NAC is marked out, along with any excess skin as follows: the breast mobilized laterally, vertical line drawn medially, then the breast mobilized medially, vertical line drawn laterally. The vertical components connected with curved line 2 to 4 cm above

FIG 5 ● A vertical reduction pattern.

the inframammary fold (IMF). A mosque-shaped marking is drawn for inset of NAC.

Assess Lumpectomy Defect and Nipple–Areolar Complex

- In the operating room, the prior lumpectomy cavity is opened and the seroma evacuated. As there will no longer be a seroma to guide radiation, it is a good idea to place several small clips at the boundaries of the lumpectomy defect.
- Confirm perfusion and support to NAC and make sure that the lumpectomy cavity is not undermining the NAC. If it is, you need to plan on supporting it with intrinsic breast tissue. If this is not possible, a free nipple graft (FNG) will be needed: The NAC is excised as a full-thickness skin graft, defatted, replaced on a well-vascularized bed in the appropriate position on the breast mound, and secured in place with a bolster dressing.

Convert to Vertical Reduction

- Additional (i.e., more than the lumpectomy) breast tissue is resected as needed to allow for an acceptable final shape. Undermining of the breast off of the pectoralis is usually confined to inferior breast. Tissue is resected medial and lateral to vertical incision to allow "rounding off" of the breast. The parenchyma is approximated centrally (approximating the medial and lateral remaining portions of the breast—the medial and lateral "pillars").
- Skin closure—excessed gathered in subcuticular closure. A small horizontal excision is made along the IMF if needed to further reduce the skin.
- This approach will result in volume loss, so a contralateral reduction will be needed in the future, approximately 3 to 6 months after radiation therapy has been completed.

VOLUME REPLACEMENT PEDICLED FLAPS

- For patients with larger defects for which displacement techniques would not work, replacement techniques may be necessary. Pedicled flaps are recommended. Free tissue transfer is not initially recommended in this situation, as it eliminates the use of a flap in the future should the patient have a local recurrence or new tumor and require a mastectomy. Free flaps should only be considered if pedicled flaps are not feasible or fail.
- Flaps can be raised from the axillary and back region (thoracodorsal, intercostal) or from the upper abdomen (superior epigastric). The two most common types of pedicled flaps are (**FIG 6**) as follows:
  - Thoracodorsal artery perforator (TAP) flap, which is based on the perforators from the descending or the horizontal branches of the thoracodorsal vessels. This is most suitable for superior defects.
  - LICAP flap, which is based on perforators arising from the costal groove. This is a good alternative to the TAP flap for lateral and inferior breast defects.
  - Defects in the medial quadrant can be approached via an anterior intercostal artery perforator (AICAP) flap, which is supplied by perforators originating from the muscular segment, or the superior epigastric artery perforator (SEAP) flap, based on perforators from the superior epigastric. These are not described here.

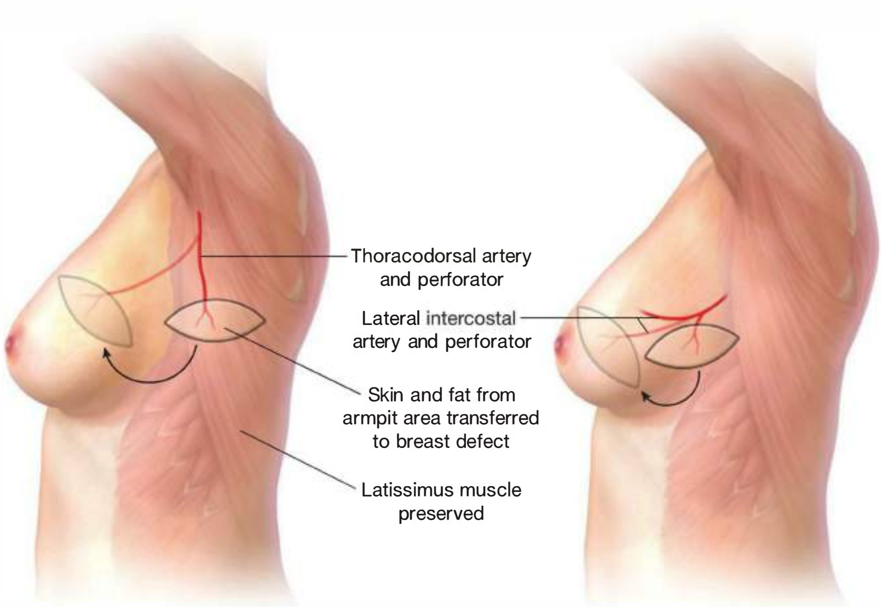

FIG 6 ● The TAP and LICAP flaps.

SUPERIOR-LATERAL LUMPECTOMY DEFECTS—THE THORACODORSAL ARTERY PERFORATOR FLAP OR MUSCLE-SPARING LATISSIMUS DORSI FLAP

Preoperative Marking

- Preoperatively, the patient should be marked in the supine and upright position. Several anatomic landmarks should be identified and marked.
    - The borders of the breast, including the IMF, should be marked. The ideal position of the NAC should be drawn using the contralateral breast as a template. This will need to be adjusted accordingly if there is a plan to either lift or reduce the contralateral breast.
    - Identify and mark the tip of scapula and the anterior edge of the latissimus dorsi muscle.
    - A ***pinch test*** should then be performed to determine the amount of redundant skin in order to determine the size of flap.
- The perforator will determine the viability of the flap and knowing its location will reduce operating time and complications. The perforator emerges approximately 8 to 10 cm from the posterior axillary crease and 2 cm posterior to anterior border of the latissimus (**FIG 7**). This can be confirmed and the perforator marked in the preoperative area with a Doppler ultrasound device.
- Based on this exam, the surgeon should anticipate how to orient the flap.
    - Horizontal—"bra line"
    - Obliquely—line of relaxed skin tension
    - Vertically—along anterior edge of latissimus

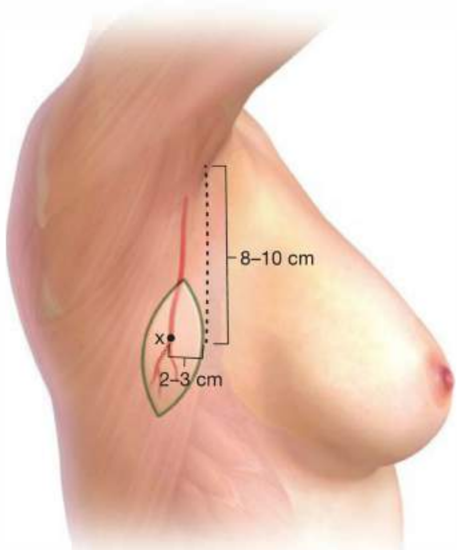

FIG 7 ● The patient is placed in the lateral decubitus position to locate the perforators and design the flap. The *dotted line* is the anterior border of the latissimus dorsi muscle. "X" marks the main perforator artery for the flap, located 2 to 3 cm from the anterior margin of latissimus and 8 to 10 cm from the posterior axillary crease.

Intraoperative Assessment and Creation of Lateral Tunnel

- The patient should be placed on a beanbag. Initially, the patient will be supine. Both breasts are sterilely prepped into the field.
- The prior cavity should be opened and the seroma evacuated. At this point, multiple small clips are placed to mark all the boundaries of the lumpectomy defect. These are important for radiation oncology to know where the lumpectomy cavity was, as there will no longer be a seroma for guidance.
- The NAC should be examined to confirm perfusion and support. It is important to make sure the lumpectomy is not undermining the NAC. Otherwise, this will require support with intrinsic breast tissue. If there is insufficient tissue for perfusion, an FNG may be necessary.
- Assess the total volume of tissue that will be needed to fill the space.
- A tunnel is then created from the lumpectomy cavity to the anterior edge of the latissimus muscle.
- Once the latissimus muscle is identified, the skin edges are temporarily reapproximated with skin staples and the wound is covered with a large sterile occlusive dressing (i.e., Ioban).

Flap Creation

- The patient is repositioned in the lateral decubitus position. All pressure points are appropriately padded and the operative field is again sterilely prepped and draped.
- The perforating vessels are identified using a handheld pencil Doppler. Once the perforators have been identified, the flap position is adjusted as necessary.
- The skin of the flap is incised with a scalpel, beveling so as to capture as much sub–Scarpa's fat as needed. Dissection is then carried down to the muscle.
- Dissect from the midline anteriorly until the perforators are identified (**FIG 8**). The latissimus dorsi fascia should be included with the flap. Complete dissection from anterior to midline is necessary to isolate the perforators.

FIG 8 ● The latissimus dorsi muscle is completely dissected from anterior to midline in order to identify the perforators.

- At this point, it becomes necessary to decide between a TAP flap and an MSLD flap based on the perfusion of the tissues, especially the venous drainage.
  - For a TAP flap, just one perforator is isolated. The muscle is then split and the descending branch of the thoracodorsal artery is dissected to the takeoff point of the transverse branch of the thoracodorsal.
  - For an MSLD flap, multiple perforators within 1 to 3 cm of the anterior edge of the latissimus need to be captured. Harvest the descending branch of the thoracodorsal artery at the takeoff point of the transverse branch.
- Once the flap has been created (**FIG 9**), a drain is placed and the skin is reapproximated. Sterile dressings are applied.

Flap Insertion

- The patient is repositioned supine, with the arms secured to the arm boards to that the table can be flexed and the two breasts compared with the patient in the upright position.
- The flap is inset in order to fill the volume defect. It is important that the NAC be supported.
- It is often necessary to de-epithelialize the skin, but a small skin island should be maintained in order to monitor the flap. The patient should be monitored in the hospital for 1 to 2 days postoperatively (**FIG 10**).

FIG 9 ● Once the flap has been elevated, a drain is placed and the skin is reapproximated. The patient is then repositioned supine.

FIG 10 ● After a poor outcome with a superior lateral lumpectomy **(A–C)**, the defect was corrected using a TAP **(D–F)**.

LATERAL LUMPECTOMY DEFECTS—THE LATERAL INTERCOSTAL ARTERY PERFORATOR FLAP

Preoperative Markings

- The borders of the breast, including the IMF, should be marked. The ideal position of the NAC should be drawn, using the contralateral breast as a template. This will need to be adjusted accordingly if there is a plan to either lift or reduce the contralateral breast.
- Identify and mark at least 5 cm posterior to axillary line at the level of the future defect. (This marking is posterior to the LICAP and thus will ensure inclusion of the perforator in the flap.)
- Mark perforator with handheld pencil Doppler.

Intraoperative Assessment

- The patient is placed supine with a beanbag on the table. Both breasts are prepped and draped into the field.
- The prior lumpectomy cavity is opened and the seroma is evacuated. Multiple small clips are placed to mark all the boundaries of the lumpectomy defect. These are important for radiation oncology to know where the lumpectomy cavity was, as there will no longer be a seroma for guidance.
- Assess the total volume of tissue that will be needed to fill the space.
- The NAC should be examined to confirm perfusion and support. It is important to make sure the lumpectomy is not undermining the NAC. Otherwise, this will require support with intrinsic breast tissue.
- The skin is then temporarily closed with staples and covered with a large sterile occlusive dressing (i.e., Ioban).

Locate Perforators

- The patient is repositioned in the decubitus position. All pressure points are carefully padded and the patient is sterilely prepped and draped.
- A handheld pencil Doppler is used to locate the perforators. It may be necessary to adjust the flap position based on the location of the perforators.

Make Skin Incision

- An elliptical incision starting approximately 5 cm posterior to the axillary fold is created at the level of the defect.
- Bevel to capture as much of the sub–Scarpa's fat as needed, and then the incision is deepened to expose the latissimus dorsi muscle.

Identify Perforators

- The dissection is carried from the midline in the anterior direction until the perforators are found. The smaller posterior branch of the lateral cutaneous branch will be identified at the anterior border of the latissimus and this can be traced to find the larger anterior branch (FIG 11).
- The latissimus dorsi muscle belly is retracted and a pedicle of 3 to 5 cm is obtained. This is adequate to reach a defect over the lateral or superior part of the breast. The fascia should be harvested into the flap as well.
- A Jackson-Pratt (JP) drain is placed, the incision closed, and the donor site is dressed.

Rotate the Flap Anteriorly and Inset

- The patient is repositioned supine with the arms secured to the arm boards so that the table can be flexed and the breasts compared with the patient sitting upright. The patient is again prepped and draped.
- The flap is now inset in order to fill the volume defect (FIG 12). It is important to support the NAC as needed.
- A good portion of the skin may need to be de-epithelialized, but it is important to leave a skin island in order to monitor the flap (FIG 13). The patient should be monitored for 1 to 2 days postoperatively.

FIG 11 ● The smaller posterior branch of the lateral cutaneous branch will be identified at the anterior border of the latissimus and this can be traced to find the larger anterior branch.

B

FIG 12 ● The LICAP flap is now inset in order to fill the volume defect.

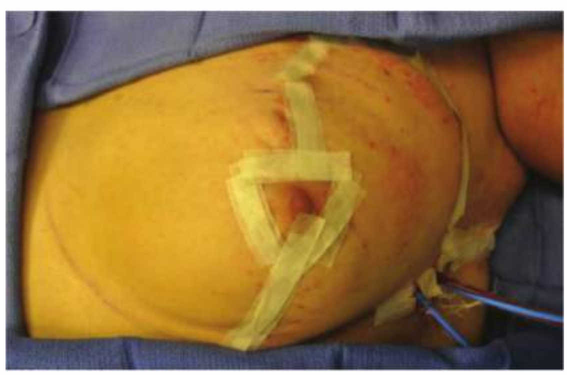

FIG 13 ● After the flap is inset, the skin is de-epithelialized except for a small skin island and the skin is then reapproximated.

CENTRAL LUMPECTOMY INCLUDING THE NIPPLE–AREOLAR COMPLEX

Preoperative Marking

- With the patient in the upright position, the new position of NAC is marked out, along with any excess skin.
- An inferior pedicle reduction pattern is marked out (**FIG 14**).

Assess Lumpectomy Defect and Nipple–Areolar Complex

- In the operating room, the prior lumpectomy cavity is opened and the seroma evacuated. As there will no longer be a seroma to guide radiation, it is a good idea to place several small clips at the boundaries of the lumpectomy defect.

Convert Reduction with Inferior Pedicle

- An inferior pedicle is designed to convert this to a reduction (**FIG 15**).
- A neoareola is created by leaving a skin paddle on the pedicle that will fill in the previous NAC when the pedicle is advanced superiorly.
- An inferior pedicle is created and advanced superiorly. Blood supply emanates from pectoral perforators from thoracoacromial artery. The pedicle design has a 3:1 ratio of length:width with a 30-cm maximal length.

FIG 14 ● An inferior pedicle reduction pattern.

FIG 15 ● After the lumpectomy and NAC have been removed, an inferior pedicle reduction pattern is designed.

FIG 16 ● A neoareola has been created by leaving a skin paddle on the pedicle and brought out through the new NAC space.

- The skin paddle is brought out in the previous NAC space.
- The excess skin and tissue is excised and the remaining skin is reapproximated (**FIG 16**).

Creation of New Nipple–Areolar Complex

- Three to 6 months after radiation therapy is completed, the patient returns to the operating room for nipple reconstruction as per standard techniques for total breast reconstruction (see Part 5, Chapter 20). They will also require a contralateral symmetry procedure at that time (**FIG 17**).

FIG 17 ● After the patient has undergone nipple–areolar reconstruction and contralateral reduction.

PEARLS AND PITFALLS

Timing 6 to 8 weeks to radiation therapy from lumpectomy	■ Evaluate patient prior to lumpectomy. ■ Schedule cases simultaneously. ■ Discuss incision location with oncologic surgeon.
Adjust for postradiation contractures	■ Likely will have a superior lift—do not err on placement of nipple being too high.
Not as much time for resolution of inferior dog ear	■ Excise as needed.
Delay contralateral reduction if possible.	■ Keeps healthy breast tissue out of the field of radiation
Postlumpectomy edema affecting venous perfusion, especially of NAC	■ Good breast support after lumpectomy ■ Convert to FNG as needed.
Will lumpectomy resection allow for NAC pedicle?	■ FNG as needed
Unsure about volume?	■ Evaluate the lumpectomy during first surgery.

POSTOPERATIVE CARE

- Monitor any flaps for at least 1 to 2 days in the hospital.
- Surgical support bra
- Immediate response to any wound dehiscence or breakdown to avoid delay to radiation therapy
- Consider drain placement to limit postoperative edema (limited time to get patient to radiation therapy)

COMPLICATIONS

- Fat necrosis
- Wound healing complications
- Potential delay to radiation therapy

Chapter 14

Direct-to-Implant Breast Reconstruction

Amy S. Colwell

DEFINITION

- Mastectomy is increasingly performed for breast cancer treatment or risk reduction in high-risk patients. The goal of breast reconstruction is to rebuild the breast and restore a sense of normalcy.

ANATOMY

- The breast glandular tissue extends to the clavicle superiorly, the inframammary fold (IMF) inferiorly, sternum medially, and latissimus dorsi laterally (**FIG 1**). With a skin-sparing or nipple-sparing mastectomy, the glandular tissue is removed and the skin is spared, thus making direct-to-implant breast reconstruction possible. In implant-based breast reconstruction, a space is created underneath the pectoralis muscle, and the serratus anterior is sometimes used to help define the lateral border of the reconstructed breast (**FIG 2**).

NATURAL HISTORY

- Mastectomy offers potential cure in breast cancer patients and prevention for those at high risk for cancer. Immediate breast reconstruction offers an improvement in health-related quality of life and patient satisfaction for women choosing mastectomy as part of their treatment plan.[1–3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient selection in immediate direct-to-implant breast reconstruction is one of the keys to success. A history is obtained to check for comorbidities that are known risk factors for increased complications including smoking, diabetes, body mass index (BMI), and previous breast radiation. On physical exam, the breast is assessed for skin quality, size, scars from previous procedures, symmetry, position of the IMF, and nipple position if a nipple-sparing mastectomy is being considered.

DIFFERENTIAL SURGICAL TREATMENT OPTIONS

- Two-stage tissue expander–implant reconstruction
- Autologous reconstruction using tissue from the body including the abdomen (TRAM, transverse rectus abdominis myocutaneous; DIEP, deep inferior epigastric perforator; SIEA [superficial inferior epigastric artery] flaps), buttocks (SGAP, superior gluteal artery perforator; IGAP [inferior gluteal artery perforator] flaps), thighs (TUG [transverse upper gracilis] flap), and back (latissimus dorsi)
- Fat transfer
- No, or delayed, reconstruction

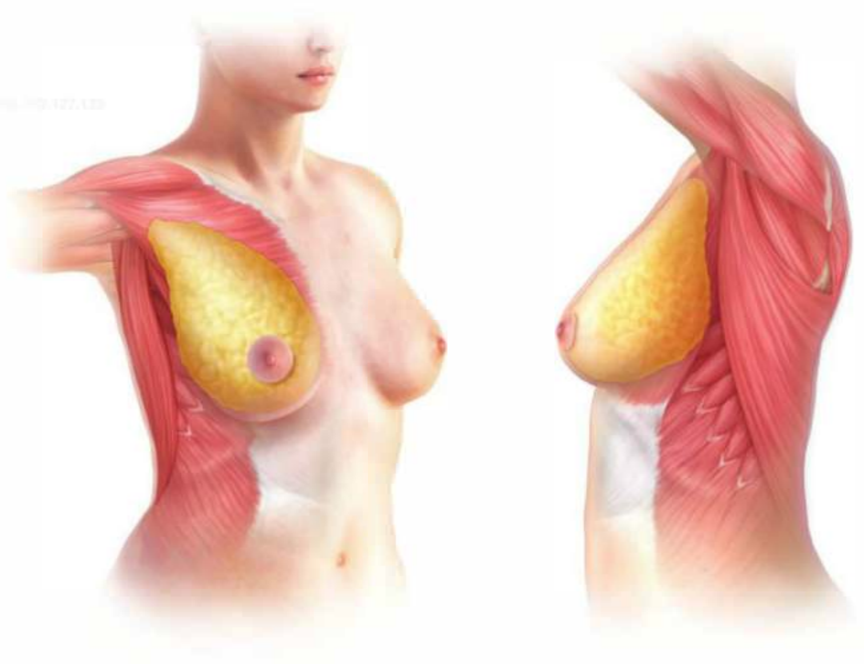

FIG 1 ● The anatomic boundaries of the breast are the clavicle, sternum, inframammary fold, and latissimus dorsi.

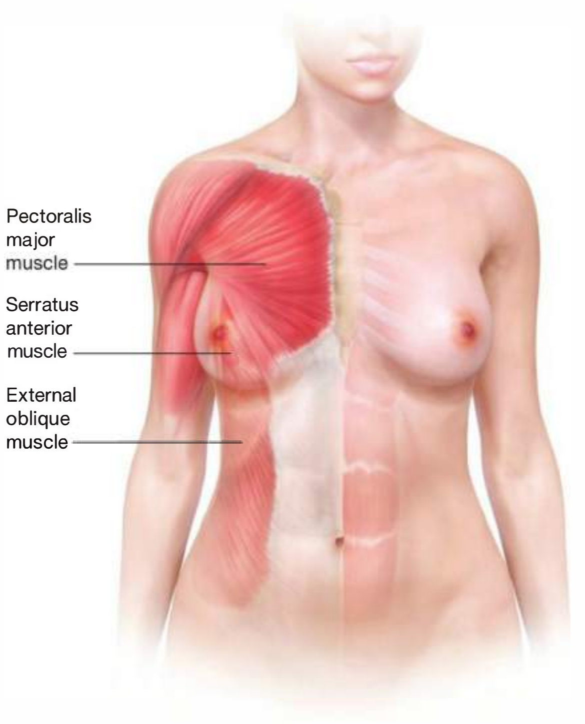

FIG 2 • A plane is created under the pectoralis muscle for implant placement. The pectoralis thus covers the implant superior and medially. The serratus muscle is sometimes elevated for lateral coverage or support.

NONOPERATIVE MANAGEMENT

- Breast reconstruction is a choice, and patients undergoing mastectomy may not elect to pursue reconstruction. If no reconstruction is planned, the breast skin is closed and the chest remains flat in contour. If desired, external breast prostheses are available for women to wear in their clothing to give the appearance of a breast.

SURGICAL MANAGEMENT

- The goals of reconstruction are considered in determining if the reconstruction is designed to augment, reduce, or maintain the current breast size. In general, if a woman wants a significant increase in breast size, this is more safely done in two stages using a tissue expander followed by exchange to implant in a second surgery (see Part 5, Chapter 15). For single-stage implant reconstruction, the implant is placed directly in a partial subpectoral pocket in order to allow superior soft tissue coverage with muscle in the cleavage area of the breast and to help prevent contracture around the implant.[4] The implant is subcutaneous inferiorly, which allows a more natural teardrop shape, and is typically supported by a surgical acellular dermal matrix (ADM) or mesh. Currently, the most common ADM is AlloDerm (human dermis, LifeCell, Branchburg, NJ), but a variety of ADM or mesh material derived from human dermis, porcine dermis, bovine pericardium, fetal bovine dermis, silk, titanium, and Vicryl exist.

Preoperative Planning

- With immediate implant reconstruction, a foreign body (implant) is placed into a skin envelope that has been partially devascularized with the mastectomy. Therefore, sterility is an important component of preoperative planning and operative management. The patient sits upright and is marked prior to the procedure. Important landmarks include the IMF position, its relation to the IMF on the contralateral breast, and the lateral border of the breast. The mastectomy portion of the procedure is performed first followed by the reconstruction.

Positioning

- The patient is positioned supine with the arms secured on arm boards at the side, angled approximately 80 to 85 degrees from the operating table (**FIG 3**). This allows access to the axillary lymph nodes for sampling during the mastectomy. Both breasts are prepped and draped into the field.

Approach

- The mastectomy and reconstruction may be performed using various incisions. If a nipple-sparing approach is chosen, the safest option is to use a radial lateral incision extending from the areola toward the axilla without a full-thickness incision around the nipple. The incision that maximizes cosmesis is an inferolateral or standard IMF incision under the breast.[5] For skin-sparing mastectomies, the incision is made around the areola and extended laterally if needed for access. For larger breasts, a skin-reducing pattern is designed to remove excess skin in a vertical or horizontal direction. The inverted T/Wise/anchor skin pattern is typically avoided (secondary to higher risk of skin necrosis and complications). The pectoralis muscle is partially released inferiorly to accommodate the implant size and allow more natural breast shape. The challenge of direct-to-implant breast reconstruction is in replacement of the breast volume with an implant that closely matches the breast base diameter but without placing undue stress on the breast skin envelope. If this cannot be achieved in one stage, a two-stage approach is used with a tissue expander intermediary step.

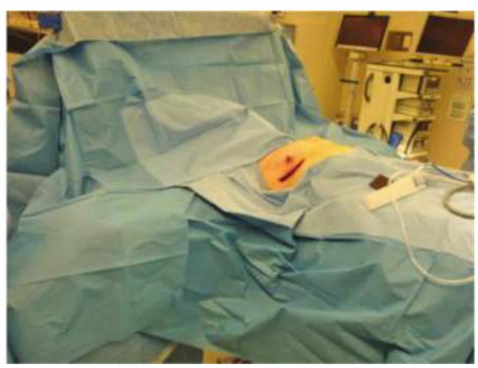

FIG 3 • The patient is positioned supine with arms out on arm boards at approximately 80 to 85 degrees from the operating room table. Care is taken to secure the arms firmly as the back of the operating room table will be raised to a sitting position to check implant placement in the breast pocket while the patient is under anesthesia.

DIRECT-TO-IMPLANT BREAST RECONSTRUCTION WITH PARTIAL PECTORALIS MUSCLE COVERAGE AND ACELLULAR DERMAL MATRIX

- Following mastectomy, the skin is reprepped using a chlorhexidine scrub, and new sterile drapes are placed over the mastectomy drapes. The patient is paralyzed in order to allow easier dissection and pocket creation under the pectoralis muscle. The color of the skin and thickness of the skin flaps are observed to determine if the patient is a candidate for direct-to-implant reconstruction. If there are ischemic changes to the skin marked by pink or blue discoloration, or if the skin flaps are very thin with areas of dermis exposed on the undersurface, it is unlikely that the skin will be able to support the additional stress and weight of a full-size implant at the time of mastectomy. If the skin color is good and the skin flaps have a uniform marbling of subcutaneous fat on the undersurface, then the patient is a candidate for direct-to-implant reconstruction.

Pectoralis Muscle Release

- Using the same access incision used for the mastectomy, the pectoralis muscle is raised from lateral to medial in the loose areolar tissue plane underneath the muscle until the medial origin on the sternum is reached. The pectoralis muscle is then detached from its origin on the external oblique aponeurosis and rectus sheath inferiorly. Dissection continues to the medial muscle origin on the sternum at approximately the 4 o'clock or 8 o'clock position on the chest wall (**FIG 4**) using electrocautery. Inadequate medial release will lead to lateral malposition of the implant. The remaining pectoralis attachment to the sternum is preserved. If necessary, the muscle may be released further to the 3 o'clock or 9 o'clock position on the chest wall to facilitate medial positioning, but this also results in greater pectoralis muscle retraction and thus less muscle coverage over the implant. The pectoralis muscle becomes the superior and medial border of the implant pocket.

Pocket Creation

- Although the pectoralis muscle serves as the superior and medial pocket borders, the inferior and lateral pocket borders are formed by the ADM. The ADM is washed and rehydrated according to the manufacturer. The ADM is then first stitched to the medial border of the released pectoralis muscle (**FIG 5**). If the IMF is intact inferiorly, the ADM is sewn to the IMF using simple buried interrupted sutures. If the IMF is not intact, the ADM is sewn to the chest wall at the desired location for the IMF using a permanent suture (0 Ethibond). Care is taken to leave the ADM loose medially in preparation for accommodating an implant. Laterally, the ADM is sewn to the chest wall at the lateral border of the breast as marked preoperatively or to a raised edge of serratus muscle if the ADM is insufficient in horizontal length. Once the pocket has been created, the base diameter is measured with a ruler to help determine implant choice. A sizer is then placed into the subpectoral, sub-ADM pocket and one or two sutures are placed from the pectoralis muscle to the ADM to keep the sizer in place in the pocket. The skin is stapled shut and the patient is sat upright on the operating room table. The breast reconstruction is observed with different sizer volumes to help determine if it is safe to place an implant, to determine volume, and to assess pocket dimensions.
- The pocket is copiously irrigated with a triple-antibiotic solution of cefazolin, gentamicin, and bacitracin. The surgeon's gloves are changed and the implant is inserted

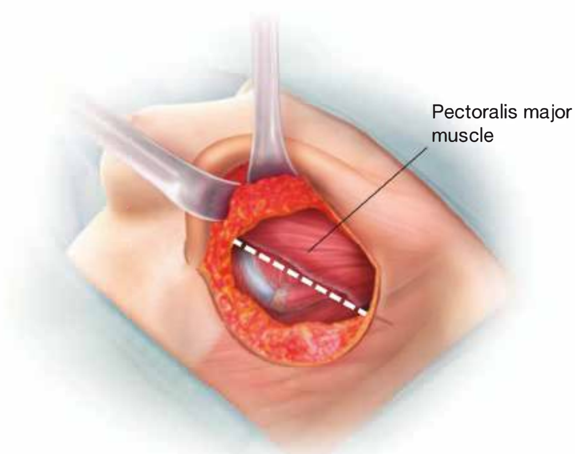

FIG 4 ● The pectoralis muscle is released from its insertion inferiorly to the 4 o'clock or 8 o'clock position on the chest wall to allow medial placement of the implant.

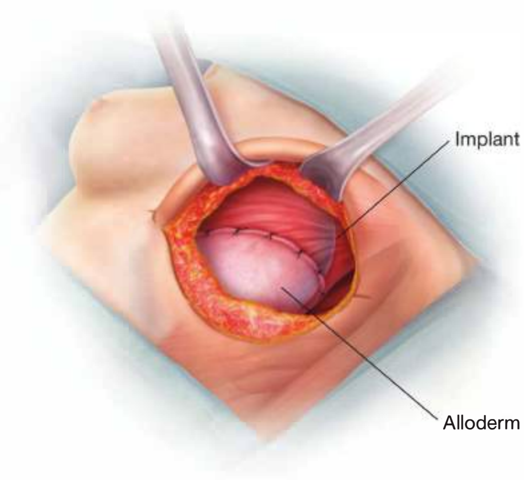

FIG 5 ● To create the inferior and lateral portions of the implant pocket, an ADM or scaffold is sewn to the IMF or chest wall inferiorly and laterally. The implant is placed inside the pocket and then the pectoralis-ADM pocket is closed using absorbable sutures.

into the newly created pectoralis-ADM pocket. The pocket is closed using figure-of-eight or horizontal mattress absorbable sutures (2-0 Vicryl) (FIG 6A,B). Two closed suction drains are placed with one inside the ADM pocket along the IMF and the other outside the pocket in the axilla. The skin edges are trimmed and closed in two layers. Incisions are sealed with surgical glue (Dermabond) and covered with a clear semipermeable dressing (Tegaderm). A chlorhexidine-impregnated sponge (Biopatch) can be used around the drains. If desired, Microfoam tape can be placed laterally and inferiorly to help support the implant position.

A B

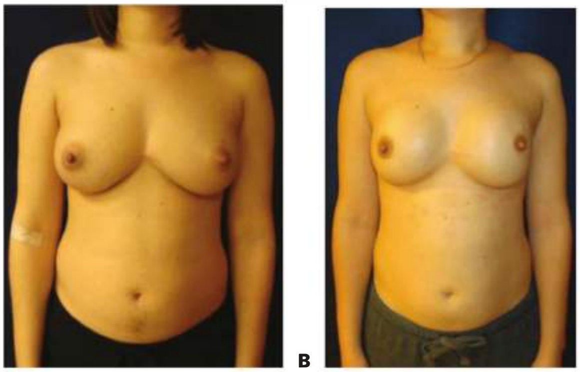

FIG 6 ● This 34-year-old female developed breast cancer and had bilateral nipple-sparing mastectomy procedures through inferolateral IMF incisions with single-stage direct-to-implant reconstructions. **A.** Preoperative photo, **(B)** postoperative photo.

DIRECT-TO-IMPLANT BREAST RECONSTRUCTION WITH TOTAL MUSCLE COVERAGE

- Direct-to-implant breast reconstruction with total muscle coverage of the implant is uncommonly performed due to limitations in achievable volume and less desirable implant shape and position. In select patients with small breast volumes, it can be performed by elevating the pectoralis muscle from lateral to the medial sternal origin. The pectoralis may be partially released inferiorly by dissecting through the rectus abdominis fascia centrally to help avoid superior malposition. A serratus flap is raised laterally to form the lateral borders of the implant pocket. Once the implant is placed, the pectoralis-serratus pocket is closed using absorbable sutures.

PEARLS AND PITFALLS

Lateral malposition of implant	■ Check placement of lateral sutures and determine if lateral border should be medialized to shift implant position. If appropriate, check base diameter of implant to ensure proper fit into pocket. Make sure pectoralis muscle is appropriately released to sternal origin medially and to the 4 o'clock or 8 o'clock position on the chest wall.
Asymmetry of IMF positions	■ Preoperative marks should determine if the IMF position is similar on the breasts. If asymmetric, a decision is typically made to change the IMF position on one breast to match the other breast. Inferior suture placement is checked on both sides for bilateral reconstruction to make sure both are sewn to similar positions on the chest wall or IMF.
Lateralization of nipples on nipple-sparing mastectomy	■ For large breasts, medial positioning of implants may result in lateralization of the nipples. A preoperative discussion with the patient sets expectations and determines whether it would be better to pursue a skin-sparing mastectomy as an alternative. A radial inferior incision yields better nipple position in these breasts but places greater tension on the skin, thus making single-stage reconstruction less likely.
Implant choice	■ For skin-sparing mastectomies, a moderate plus profile implant best matches goals for projection and breast base diameter in most patients. For nipple-sparing mastectomies, a moderate profile implant is used more often to help centralize the nipple.
Learning curve	■ There is a learning curve for surgeons using this technique that is primarily related to the ability to assess the perfusion of the breast skin flap. If the limits of perfusion are surpassed, the result is skin necrosis. Experience with the technique, experience with the breast surgeon, and novel devices to assess skin perfusion decrease the complication rate for this technique.
Fat transfer	■ Fat transfer is increasingly used in implant-based breast reconstruction to fill in defects around the implant. This is not recommended at the time of immediate breast reconstruction with implants, but may be safely done in a second procedure.

POSTOPERATIVE CARE

- The patient stays in the hospital for one or two nights. Prior to discharge, a loose-fitting surgical bra is placed. Care is taken to avoid a tight or constricting dressing or bra that may compromise the blood flow of the mastectomy skin flaps. Patients are seen weekly until drains are removed. Criteria for drain removal is less than 30 mL per day. If skin necrosis develops, it is treated aggressively with sharp debridement and closure. For smooth round implants, gentle medial massage of the implants is started 4 weeks postoperatively to help prevent implant contracture.

OUTCOMES

- Immediate breast reconstruction following mastectomy leads to improved psychosocial outcomes and patient satisfaction compared to patients who decide not to have reconstruction.

COMPLICATIONS

- Total complications following direct-to-implant reconstruction are 3% to 15%.[6,7] The explant rate ranges from 1% to 4%. The most common complication is skin necrosis. Other complications include infection, seroma, hematoma, nipple necrosis, implant malposition, and deep venous thrombosis. The most common late complication is capsular contracture.

Chapter **15**

Two-Stage Implant Breast Reconstruction

Eric G. Halvorson

DEFINITION

- Two-stage implant breast reconstruction is performed in either the immediate or delayed setting following mastectomy.
- The advantages of two-stage implant reconstruction (compared to autologous reconstruction) include shorter operation, lack of donor site, shorter hospital stay, shorter recovery, patient control over final volume, and a "perkier" result.
- The disadvantages of two-stage implant reconstruction include multiple postoperative office visits for expansions, discomfort associated with the expansion process, a second (albeit outpatient) surgery, and the permanent risks of implants (capsular contracture, rupture, rippling, infection, malposition, and exposure).

PATIENT HISTORY AND PHYSICAL FINDINGS

- It may be beneficial for the initial consultation to occur separate from multidisciplinary clinic visits focused on cancer care. Patients presenting to the plastic surgeon after such visits are often overloaded with information and overwhelmed by all the options and information related to reconstruction. It is critical to determine the patient's goals for reconstruction and to ascertain their preferences with respect to breast size, breast shape, willingness to accept surgical risk, willingness to accept donor site morbidity, operative length, hospital stay, recovery process, postoperative follow-up protocol, secondary surgeries, and long-term complications.
- Having a clinic nurse well versed in reconstructive options to meet with patients and show them patient photographs is an incredibly helpful prelude to the physician–patient consultation.
- Physical examination of the breasts is performed to evaluate any masses and whether or not skin involvement or peau d'orange is present. The overall size and degree of ptosis is noted. Patients with significant ptosis will typically require skin excision. If performed as an inverted "T" or Wise pattern, there is significant risk for mastectomy flap necrosis. Alternatively, one can perform a generous horizontal ellipse, vertical ellipse, or two-stage Wise pattern excision with the vertical closure first and a horizontal excision at the inframammary fold (IMF) 3 to 6 months later.
- The breast width, height, and projection is measured in centimeters. These measurements are used for selecting a tissue expander (as described in the following text).

SURGICAL MANAGEMENT

- Ideal candidates for two-stage implant reconstruction are thin, nonsmokers undergoing bilateral mastectomy who have not, and will not, receive radiotherapy. Smokers are prone to mastectomy flap necrosis and infection. Radiotherapy increases the risk of infection, implant exposure, and capsular contracture. Previously radiated skin will not expand well.
- Although obesity increases the risk of complication for any type of reconstruction, heavier patients tend to have better cosmetic results with autologous reconstruction than with implants, as it can be difficult to match the opposite breast after a unilateral mastectomy or give adequate volume/ptosis after a bilateral mastectomy.
- Patients with very large breasts who require skin removal during mastectomy are at risk for mastectomy flap necrosis and tend to require secondary procedures to address residual excess skin. These patients often have ample donor sites for autologous reconstruction, which may be a better option. Patients with small breasts who want them to be larger can achieve that goal through expansion. Patients who have minimal ptosis and want their breasts to be slightly smaller are candidates for single-stage implant reconstruction.

Preoperative Planning and Implant Selection

- Good communication with the breast surgeon is important to ensure oncologic goals are maintained and that reconstruction is appropriately staged. Patients with advanced disease, requirement for immediate postoperative adjuvant therapy, unstable social environment, and/or uncertainty regarding goals for reconstruction may be better served by delayed reconstruction.
- Prior to mastectomy, the patient must be marked in the standing position. The IMF is marked on each side and the midline is drawn between the sternal notch and xiphoid process. The overall outline of the breasts is marked. Although a transverse ellipse around the nipple–areolar complex (NAC) is commonly used for the mastectomy incision, the author's preference is an oblique ellipse parallel to the pectoralis major fibers (**FIG 1**). This renders the medial scar less visible

FIG 1 ● This patient will be used for the majority of photographs in this chapter. She is a woman in her late 20s with genetic predisposition (*BRCA* gene) undergoing bilateral prophylactic mastectomy and two-stage implant reconstruction. Preoperative markings for the mastectomy are shown, demonstrating the oblique ellipses for incision preferred by the author.

in clothing, allows for better subincisional muscular coverage, and facilitates a stair-step approach during the exchange procedure (as described in the following text).

- Tissue expanders are selected preoperatively based on the width of the patient's breast. There are many different tissue expanders to choose from, but most are textured and anatomic, providing lower pole projection. Some are taller than they are wide, some are wider than they are tall, and some are semicircular or crescentic and focus on lower pole expansion. Most have integrated metal ports that are located with magnets, although a remote port is useful when placing the expander under a thick flap (such as a latissimus dorsi flap in an obese patient). In such patients, finding the port with a magnet can be difficult and a long needle is required, placing the expander at risk for rupture.
- Intraoperatively, a ruler is used to measure the width of the surgically created implant pocket, which ultimately determines the expander to be used. Alternatively, one can create a pocket wide enough to accommodate the desired expander. The author's preference is to measure the surgically created pocket based on native patient anatomy and choose an expander that is 1 cm narrower in width.
- Prior to the exchange procedure, the patient is again marked in the standing position. The midline is marked and asymmetries in implant position are noted. The ideal contour for the final implants is marked.
- Final implants are selected primarily based on volume, although width should be taken into consideration. A full discussion of implant types is beyond the scope of this chapter. The majority of surgeons use smooth, round, high-profile implants for reconstructive purposes, although textured anatomic silicone implants may gain popularity if or when they gain U.S. Food and Drug Administration (FDA) approval. Patients with very wide chests may require a moderate-profile implant that will have a larger base diameter for a given volume (although less projection). A comparison of saline versus silicone implants is also beyond the scope of this chapter, but suffice it to say that the issue is controversial. The author's preference is to offer both types to patients noting the following advantages and disadvantages for each implant type:
  - Saline
    - Advantages: Implant rupture is immediately detected; removal of a ruptured implant is simple and quick.
    - Disadvantages: Reexpansion may be required if implant ruptures and is not replaced expeditiously; firmer than silicone, although this difference is diminished when good soft tissue coverage is present; higher potential for rippling if underfilled.
  - Silicone
    - Advantages: Softer, more "natural" feel
    - Disadvantages: Rupture is often clinically silent until extracapsular rupture and silicone granuloma formation is present, removal of a ruptured implant is a difficult operation that often involves removal of native tissue thus compromising subsequent reconstruction, and monitoring for silent implant rupture using magnetic resonance imaging (MRI) is not proven and has a definite risk of false positives and unnecessary surgeries.

Positioning

- Patients are placed in the supine position under a general anesthetic with arms padded circumferentially and abducted at 80 degrees. Following mastectomy, the patient is positioned such that the sternum is parallel to the floor.

TISSUE EXPANDER PLACEMENT

First Step—Wound Assessment

- Following mastectomy, the wounds are irrigated and hemostasis is obtained. The mastectomy flaps are evaluated by examining their thickness and assessing color and capillary refill. Areas where dermis is exposed internally should be carefully evaluated externally. Areas where the external skin is pale without capillary refill should be considered for debridement. Laser-assisted indocyanine-green fluoroscopy has been promoted to assess mastectomy flap perfusion; however, guidelines for its use and interpretation have not been firmly established.[1]
- Use of tumescent solution by the extirpative surgeon makes assessment of mastectomy flaps difficult and has been shown in some studies to be associated with a higher rate of mastectomy flap necrosis.[2–4]
- When there is significant concern for mastectomy flap necrosis, or if debridement of questionable tissue will lead to closure under tension or an open wound, then aborting reconstruction is strongly advised.
- If necessary, the IMF can be recreated with interrupted suture; however, the position of the inferior edge of the expander will ultimately determine the IMF, which can be adjusted further during an exchange procedure if desired. Some surgeons try to establish the native IMF during this initial procedure (which may make the exchange procedure simpler), whereas others intentionally place the expander lower than the IMF to increase lower pole expansion and projection (which requires recreation of the IMF with suture during the exchange procedure). The author's preference is to preserve the native IMF when performing single-stage implant reconstruction, when placing a significant initial fill volume in the expander, or when the IMF is already low. When performing delayed two-stage implant reconstruction or when placing minimal initial fill volume in the expander, placing the implant below the IMF will preferentially expand the lower pole and permit the surgeon to create minimal ptosis at the exchange procedure (as described in the following text).

Second Step—Creation of Implant Pocket

- The tissue expander cannot be covered by the mastectomy flaps alone, which are thin and offer poor soft tissue coverage. Ideally, the surgeon should provide complete musculofascial coverage with the pectoralis major and serratus anterior muscles (**FIG 2**), or use an acellular dermal allograft (ADA) or other product in addition to the pectoralis major muscle.

FIG 2 ● Following mastectomy, the pectoralis major and serratus anterior muscles are visualized as these are the muscles used for expander coverage. If these muscles have been affected by mastectomy, using an ADA in their place is considered.

- The lateral edge of the pectoralis major muscle is pinched between the surgeon's index finger and thumb and pulled away from the chest, revealing a loose areolar plane between the pectoralis major and minor muscles. Dissection in this plane commences with Bovie cautery, but once the subpectoral space is entered, much of the superior and medial implant pocket can be created via blunt digital dissection before using lighted retractors for direct visualization. A lighted retractor is quite helpful to finish medial dissection, as great care must be taken to ligate or cauterize the intercostal perforators of the internal mammary vessels (FIG 3).
- The medial boundary is defined externally by the preoperative markings that define the patient's native breast form. Internally, it is quite common to release the medial and inferomedial origins of the pectoralis major muscle.

FIG 3 ● A lighted retractor is very helpful for both expander placement and the implant exchange procedure. Here, the lighted retractor is shown during creation of the subpectoral pocket superomedially, where dissection proceeds carefully so intercostal perforators can be visualized and carefully ligated if necessary.

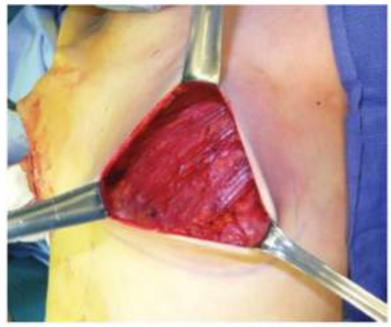

FIG 4 ● The relationship between the most caudal extent of the pectoralis major muscle and the IMF determines whether or not the anterior rectus sheath will be necessary to provide complete submusculofascial coverage of the expander. If the muscle originates at or below the IMF, as shown in this figure, then there is no need to elevate the anterior rectus sheath.

It is important not to release this area excessively, as symmastia can result and is difficult to correct.

- After the subpectoral plane is developed, the inferior insertion of the pectoralis major muscle is examined (FIG 4). If the patient's muscle reaches the IMF, then a submuscular pocket can be created down to the IMF with supple and adequate soft tissue coverage that will respond well to expansion (FIG 5). More commonly, however, the pectoralis major inserts above the IMF. In this scenario, to provide autologous implant coverage inferiorly, one must continue dissection past the pectoralis major insertion and under the anterior rectus sheath until just below the IMF. Transitioning from the subpectoral plane to underneath the anterior rectus sheath is sometimes technically difficult and may result in a few gaps in coverage that can be closed after the pocket is fully created. A lighted retractor is necessary for this portion of the procedure. The anterior rectus sheath is quite stiff and will not expand well unless an incision is made transversely across the sheath just below the IMF, entering the subcutaneous

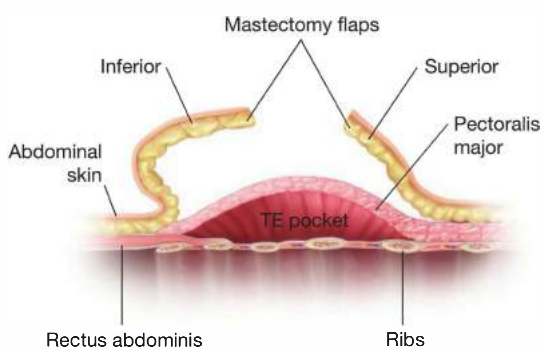

FIG 5 ● Schematic diagram patient anatomy when the pectoralis major originates at or below the IMF. In this case, a submuscular pocket can be created down to the IMF that will be supple and respond well to expansion. TE, tissue expander.

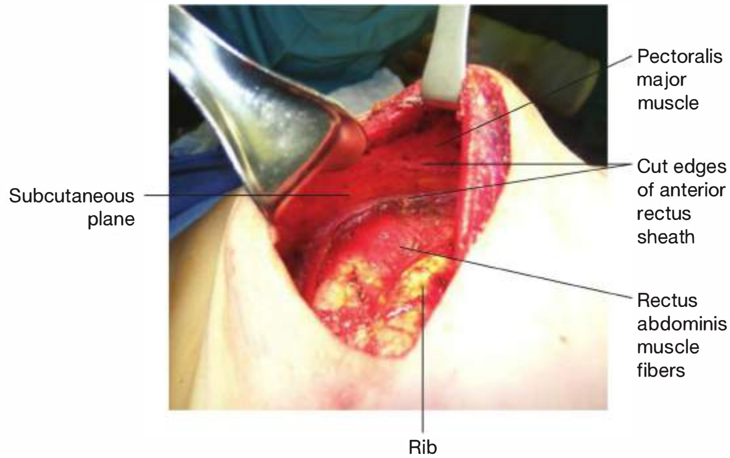

FIG 6 ● At or just below the IMF, the anterior rectus sheath is divided horizontally to enter the subcutaneous plane. If this is not performed, lower pole expansion will be limited by the stiff anterior rectus sheath.

plane (**FIGS 6** and **7**). If the anterior rectus sheath is released above the IMF, one would obviously enter the implant pocket. The goal is to provide complete and supple submusculofascial coverage without gap between the pectoralis major and the IMF. Alternatively, the pectoralis major can be released from the chest wall and a piece of ADA (or other product) can be sewn to the IMF inferiorly and the cut edge of the muscle superiorly.

- Following creation of a subpectoral pocket with or without elevation of the anterior rectus sheath, inferolateral coverage must be provided. Autologous coverage is provided by elevating the serratus anterior fascia if robust, or a partial thickness muscle flap if the fascia is thin or traumatized from the mastectomy. An incision in the serratus anterior is made at the level of, and parallel to, the inferolateral edge of the pectoralis major muscle and a fascial or musculofascial flap is elevated to the anterior axillary line (**FIG 8**). Alternatively, one can determine the width of the implant pocket based on the width of the desired tissue expander and stop lateral dissection when a sufficient pocket width is achieved (usually 1 cm wider than tissue expander). At this point, the inferior and lateral dissections will be complete, but the inferior serratus and superolateral external oblique muscles will still be attached to the chest wall. By retracting inferiorly and laterally, this plane is exposed and the muscles can be elevated off the chest wall to open the inferolateral pocket (**FIG 9**).

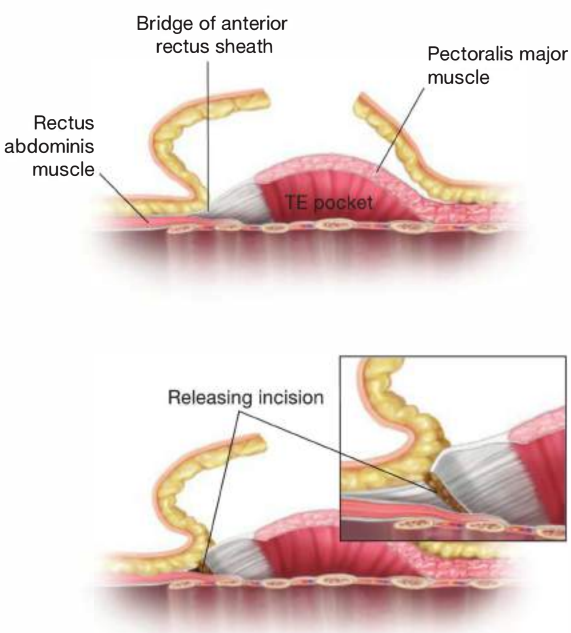

FIG 7 ● Schematic diagram patient anatomy when the pectoralis major muscle originates above the IMF. In this case, the gap between the caudal border of the pectoralis and IMF must be bridged by elevating the anterior rectus sheath. At or just below the IMF, the sheath must be incised horizontally to enter the subcutaneous space; otherwise, the inferior pocket will not expand well. Alternatively, an ADA can be used to bridge this gap. TE, tissue expander.

FIG 8 ● For lateral and inferolateral coverage, a partial-thickness serratus anterior muscle flap is elevated and shown in this photograph. If the fascia is robust and intact, that can be used alone; however, this is seldom the case. An incision in the muscle parallel to the inferolateral edge of the pectoralis major muscle is made and the flap is elevated laterally until the anterior axillary line or sufficiently to create the desired pocket width for the chosen expander.

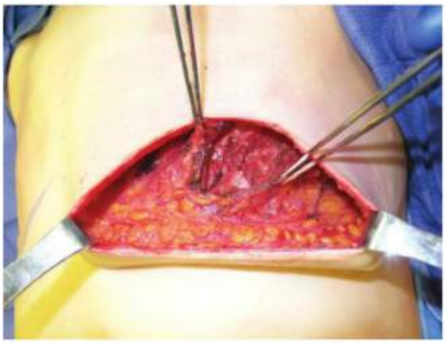

FIG 9 ● Following elevation of the serratus anterior muscle, the inferolateral aspect of the implant pocket will still be adherent to the chest wall. If retractors are placed under the pectoralis major and serratus anterior muscles, this area of adhesion will be exposed and inferolateral dissection will elevate the serratus anterior and external oblique muscles off the chest wall to complete implant pocket dissection.

FIG 11 ● A piece of ADA is prepared appropriately, according to the manufacturer's recommendations, and is sewn in with the epidermis side facing the implant. A 6 × 16 cm piece is usually sufficient. The inferomedial and inferolateral corners of the ADA are trimmed to create a curved inferior border and it is secured to the IMF and lateral pocket using a running 2-0 monofilament slowly absorbing suture. The transition from the IMF to the lateral pocket must be a gentle arc that mimics the opposite side.

- If an ADA is used, the origin of the pectoralis major is taken down starting inferolaterally and extending medially and then superiorly along the sternal origin to approximately the 3rd or 4th rib (**FIG 10**). The ADA will provide inferolateral implant coverage and there is no need to elevate the serratus anterior. In this case, the IMF and anterior axillary line are marked internally and the ADA is sutured along a line that transitions in an arc from the IMF to the anterior axillary line (**FIG 11**). Alternatively, one can mark the lateral mammary fold based on the width of the desired tissue expander and suture the ADA to this line (**FIG 12**). One can tailor the surgically created IMF to match the contralateral native IMF during unilateral reconstruction. If performing bilateral reconstruction, then it is imperative to create symmetric IMFs.
- The advantages of using an ADA are that it avoids any morbidity associated with elevation of the rectus sheath and serratus anterior, it allows for a greater initial fill volume (and thus fewer postoperative expansions), it allows precise control of the IMF, it may reduce operative time, and it may preserve lower pole fullness. Disadvantages include cost and an increased incidence of seroma, infection, and reconstructive failure in patients with risk factors such as obesity, smoking, and/or radiation.[5] Although some surgeons use an ADA routinely and others do not, the author's preference is to use ADA selectively (**FIG 13**). If the anterior rectus sheath or serratus anterior have been affected by the mastectomy and will not provide adequate coverage, ADA is an option, provided the patient does not have risk factors such as prior radiation, obesity, or smoking. In patients who have excess skin, it is advantageous to take advantage of this by placing a higher initial fill volume and an ADA will allow the surgeon to do this (again, provided the patient does not have the risk factors mentioned earlier). When the pectoralis major does not extend down to the IMF in a patient with some excess skin and no risk factors, ADA is a good option. However, in a patient without skin excess, who desires small breasts, and in whom very little initial fill volume will be placed, submusculofascial coverage is provided without ADA.

FIG 10 ● If an ADA is used, the pectoralis major muscle is elevated from the chest wall by dividing its inferior and inferomedial origin.

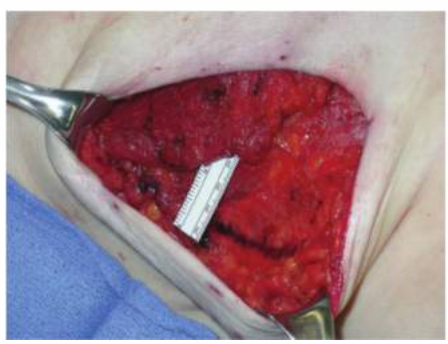

FIG 12 ● A ruler is used to measure the width of the surgically created pocket. The proper pocket width can be determined either by patient anatomy (e.g., the anterior axillary line) or the dimensions of the expander desired.

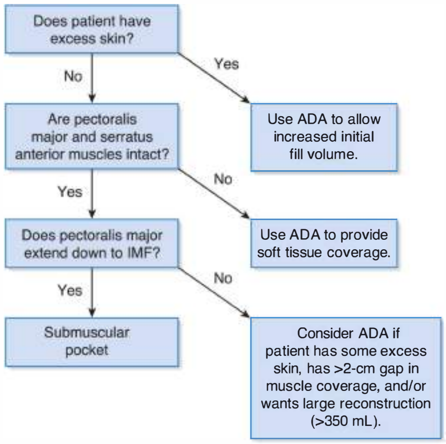

FIG 13 ● Algorithm to determine when to use ADA. IMF, inframammary fold.

Third Step—Preparation of Tissue Expander

- Tissue expanders come with air in them to prevent the inner shell from sticking to itself. There are usually markings for orientation, but it is helpful to draw a vertical line on the expander with a marking pen to assist with positioning the expander in the pocket. A needle (usually 23 gauge) is inserted into the port and all air is removed. The most commonly used tissue expanders are anatomic (creating lower pole expansion) and thus they are textured (to prevent rotation). There is typically more shell inferiorly, and while deflating the expander, it is important to fold excess shell inward as opposed to folding it upward and on to itself, where it might cover the port and get punctured (**FIG 14**).
- The author's preference is to place 60 to 180 mL of sterile saline in the tissue expander prior to placement, which allows the anterior shell to move away from the rigid backing. It is important to control positioning of this backing as it is what determines final expander position.

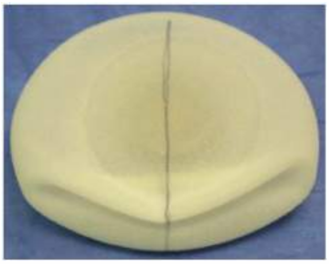

FIG 14 ● The tissue expander is marked with a vertical line for orientation. All air is removed with the excess inferior implant folded inward as shown to avoid puncturing the inferior implant while placing needles for expansion in clinic postoperatively. A minimum of 60 mL of saline is instilled, dyed with methylene blue. This allows for quick identification of inadvertent implant rupture during wound closure and also allows the clinic staff to confirm placement of the filling needle during subsequent expansions.

- It is extremely helpful to put 1 mL of methylene blue in 1 L of injectable saline and use this for the initial expander fluid. If the expander is punctured during closure, it will be evident due to the dye. Additionally, during expansions in clinic, the blue dye will confirm when the port is accessed.

Fourth Step—Placement of Tissue Expander and Closure

- The pectoralis is retracted away from the chest wall and the expander is placed into the pocket taking great care to orient it correctly. It is important to note the rigid backing of the expander and place the caudal edge at the IMF or below if desired. Be sure to unfold all edges of the expander. If performing bilateral reconstruction, symmetry in expander placement should be confirmed by palpating the expander ports on each side and ensuring symmetric horizontal and vertical positioning. If an expander requires adjustment in positioning, it is critical to grasp the rigid backing of the implant and then adjust the position. If only the ports or anterior shell are adjusted, this usually has no effect on the position of the backing, which determines implant position once fully inflated.
- The inferolateral edge of the pectoralis major muscle is sutured to the anteromedial edge of the serratus anterior muscle with running absorbable 2-0 braided suture, closing the pocket. A small opening is left superolaterally to allow egress of fluid. Alternatively, if an ADA is used, the pectoralis major muscle is sewn to the ADA with interrupted figure-of-eight braided absorbable 2-0 suture (**FIG 15**).
- The author's preference is to inflate the tissue expander with sterile saline as much as the soft tissue (muscle/skin) will allow without undue tension. This is typically 180 to 240 mL. It is important to do this prior to skin closure, as placing the needle through the muscle will occasionally cause bleeding, which can be controlled directly. Otherwise, a hematoma could expand in the subcutaneous space without notice until the patient is

FIG 15 ● The inferolateral edge of the pectoralis major is sewn to the superomedial edge of the serratus anterior with a running 2-0 absorbable polyfilament suture to cover the implant. If an ADA is used, the pectoralis major is sewn to the edge of the ADA with interrupted figure-of-eight 2-0 absorbable polyfilament suture, as shown.

out of surgery. In cases where there is significant concern regarding the cutaneous circulation, then only 0 to 60 mL of inflation is advisable.

- Two closed suction drains are placed in the subcutaneous space. One is oriented superiorly and the other inferiorly. The skin is closed with interrupted 3-0 absorbable monofilament suture for the dermis and a running 4-0 absorbable monofilament suture for subcuticular closure (**FIG 16**). The author's preference is to use skin glue alone as a dressing, without placement of a surgical bra, which applies pressure to the tenuous mastectomy flaps and is an impediment to physical examination.
- Antibiotics are continued parenterally for at least 24 hours postoperatively and transitioned to oral antibiotics for a week, as withholding postoperative antibiotics has been shown to be associated with an unacceptable rate of implant infection.[6] Drains are removed when output is less than 30 mL per 24 hours and expansion is begun typically 2 weeks postoperatively. Expansion can continue on a weekly basis, adding as much fluid as the patient will tolerate without discomfort (usually 60 to 120 mL). Once expansion is complete according to patient preference and surgeon's satisfaction, the author's preference is to perform one additional overexpansion, which can provide some additional tissue to create minimal ptosis at the exchange procedure at least 1 month later (as described in the following text).

FIG 16 ● The patient is shown following placement of tissue expanders and closure over two closed suction drains. Internal absorbable sutures are used, with skin glue as the only dressing. No bra is applied, which might apply pressure to tenuous mastectomy flaps.

IMPLANT EXCHANGE

First Step—Removal of Tissue Expander

- As noted earlier, the patient is marked in the standing position. Asymmetries are noted and the ideal contour for the final implants is marked.
- The mastectomy scars have often widened during expansion and these can be excised. A stair-step approach to the implant pocket is usually performed, so any wound breakdown in one layer does not expose the suture line of the other layer. If the scar is oriented obliquely (**FIG 17**), 2 to 4 cm of superomedial skin elevation will expose the pectoralis major, which can be incised parallel to the muscle fibers (**FIGS 18** and **19**). If a transverse approach was used, then superolateral and inferomedial skin elevation is required to expose the pectoralis major and allow for an incision parallel to the muscle fibers.
- The implant pocket is entered and the capsule is bluntly separated from the expander, which is removed. If the expander is too large, it can be ruptured with a needle or scalpel to assist in removal. If there was any doubt about the final expander volume, it can be measured at this point.

FIG 17 ● The patient is shown prior to the exchange procedure, 1 month following the last expansion in clinic. She has been expanded to 600 mL and desires 550 mL implants.

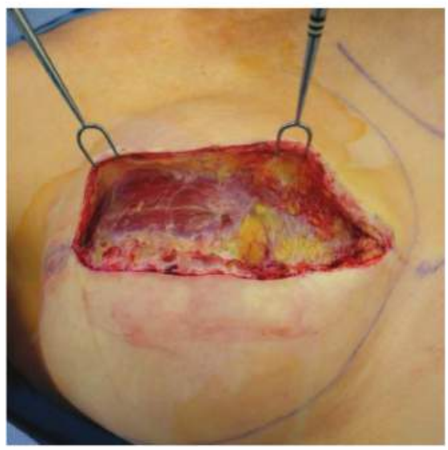

FIG 18 ● If the oblique incision is used for mastectomy, it is easy at the exchange procedure to elevate a superomedial flap exposing the pectoralis major muscle where it tends to be thicker. This will allow a "stair-step" approach to the implant pocket. Any wound healing issue at one level will not expose the suture line at the other level.

Second Step—Creation of Implant Pocket

- Ideally, the expanders can be removed and the permanent implants placed without further intervention; however, this is almost never the case. Superior and superomedial capsulotomy is often required to soften the transition from the chest wall to the implant (**FIG 20**). The pocket may need to be medialized, lateralized, elevated, or displaced inferiorly.

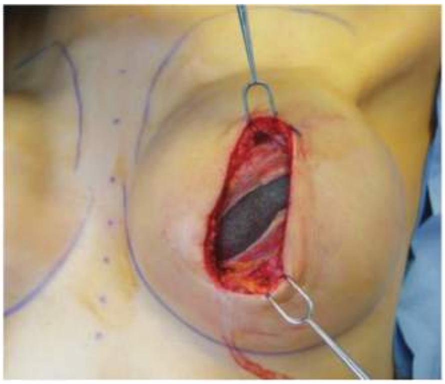

FIG 19 ● A muscular incision is made parallel to the pectoralis major muscle fibers to access the implant pocket. The capsule is also incised with cautery and the expander is bluntly separated from the capsule.

FIG 21 ● The patient is positioned upright with both upper extremities well padded and secured to arm boards abducted less than 90 degrees.

These can all be accomplished through capsulotomy. If the final implant is roughly the same width as the expander, then a corresponding capsulorrhaphy at the opposite side of the pocket is necessary using figure-of-eight interrupted 0 absorbable suture. If the implant is wider than the expander, this may not be necessary as the capsulotomy will increase pocket diameter.

- If the expander was placed below the IMF, or if the IMF needs to be elevated, this is accomplished with figure-of-eight interrupted 0 absorbable suture. The patient is sat upright (**FIG 21**) and the inferior mastectomy flap is lifted away from the chest wall. Usually, the old IMF can be visualized and marked (**FIG 22**); otherwise, the desired IMF can be marked. The needle is passed through the capsule and the IMF marking externally is visualized. The needle tip should just catch the deep dermis, resulting in a small indentation when tied. These indentations will resolve in several weeks. After passing the needle through the capsule/dermis, tension can be adjusted by examining the fold externally (**FIG 23**) and elevating it

FIG 22 ● When the inferior mastectomy flap is elevated gently from the chest wall, the patient's original IMF is still visible and can be marked for recreation of the native IMF. A higher or lower IMF can also be created.

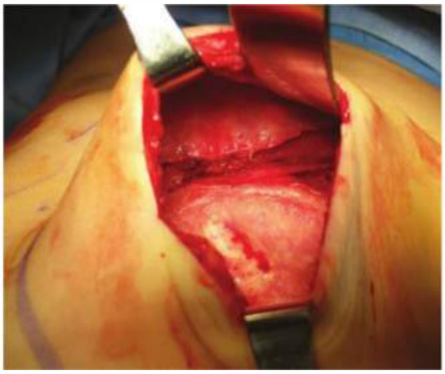

FIG 20 ● A superomedial and superior capsulotomy is made just above the chest wall using a lighted retractor. This will soften the transition from chest wall to implant and allow for more implant mobility within the pocket.

FIG 23 ● A suture is placed in the center of the IMF, through the capsule and just catching the deep dermis. The suture is pulled upward and the level of the IMF adjusted as desired to recreate a sharp and well-defined IMF. Once held in appropriate position, internal inspection will reveal where a suture should be placed on the chest wall. To minimize pain, suturing to the ribs should be avoided if possible. If the lower portion of the expander was placed at the IMF and good lower pole expansion and a crisp IMF in good position has resulted, then this maneuver is unnecessary.

FIG 24 ● The IMF has been reestablished with multiple figure-of-eight capsulorrhaphy sutures, starting in the center of the IMF and proceeding medially and laterally until an adequate IMF is recreated. A temporary implant sizer is helpful to assess the reconstructed IMF during this process.

FIG 26 ● A horizontal capsulotomy approximately half way up the inferior mastectomy flap is performed to further expand the lower pole and create minimal ptosis. Multiple radial capsulotomies (perpendicular to the horizontal capsulotomy and extending from the IMF to the incision) will further expand the lower pole.

as desired. Internal inspection with the suture still under tension will indicate where the corresponding suture throw in the chest wall must be made. Suturing into the rib should be avoided, as this results in pain. The first suture is placed at the center of the IMF and then one to two sutures are placed medially and laterally until an adequate fold is created (**FIGS 24** and **25**).

- Some surgeons prefer to establish the IMF at the initial operation, potentially with an ADA, which has the added benefit of permitting a higher initial fill volume. A higher initial fill volume has the potential to better preserve lower pole fullness. No time is spent reconstructing the IMF at the exchange procedure. Although this may be a simpler approach, it may result in a blunted IMF. The author's preference is to treat each case individually and surgically create a crisp IMF at the exchange procedure if necessary. For example, patients undergoing delayed reconstruction will benefit from significant lower pole expansion and thus the expander is placed inferior to the desired IMF and the IMF is reconstructed at the exchange procedure. A patient with minimal excess skin and ptosis undergoing immediate reconstruction will benefit from an ADA to maximize the initial fill volume (preserve lower pole fullness), establish the IMF, and avoid inferior capsulorrhaphy at the exchange procedure.
- To further expand the lower pole and create minimal ptosis, capsulotomy of the inferior pocket is then performed. A horizontal capsulotomy half way up the inferior mastectomy flap, at least 4 cm off the chest wall, will expand the lower pole of the pocket (**FIG 26**). Additional radial capsulotomies can be added for further lower pole expansion or elsewhere to create symmetric pockets.

FIG 25 ● Comparison of the left side, where the IMF has been recreated, and the right side, where it has not.

- During pocket creation, it is helpful to have a temporary sizer inflated (with air or saline) to roughly the desired implant volume, which can be placed into the implant pocket to assess position, shape, and volume. This is particularly important in bilateral reconstructions, where two sizers are required to confirm pocket symmetry.

Third Step—Implant Selection and Closure

- When ordering implants for the exchange procedure, it is wise to order implants that are one size smaller and one size larger than the implant size determined by the patient's final expansion volume (prior to final overexpansion). As mentioned earlier, temporary sizers are usually used and can be adjusted to determine an acceptable final implant volume. Inflating the sizer beyond the final expander volume usually results in excessive upper pole fullness, a noticeable step-off between the chest and implant, and tight closure. The chest should transition to the implant smoothly and the breast mound should have slight ptosis.
- When placing saline implants, choose an implant that has the desired volume as the upper end of its volume range. For example, if 380 mL is the desired implant volume, use an implant with a volume range of 360 to 390 mL. This avoids rippling at the expense of making the implant slightly firmer. Some surgeons will in fact overfill the implant by 10% to avoid rippling.
- The pockets are irrigated, hemostasis is obtained, and the final implants are opened. Although many surgeons will reprep the patient, place new drapes, dip retractors in prep solution, and handle the implants with fresh gloves, there is no data to support these practices. The author does not take any special precautions, as the procedure is a clean, sterile procedure. The implants are placed and the muscular closure is performed with a running 2-0 braided absorbable suture. The capsule is not included

FIG 27 ● The implants have been placed and the wounds closed without drains. Skin glue has been applied. The dimpling observed at the IMFs will resolve in several weeks.

in this closure if possible, thus creating an anterior capsulotomy (made upon initial approach to the implant pocket). No drains are placed. The skin is closed with interrupted deep dermal 3-0 monofilament absorbable suture and a running 4-0 subcuticular absorbable suture (**FIG 27**). A skin glue is applied, and a bra is only used if supporting the implant in a particular position is desired.

FIG 28 ● Three months following the exchange procedure, the patient is very happy and interested in nipple reconstruction. The right IMF is 2 cm lower than the left IMF, but the patient does not desire correction. It is important to establish the final implant position prior to nipple reconstruction; otherwise, later implant repositioning will affect how the nipple is positioned on the breast mound. There is minimal step-off from the chest wall to the implants, which is the result of mastectomy and commonly seen in implant reconstruction. This can be corrected with fat grafting—an effective and popular but controversial procedure at this time. The patient did not desire fat grafting.

Additional Procedure—Nipple Reconstruction and Revisions

- When examined with a critical eye, almost all patients have some degree of asymmetry following reconstruction (**FIG 28**). Approximately 30% will request a third procedure to address this asymmetry. Correcting the unfavorable result in implant breast reconstruction is a complex subject, involving techniques to alter implant position, breast shape, implant type, and soft tissue characteristics. Many patients ultimately opt for NAC reconstruction (**FIG 29**) (see Part 5, Chapter 20). In many cases, minor revisions can be performed at the time of NAC reconstruction; however, the nipple should only be created once the breast mound is in its final position, and thus it is not advisable to adjust the implant pocket and create the nipple during the same operation.

FIG 29 ● Options for nipple–areolar complex (NAC) reconstruction include tattoo only, nipple reconstruction with areola tattoo, and nipple reconstruction with areola graft. This patient opted for a "3-D" tattoo performed by a professional tattoo artist that specializes in NAC tattoo (Vinnie Myers in Finksburg, MD—http://www.vinniemyers.com). She is very happy with the aesthetic result, although she has some chronic discomfort lateral to the right breast. It is very common for patients to have some degree of chronic sensory dysfunction following mastectomy. Much of this resolves with time and can improve with therapy and massage; however, every patient should be counseled of this risk. It is also very common for patients with implants to be aware of their presence permanently. No patients think the implants feel just like their native breasts. The implants have dropped slightly, resulting in a more obvious step-off from the chest wall to the implants, and could be corrected with elevation of the implants (which would affect NAC position on the breast mound) or fat grafting.

PEARLS AND PITFALLS

Indications	■ Patients with a history of radiation are poor candidates for implant reconstruction. ■ Risk factors for infection and wound healing complications include smoking, radiation, and obesity.
Incision placement	■ An oblique incision parallel to the pectoralis muscle fibers provides the best cosmesis and easiest approach for the exchange procedure. ■ Excess skin can be excised through a linear incision only, as additional incisions will compromise circulation and risk mastectomy flap necrosis. Secondary procedures are frequently necessary in patients with excess skin.
Expander selection	■ Expanders are selected based on breast width, not volume.

Expander placement	■ Marking the expander assists in correct orientation. ■ Remove all air and place saline dyed with methylene blue to allow detection of implant rupture as well as confirmation of port access for staff performing expansions. ■ Provide at least 24 hours of postoperative antibiotics.
Implant selection	■ Implants are selected based on volume primarily, taking breast width into consideration. High-profile implants are typically used, except in patients with wide chests who benefit from moderate profile, wider implants.
Patient expectation	■ Two-stage implant breast reconstruction is typically a year-long process. ■ Symmetry in the nude is always the goal but is seldom achieved. Symmetry in clothing is the most reasonable expectation.

POSTOPERATIVE CARE

- Following the mastectomy and tissue expander placement, the patient is maintained on antibiotics for at least 24 hours and more commonly for 1 week or until drains are removed. Drains remain in place at least 3 days and then are removed when output is less than 30 mL per day. Only one drain from each side should be removed at a time, as sometimes the output of the second drain will increase after the first drain is removed. The author's preference is to allow patients to shower with drains in place. The patient should be seen within 1 week to evaluate for postoperative infection and/or mastectomy flap necrosis and to remove drains if appropriate. Expansion is begun 2 weeks after surgery and continued on a weekly basis thereafter until the patient and surgeon are happy with the final volume. One additional "overexpansion" is performed and the exchange procedure is scheduled at least 1 month later to allow the tissues to soften.
- Following the exchange procedure, patients may shower after 48 hours. Although the author feels very strongly about giving patients extended postoperative prophylactic antibiotics after mastectomy and expander placement, the exchange procedure is a clean procedure and the mastectomy flaps have been delayed and have robust perfusion. Thus, no postoperative antibiotics are usually given. Although there is little data to support practices such as repreping the patient, changing drapes, changing gloves, or dipping retractors in prep solution, this is commonly performed by surgeons placing implants.

FIG 30 ● This patient is 1 year out from the exchange procedure and 6 months out from NAC reconstruction with local flaps to reconstruct the nipple and areola tattoo. She has a higher body mass index (BMI) and more subcutaneous fat, and the mastectomy did not extend very far superiorly. Thus, she has a smooth transition from the chest wall to the implants.

OUTCOMES

- Patient satisfaction with implant breast reconstruction is high, provided the preoperative consultation appropriately identified the patient's priorities, goals, and preferences with respect to reconstructive options, and realistic expectations were discussed (**FIGS 30** to **32**). Although some studies have indicated that patients undergoing prosthetic reconstruction are less satisfied than those undergoing autologous tissue reconstruction,[7,8] other studies have shown significant improvements in psychosocial outcomes regardless of the type of reconstruction.[9]
- It is common to tell patients undergoing implant reconstruction that, on average, they will require some form of surgery every 10 years. These could be procedures for symmetry, infection, rupture, or capsular contracture. Although some surgeons exchange silicone implants every 10 years to avoid extracapsular ruptures, most only offer surgery if a problem is identified. One study evaluated long-term outcomes of autologous versus implant reconstruction and noted stable survival of 90% of autologous reconstructions

A

B

FIG 31 ● **A,B.** This patient is 6 months out from unilateral reconstruction. She did not desire NAC reconstruction or a contralateral mastopexy for symmetry. She has a very acceptable appearance in a bra.

FIG 32 ● This patient is 9 months out from her exchange procedure. She had prior augmentation mammaplasty and thin soft tissue coverage inferiorly; therefore, an ADA was used to augment soft tissue coverage of the expanders.

versus a gradual decline to 70% survival of implant reconstructions.[10] In general, autologous reconstructions improve or remain stable with time, whereas implant reconstructions tend to worsen slightly over time.

- There is no increased risk of breast cancer recurrence in patients undergoing therapeutic mastectomy and implant reconstruction. Detection of recurrence and outcome when recurrence is detected are not affected by the presence of an implant reconstruction.[11]

COMPLICATIONS

- Bleeding
- Infection
- Injury to surrounding structures (e.g., cutaneous nerves)
- Mastectomy flap necrosis
- Long-term risks of implants: capsular contracture, rupture, rippling, infection, malposition, and exposure
- Asymmetry, imperfect cosmetic result

Chapter 16

Pedicled Latissimus Dorsi Flap Breast Reconstruction after Mastectomy

Frank Fang Adeyiza O. Momoh

DEFINITION

- The latissimus dorsi myocutaneous flap was originally performed for chest wall reconstruction after radical mastectomy by Iginio Tansini in 1906 but fell out of favor when mastectomies were primarily closed or skin grafted.[1] Although the latissimus flap remained a dependable option for anterior chest wall reconstruction,[2–4] it was not until 1977 when it was first described to reconstruct a true breast mound in combination with a prosthetic implant.[5]
- The latissimus dorsi myocutaneous flap currently remains a viable and frequently used option for breast reconstruction. Typically, patients who required chest wall irradiation and are either unwilling or unable (lack of donor site tissue volume) to undergo one of the other autologous flap options for breast reconstruction will proceed with this option. Furthermore, this flap has found use in the reconstruction of congenital defects such as Poland syndrome in the younger patient population.[6] For the purpose of breast reconstruction, this technique usually requires flap transfer combined with an initial tissue expansion process followed by a subsequent saline- or silicone-filled prosthetic implant placement. Breast reconstruction with a latissimus dorsi myocuataneous flap without an implant is also possible but less commonly used due to flap volume limitations.[7]

ANATOMY

- The latissimus dorsi is a large, flat, triangle-shaped muscle on the back measuring approximately 25 × 35 cm; it mirrors the pectoralis major posteriorly.
- The muscle origin is a broad aponeurosis that spans the lower six thoracic vertebrae (superomedially), supraspinous ligament (central medial region), thoracolumbar fascia (inferomedially), and posterior iliac crest (inferiorly).
- The lateral border of the muscle separates from the serratus anterior as a free potential space until one encounters the small slips of origin from the 10th to 12th ribs, where the latissimus interdigitates with the slips of origin of the external oblique and serratus anterior muscles.
- The superior border of the muscle has an area of adhesion to the region of the inferior angle of the scapula but otherwise contains free potential space with the underlying layer.
- The muscle converges in the axilla to insert on the crest of the lesser tuberosity of the humerus.
- The latissimus dorsi adducts, extends, and rotates the humerus medially (“pull-up,” rowing, or free-style swimming motions).
- The latissimus dorsi flap is a Nahai-Mathes type V myocutaneous flap, meaning that it may survive based solely on either the thoracodorsal artery or the segmental perforators from the intercostal and lumbar arteries.
- The thoracodorsal artery (arising from the subscapular branch off the axillary artery) enters the deep surface of the latissimus dorsi muscle in the posterior axilla approximately 10 cm inferior to the muscle insertion into the humerus and 2.6 cm medial to the lateral border of the muscle (**FIG 1**).
- The artery then divides into the medial (also known as transverse) and the lateral (also known as vertical or descending) branches. The medial branch is located approximately 3.5 cm below and parallel to the superior border. The lateral branch

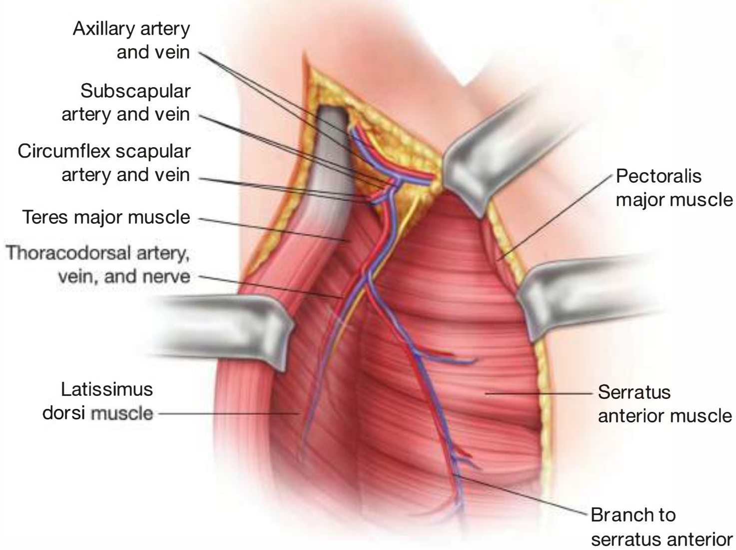

FIG 1 • Vascular anatomy of the thoracodorsal artery and vein.

is located approximately 2.6 cm medial and parallel to the lateral border. The serratus branch (artery to the serratus anterior), which joins the thoracodorsal artery just before its entrance to the latissimus muscle, is a useful landmark as it guides one directly to the thoracodorsal pedicle. There is usually a single vena comitans of the thoracodorsal artery.[8,9]

- The thoracodorsal motor nerve enters the muscle with the vascular pedicle. Cutaneous sensory nerves arise from the intercostal nerves at the midaxillary line and also in the paraspinal region.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination are critical in preparing for reconstruction.
- Pertinent aspects of the history include previous axillary operations (e.g., lymph node dissections or biopsies) and medical conditions that would preclude patients from an operation of moderate length under general anesthesia.
- Certain patients (e.g., paraplegic or wheelchair-dependent individuals who cannot afford even a minimal weakening of shoulder strength) probably should not undergo latissimus dorsi breast reconstruction. The average patient, however, will likely not notice a difference in shoulder function after a period of full recovery.
- A focused exam of the axilla and back for scars that may preclude use of the muscle flap or affect placement of the skin paddle is necessary.
- The presence of a viable and innervated muscle may be confirmed by having the patient activate the muscle by placing the hands on the hips and pushing firmly. However, a vigorous muscle contraction does not necessarily indicate an intact thoracodorsal arterial pedicle, as the nerve is quite separated from the thoracodorsal artery proximal to the branch point from the subscapular artery and could be potentially preserved despite ligation of the thoracodorsal artery.
- A team-based approach involving surgeons, anesthesiologists, primary care physicians, and other specialists such as cardiologists when needed ensures that patients are evaluated as a whole and all key concerns are addressed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative computed tomography (CT) angiography of the donor site (**FIG 2**) is recommended in patients with previous surgical procedures during which the thoracodorsal arterial pedicle may have been sacrificed (e.g., axillary lymph node dissection or modified radical mastectomy).

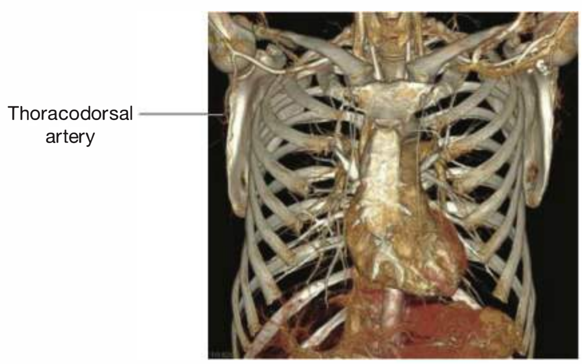

FIG 2 • Preoperative CT angiography of the thoracodorsal vessels.

SURGICAL MANAGEMENT

- In consulting with patients, decisions about the timing of reconstruction (immediately after mastectomy or delayed) and the type of reconstruction are made taking patient factors and tumor characteristics into consideration.
  - Patient factors of significance include the following:
    - Patient preference
    - Smoking history
    - History of previous axillary operations that compromise the vascular pedicle of the donor site
    - Medical comorbidities that would preclude patients from undergoing an operation of moderate length.
  - Tumor characteristics as they relate to the following:
    - The need for postmastectomy radiation therapy
    - The need for close postmastectomy surveillance prior to reconstruction
    - In general, patients known to require postmastectomy radiation therapy are reconstructed in a delayed fashion to avoid the detrimental effects of radiation on flaps. A history of radiation therapy also serves as a relative indication for use of an autologous form of reconstruction, as implant-only reconstructions in the setting of radiation are prone to higher rates of complications and failure.

Preoperative Planning

- Basic labs (chemistry and blood counts)
- All anticoagulant and antiplatelet medications should be stopped a week prior to the operation. Warfarin can be bridged with enoxaparin a week prior.
- Smokers are required to quit for a minimum of 4 weeks prior.
- Patients receive preoperative antibiotics with intraoperative redosing.
- Patients receive deep vein thrombosis (DVT) prophylaxis with use of a pneumatic compression device at the beginning of the case; preoperative subcutaneous heparin is not typically used in our practice.
- A Foley catheter will be needed, given the length of the case.
- A headlight may be helpful in the harvest of the latissimus dorsi muscle.
- A beanbag is needed for lateral decubitus positioning.
- A sterile Doppler probe is helpful to have available in case there is any concern for the location or integrity of the thoracodorsal pedicle during the case.

Positioning

Marking/positioning

- The inframammary fold (IMF), medial limit, and lateral limit of the breast should be marked with the patient upright.
- With the patient in the sitting position, have the patient activate the latissimus muscle (by placing hands on the hips and coughing) and mark anterolateral margin of the muscle.

- Other key landmarks for the limits of the latissimus muscle are the tip of scapula, vertebral column, and posterior iliac crest. They should be marked for additional orientation.
- The pivot point for the flap is the approximate pedicle location: It should be marked 2 to 3 cm medial to lateral border and 9 cm below the apex of the axilla.
- Eight to 10-cm–wide skin paddles can generally be closed primarily (verify adequate skin laxity by pinching). The skin paddle must be placed over the muscular portion of the latissimus, as the vascularity of the skin over the thoracolumbar fascia is notoriously poor. In most patients, it is necessary to stay at least 8 cm superior to the posterior iliac crest to avoid the thoracolumbar fascia (**FIG 3**).
- Verify that the skin paddle has been designed correctly for rotating to the planned anterior position by measuring from the estimated pedicle pivot point to the inferolateral tip of the skin paddle. This distance must equal the distance from the pivot point to the medial limit of your planned mastectomy incision.
- The orientation of the axis of the skin paddle can be varied (**FIG 4**). A horizontally oriented skin paddle allows the scar to be hidden by a bra strap but may limit the size of the paddle harvested.

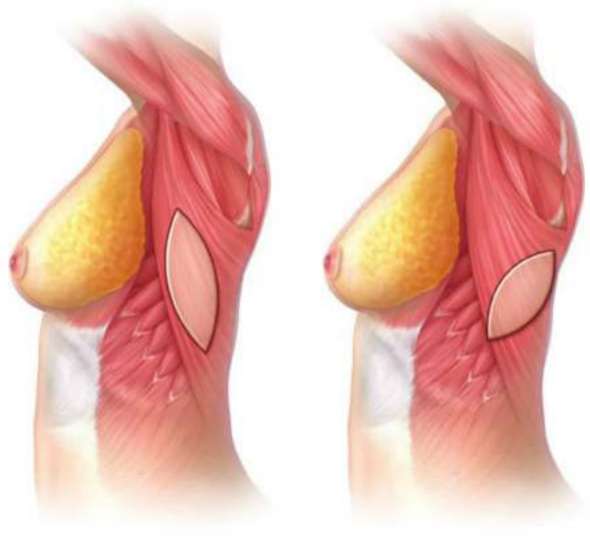

FIG 4 ● Possible orientations of the latissimus dorsi flap skin paddles.

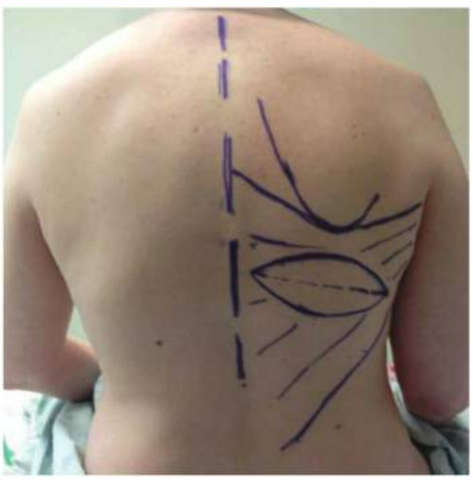

FIG 3 ● Flap markings.

- Measure the breast base width to guide your choice of tissue expander size.
- Patient positioning varies by surgeon. Harvesting a full latissimus dorsi flap requires a lateral decubitus position with a special arm support for the ipsilateral arm and an axillary roll under the contralateral axilla to prevent brachial plexopathy. The lower extremities will also require adequate padding.
- Placing patients in the supine position during the earlier or latter parts of the case is based on surgeon preference and laterality of reconstruction (unilateral vs. bilateral). Bilateral procedures absolutely require position changes.
- The description in the following text will include multiple position changes to make clear the sequence of events for the procedure. This sequence can then be modified.

RECIPIENT SITE PREPARATION (IN EITHER SUPINE OR LATERAL POSITION)

- Develop the recipient site with the patient in supine position: Elevate the skin and subcutaneous flaps off the pectoralis major to recreate the mastectomy defect in cases of delayed reconstruction; for immediate reconstruction, the mastectomy skin flaps are already developed by the breast surgeon.
- Natural borders of the breast should be preserved, including the IMF and skin adherence to the sternum along the midline. A possible exception would be in delayed reconstruction where the inferior dissection can extend approximately 0.5 to 1.0 cm inferior to the IMF to allow the expander to sit at the IMF after the latissimus is inset.
- Limit the lateral dissection, when possible, to the anterior axillary line with the exception of a three to four fingerbreadths tunnel created to allow for transfer of the flap. This tunnel should not violate the IMF.
- The lateral dissection is performed in a suprafascial plane within the tunnel and extends to the lateral border of the latissimus.
- Dissect 2 to 3 cm past the border of the latissimus, on its deep surface, to facilitate flap elevation when the patient is repositioned (**FIG 5**).
- Elevation of the pectoralis major muscle is then performed, disinserting the muscle from its attachments to ribs at the IMF. This disinsertion is terminated at lateral border of the sternum.

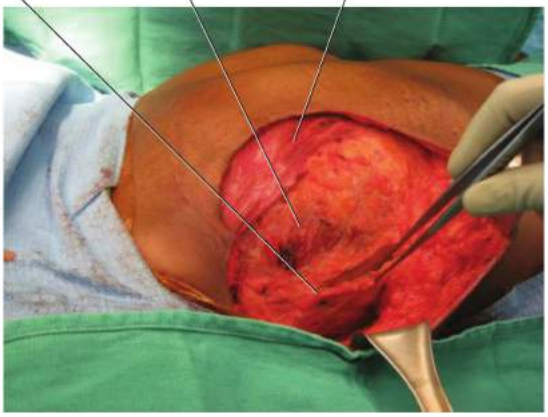

FIG 5 ● View of the chest wall with exposure of the pectoralis major, serratus anterior, and lateral border of the latissimus dorsi muscle.

- The anterior chest surgical site is then packed with moist laparotomy sponges, tucking a sponge laterally under the lateral border of the latissimus. This also helps identify this border of the flap during harvest in the lateral decubitus position. An Ioban sheet is then used to seal the mastectomy defects.

FLAP HARVEST

- The patient is either placed in a lateral decubitus position (**FIG 6**) for a unilateral flap harvest or in a prone position for bilateral flap harvests.
- All position changes require reprepping and redraping of the operative fields.
- The incision is made on the lines of the designed skin paddle. As soon as subcutaneous fat is visualized, the plane of dissection should be beveled outward in a fashion to preserve as many vascular perforators as possible.
- The skin and subcutaneous tissue are elevated off the latissimus muscle until the superior, medial, and inferior limits of the muscle are visualized.

FIG 6 ● Patient positioning (lateral decubitus) for flap harvest.

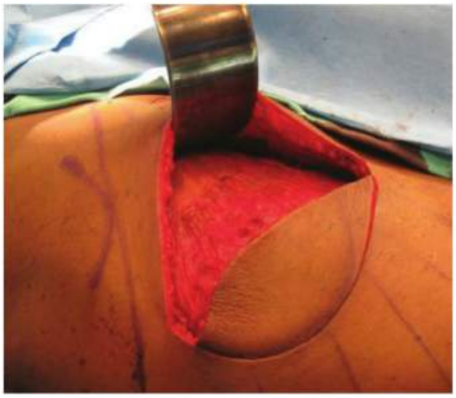

FIG 7 ● Exposure of superficial surface of the muscle during flap harvest.

- Retraction can be a challenging aspect of this step. A Deaver or Harrington retractor and Bovie electrocautery extension are helpful (**FIG 7**).
- Dissection under the lateral edge of the latissimus is now initiated, starting in the area inferolaterally. Note that the anterior edge of the muscle often approaches the midaxillary line.
- Identification of the lateral border of the muscle is easy if elevation is begun while the patient is supine, with placement of a laparotomy sponge under the muscle edge as outlined previously.
- Dissection deep to the latissimus near the pedicle should be done cautiously with electrocautery to minimize the chance for pedicle damage.
- Visualization of the pedicle is not necessary for most pedicled flaps with the exception of flaps requiring

a division of the muscle insertion or flaps requiring denervation.

- Note that the serratus branch artery (**FIG 1**) can guide you from the serratus anterior muscle to the superiorly located thoracodorsal vessels.
- Lateral and medial row segmental pattern perforators to the skin will be encountered in the paraspinal region and should be meticulously cauterized.
- The latissimus muscle is divided medially and inferiorly at the point where the muscle fibers transition into the thoracolumbar fascia.
- Deep to the latissimus muscle, the dissection should be limited to muscle only, leaving behind adipose tissue, as this contains many lymphatic channels; preserving this lymphatic circulation is thought to reduce the risk for seroma.
- The fully elevated flap (**FIG 8**) is then rotated into the previously created lateral chest wall tunnel for passage to the mastectomy defect.
- Placing a large silk stitch on the medial edge of the flap skin paddle is helpful for locating the flap within the tunnel and subsequently for traction to slide the flap through the subcutaneous tunnel.
- A drain tube is placed in back donor site.

FIG 8 ● Elevated latissimus dorsi myocutaneous flap.

- The back donor site is then closed in layers.
- Prior to closure, fibrin sealant such as Tisseel or Evicel can be instilled into the donor site. Although not absolutely necessary, this maneuver is thought to reduce the risk for seroma.
- Dressings in the form of a skin glue product, Steri-Strips, or an ointment are then applied to the suture line.

INSETTING OF THE FLAP

- The patient is repositioned to the supine position.
- The latissimus muscle is advanced into the recipient site. Any restricting bands of tissue near the pedicle pivot point can be carefully lysed to yield better flap rotation and an ideal position of the pedicle.
- Complete skeletonization of the pedicle is not necessary. Disinsertion of the muscle attachments to the humerus can be performed to gain a few additional centimeters of reach.
- Ligation of the thoracodorsal nerve eliminates contraction of the muscle, which can be bothersome to some patients. Most patients, however, do not complain about persistent muscle contractions after transposition of this muscle without sacrificing the motor nerve.
- The latissimus muscle is then inset to the IMF with interrupted absorbable sutures.
- A tissue expander selected based on the patient's chest wall dimensions (primarily breast base width) is then placed in the pocket flanked superiorly by the pectoralis major muscle flap and inferiorly by the latissimus dorsi myocutaneous flap (**FIG 9**).
- Tissue expanders with suture tabs can be used, as they allow the expander to be secured to the chest wall temporarily, preventing migration and optimizing expansion of desired areas of the breast mound.
- The pectoralis major muscle is then approximated to the latissimus with interrupted or running absorbable sutures.
- If there are concerns for tension on the flap, filling of the tissue expander (**FIG 10**) should be delayed.

FIG 9 ● Tissue expander placed behind the pectoralis major (superior) and latissimus dorsi (inferior) muscle flaps within the mastectomy defect.

FIG 10 ● Intraoperative fill of the tissue expander.

- The subcutaneous tunnel opening to the lateral tissue expander pocket can be closed to prevent lateral migration of the implant.
- A drain tube is placed deep to the skin flaps but superficial to the muscle flaps at the inferior pole of the breast, exiting at the lateral chest wall.
- Skin closure is performed in layers with absorbable interrupted deep dermal sutures and a running subcuticular suture (**FIG 11**).
- Dressings in the form of a skin glue product, Steri-Strips, or an ointment are then applied to the suture line.

FIG 11 ● Inset flap skin paddle.

PEARLS AND PITFALLS

Preoperative planning	■ Preoperative CT angiography is worthwhile when axillary lymph node dissection has been performed previously. The thoracodorsal vessels are occasionally ligated during axillary dissections.
Positioning	■ Minimizing the position changes will reduce surgical duration. For instance, a lateral position for both recipient site preparation and donor site harvest followed by supine positioning for the inset and expander placement takes advantage of a single position change.
Freeing the latissimus dorsi	■ Identifying and beginning the dissection underneath the lateral border of the latissimus while the patient is supine allows for an easier flap elevation once the patient is in a lateral position. ■ Disinserting the muscle attachments to the humerus improves the reach of the muscle.
Postoperative seroma	■ Avoid taking out donor site drains too early as seromas are common with this flap elevation.

POSTOPERATIVE CARE

- Patients can be transferred from the operating room (OR) to a postanesthesia care unit (PACU) or directly to a unit with nursing capabilities for flap monitoring.
- Flaps are monitored by physical exams (color, temperature, capillary refill) performed every hour for the first 4 hours and then checks can be spaced out to every 2 hours and 4 hours over subsequent hospital days.
- DVT prophylaxis is the only form of anticoagulation used routinely.
- Diet is advanced from clear liquids to regular on postoperative day 1; there are no restrictions on caffeine.
- Patients are assisted to ambulate beginning on postoperative day 1.
- Foley catheters and intravenous (IV) fluids are discontinued; IV medications/patient-controlled analgesias (PCAs) are converted to orals on postoperative day 1.
- Patients are typically ready for discharge home from postoperative days 2 to 4.
- Surgical drains are discontinued once the output is less than 30 mL for 2 consecutive days.
- Activities are limited and weight-lifting restrictions are in place for 6 weeks postoperative.
- The first postoperative visit is at 1 week following discharge.
- Postoperative results for a left delayed breast reconstruction in an irradiated patient (**FIG 12**).

OUTCOMES

- Breast reconstruction outcomes may be assessed in several ways. Patient satisfaction, shoulder girdle function and reoperation rates are all parameters that have been analyzed in recent literature. An evaluation of patient satisfaction showed that latissimus dorsi breast reconstruction patients are generally satisfied with their decision, with 80% of surveyed patients indicating that they would both recommend the surgery to another person and undergo the surgery again if given the choice. Over 70% of surveyed patients found the size, shape, and scars associated with their reconstructions to be "good" or "excellent." However, contrary to what is previously believed, over one-third of patients questioned reported moderate to severe loss of shoulder force and function. By strict physiometric measurements, there is comparable shoulder range of motion and slight decrease in shoulder strength when compared to preoperative measurements at 1 year postoperatively. This amount of change does not substantially affect the ability to perform daily activities for most patients.[10] Also, reoperation rate was 50% for prosthesis-related problems at a mean follow-up time of 14.9 years.[11]

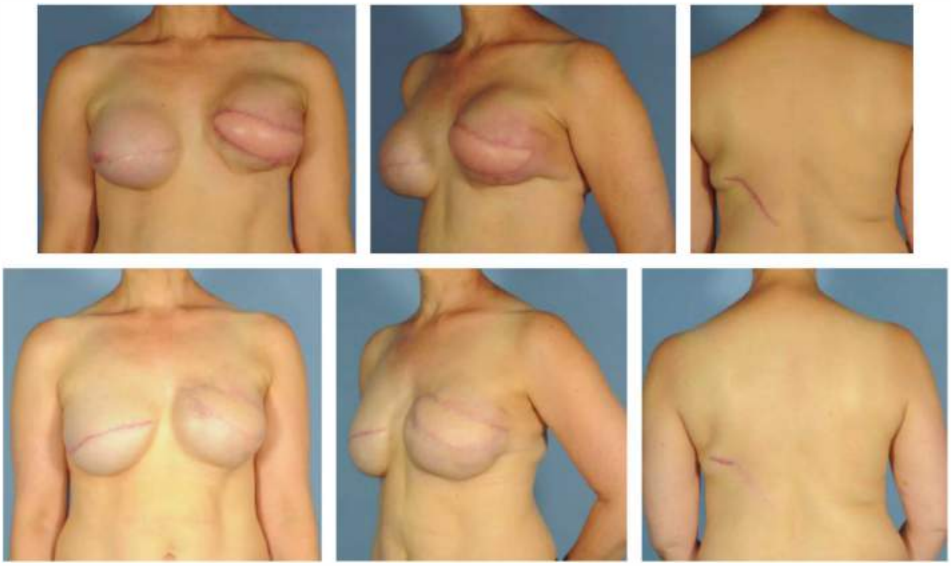

FIG 12 ● A patient with left breast invasive ductal carcinoma who underwent bilateral mastectomies, adjuvant chemotherapy, and left chest wall radiation. *Above*, 4-month postoperative result after completion of tissue expansion. *Below*, 9 months after exchange of the tissue expanders for silicone implants.

- Breast reconstruction patients are typically satisfied in the short term (<5 years) with their choice of reconstruction across implant-based to autologous forms of reconstruction.[12]
- Over the long term (>8 years), satisfaction with abdominal-based flap reconstruction is maintained, whereas satisfaction with implant-based techniques tends to depreciate.[12]
- Studies have also shown greater satisfaction with autologous reconstruction in patients requiring unilateral reconstructions. This is likely the result of better symmetry with the natural contralateral breast.[12]
- Patient satisfaction in bilateral reconstructions has been found to be similar across all techniques provided that the same technique is used on both sides,[12] highlighting again the importance of symmetry.

COMPLICATIONS

Flap-Related Complications

- Infections/implant extrusions—risks for these complications are elevated for implant-only reconstruction of irradiated sites. Autologous tissue transferred to the chest over a prosthesis offers greater resistance to infection or implant extrusion than do prostheses alone on irradiated sites.[13,14]
- Delayed wound healing—this complication typically occurs at the interface between the mastectomy flap and latissimus flap skin paddle. It often is a result of marginal mastectomy flap necrosis from poor skin perfusion, which is more likely in smokers and in the previously radiated breast skin.
- Partial flap loss—an uncommon complication (~3% or less) that is also related to poor perfusion.[15,16] It can be the result of poor skin paddle design. An excision of the necrotic segment is usually required.
- Total flap loss—this is one of the most devastating complications encountered and it occurs in less than 1% of reconstructions.[15,16]
- Capsular contracture—recent studies based on the newest generation implants report approximately 16%.[17]

Donor Site Complications

- Seroma—approximately 9% of latissimus dorsi flap donor sites encounter a seroma.[15,16] Some studies report as high as 34%.[17]
- Delayed wound healing—wound healing problems are encountered often in morbidly obese patients, diabetics, and smokers. These wounds are managed by debridement and dressing changes with healing by secondary intention.

Chapter 17

Pedicled Transverse Rectus Abdominis Myocutaneous Flap Breast Reconstruction

Dale Collins Vidal   Emily B. Ridgway

DEFINITION

- All patients undergoing mastectomy, or those who have undergone a prior mastectomy, are potential candidates for breast reconstruction. The choice to have breast reconstruction is personal, and the options available for breast reconstruction are affected by an individual's anatomy, weight, prior surgical procedures and radiation, and personal preferences. Each patient is unique and consideration must be made of their current breast size, goal breast size, and anatomic limitations.
- The pedicled transverse rectus abdominis myocutaneous (TRAM) flap was first described by Hartrampf in the 1980s and remains the autologous "workhorse" of breast reconstruction. Diabetic patients, smokers, and patients with an elevated BMI or a pendulous panniculus have higher risk for flap failure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete medical and surgical history is essential.
- Prior comorbidities should be identified and the decision for preoperative anesthesia evaluation should be made.
- Current related history must include cancer stage; *BRCA* status; and prior treatments including lumpectomy, biopsy, neoadjuvant chemotherapy, and radiation.
- Accurate documentation of any prior abdominal, pelvic, cardiac, and groin surgery is necessary in order to evaluate the candidacy for a TRAM flap.
- Current breast size, the patient's goal for breast size, and the amount of abdominal tissue will also guide surgical planning and the need for a contralateral symmetry surgery.
- Risks, benefits, and alternate therapies must also be reviewed with the patient including other autologous options (free and pedicled) and implant-based reconstruction options.

Anatomy

- As with any surgical technique, a thorough working knowledge of the anatomy of the chest and abdominal wall and any variants is essential. The primary blood supply of the breast originates from internal mammary perforating branches. Secondary blood supply is received via perforating arteries from the lateral thoracic, pectoral, thoracic, and lateral intercostal arteries. Many of these vessels are injured during mastectomy and much of the mastectomy flap blood supply is compromised and relies on dermal and subcutaneous vessels running just deep to the dermis.
- The abdominal wall is made of skin, varying thickness of subcutaneous adipose tissue, and an anterior rectus fascia overlying the paired rectus abdominis muscles (**FIG 1**).
- Deep to the muscles is the posterior rectus fascia made up of the transversus fascia and internal oblique muscle fascia above the arcuate line and the transversus fascia below the arcuate line.
- The paired rectus muscles originate from the pubic bone and extend to the cartilage of the 6th, 7th and 8th ribs. The blood supply comes from the dominant deep inferior epigastric artery and the superior epigastric artery (**FIG 2**).

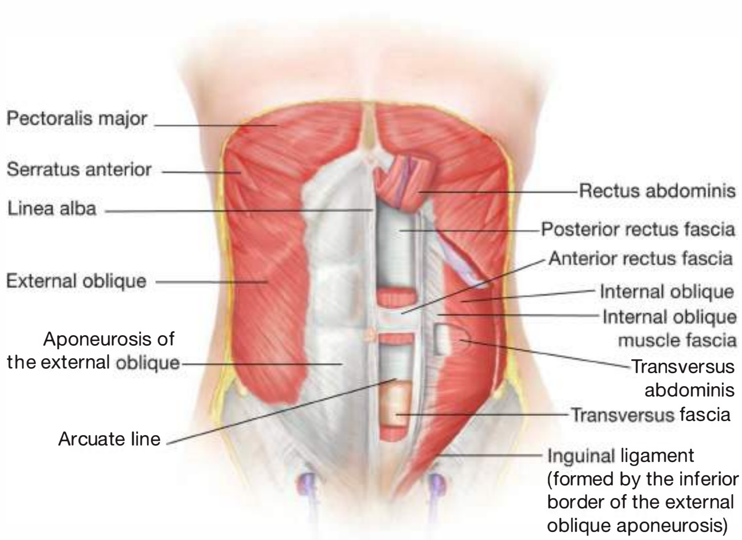

FIG 1 • Abdominal wall musculature.

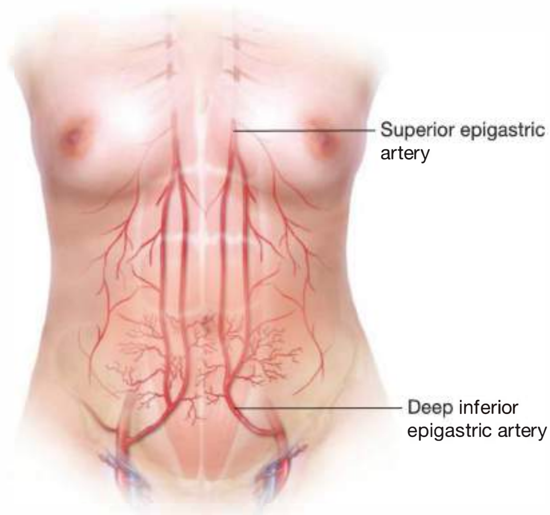

FIG 2 ● Abdominal wall blood supply.

Additional blood supply comes from the posterior perforating vessels accompanying the 8th through 12th intercostal neurovascular bundles.

- Within the muscle, the superior and inferior epigastric arteries may not have direct anastomoses under normal conditions. These connections are made or increased with surgical delay of the deep inferior epigastric artery.
- Musculocutaneous perforators pass through the muscle and anterior rectus fascia (**FIG 3**). They are often gathered in the periumbilical area and in mirrored medial and lateral rows of perforators. The medial and lateral row of perforators on a given side is separated by approximately 1.5 to 2 cm.

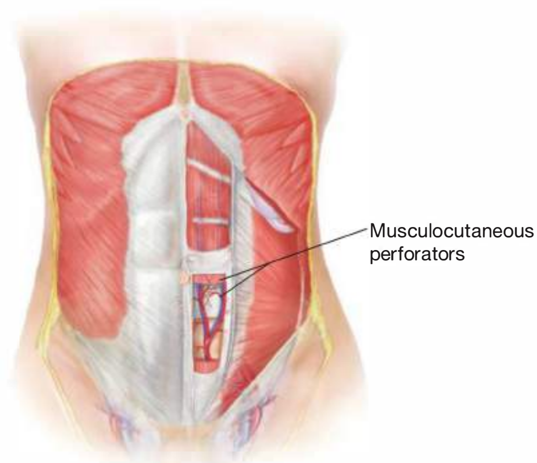

FIG 3 ● Surgical delay is performed to ligate the deep inferior epigastric artery and vein.

In the case of the pedicled TRAM flap, the flap is based on the superior epigastric vessels.

SURGICAL MANAGEMENT

Preoperative Planning

- For high-risk patients, ligation of the inferior epigastric artery (surgical delay) should be considered. Surgical delay of the inferior epigastric artery is performed 10 to 14 days prior to the mastectomy. This is often performed at the time of sentinel lymph node biopsy in order to limit events requiring anesthesia.
- On the day of reconstruction, the patient is marked first in the standing position. At the breast, the inframammary fold (IMF), midline and a line 1 cm off the midline on either side, the lateral breast extension, and proposed or prior mastectomy skin incision approach are marked. The width of the proposed breast reconstruction is measured as this will guide the ideal width of the abdominal flap, which is particularly important in delayed breast reconstruction where there is often a paucity of breast skin (**FIG 4**).
- On the abdomen, the midline is marked and an ellipse of skin including the umbilicus is marked. In our experience, all patients offer at least 13 cm in width of the ellipse and this can be assessed with a pinch test (**FIG 4**).
- The patient is then seated and any further extensions of the incisions are laterally marked to remove any “dog ear.”

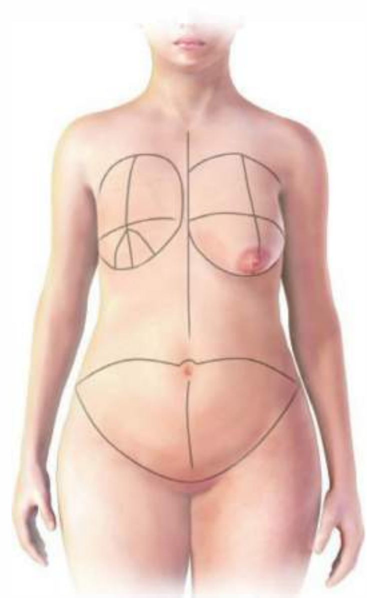

FIG 4 ● Preoperative marking of chest and abdomen in the standing position. Note the lateral dimension of the planned breast should correlate to the height of the planned TRAM flap. The TRAM flap is centered around the site of largest perforators at the periumbilical region.

- Perioperative antibiotics are provided and a Foley catheter and sequential compression device (SCD) boots are placed.
- The flap can be raised while the mastectomy is being performed. No tumescence is used. The superior incision is made first, and the upper abdominal wall is raised to the level of the costochondral cartilages. On the side of the planned reconstruction, a tunnel is made through the IMF into the mastectomy pocket that fits a fist and the planned flap.
- The patient is then flexed and the superior abdominal flap brought down to verify its pending closure and the possible height of the flap to be created. The inferior incision is then made. Beginning laterally on each side, the flap is then elevated with electrocautery above the level of the fascia until the lateral border of the rectus abdominis is seen. At this point, either bipolar or very low cautery is recommended for continuing to complete the identification of both the medial and lateral rows of perforators (**FIG 5**). If a bilateral reconstruction is planned, the midline incision may also be made to help in exposure for dissection (**FIG 6**). No perforators should be sacrificed at this time.
- Once all perforators have been identified, the flap vascularity is assessed. In unilateral reconstruction cases, if one flap has a heartier blood supply, this flap is chosen.
- Methylene blue is then used to mark the planned fascia incisions including each row of perforators and only the intervening fascia. A no.10 blade is used to incise the fascia and sharp dissection around the outside of each medial and lateral perforator under loupe magnification (**FIGS 7** and **8**). The width of this fascia (approximately 2 cm) is also included in the flap superiorly to the level of the costochondral cartilage (**FIG 8**). The underlying rectus muscle is then secured to the anterior rectus fascia and overlying Scarpa's fascia with several 3-0 Vicryl sutures on either side to prevent the flap from being avulsed from the muscle.

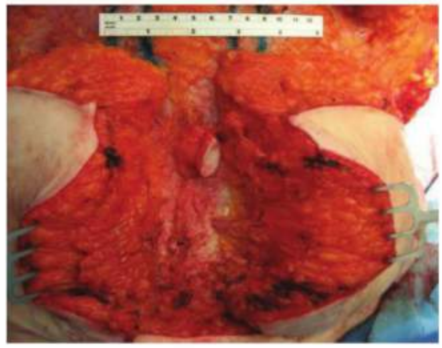

FIG 6 ● If a bilateral reconstruction is planned, the midline incision may also be made to help in exposure for dissection.

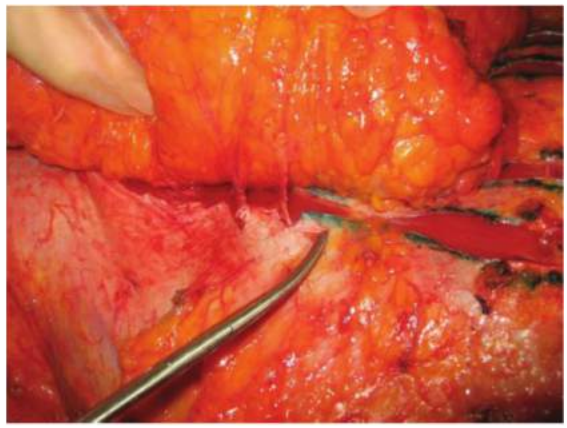

FIG 7 ● Methylene blue is then used to mark the planned fascia incisions including each row of perforators and only the intervening fascia.

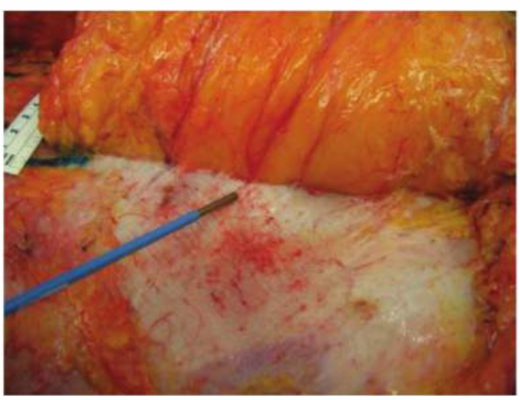

FIG 5 ● Lateral flap elevation: Beginning laterally on each side, the flap is elevated with Bovie cautery above the level of the fascia until the lateral border of the rectus abdominis is seen. At this point, either bipolar or very low cautery is recommended for continuing to complete the identification of both the medial and lateral rows of perforators.

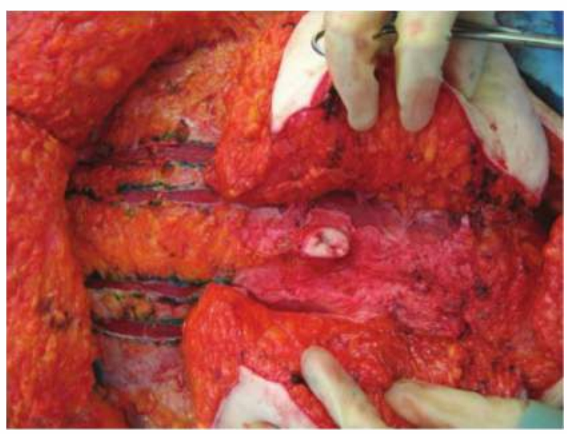

FIG 8 ● Perforator dissection. A no. 10 blade is used to incise the fascia and sharp dissection around the outside of each medial and lateral perforator under loupes magnification.

FIG 9 ● Flap elevation: The width of the fascia within the TRAM (approximately 2 cm) is also included in the flap superiorly to the level of the costochondral cartilage.

- Circumferential muscle dissection is then completed, the deep inferior epigastric artery identified and clipped, and the inferior portion of the muscle divided. The flap is then raised and any posterior perforators and intercostal nerves clipped such that there is no tethering of the flap (**FIG 9**. At the superior border of the fascial dissection, a back cut is made to allow the flap to rotate superiorly without tension or kinking of the blood supply. The flap is then placed within the mastectomy pocket.
- The donor site is then verified for hemostasis particularly at the site of the deep inferior epigastric artery ligation and the narrow gap in the anterior rectus fascia closed with 0-Vicryl and 0-polydioxanone (PDS) sutures (**FIG 10**).

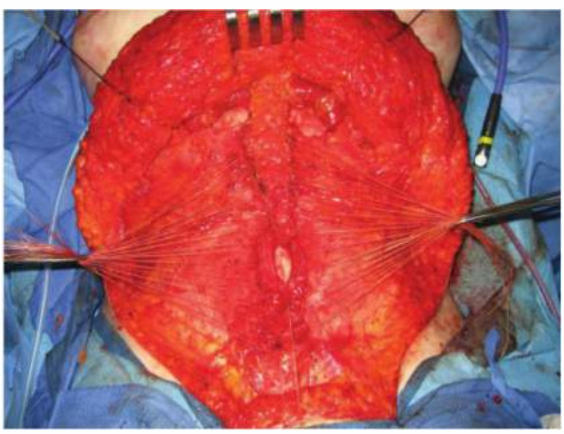

FIG 10 ● Fascia closure: The anterior rectus fascia is closed with interrupted 0-Vicryl and a running 0-PDS suture. The posterior sheath has not been violated. Hemostasis is crucial prior to closure of the fascia.

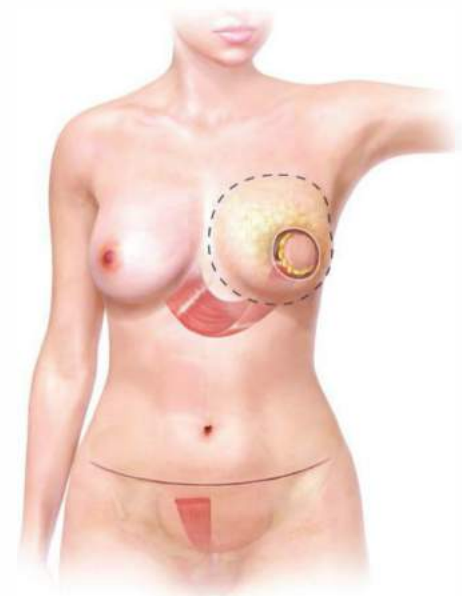

FIG 11 ● Flap placement: The flap is then rotated into the ipsilateral or contralateral mastectomy defect via the prepared tunnel.

In unilateral cases, a plication may be performed on the contralateral side to restore the umbilicus to the midline. This plication and closure should extend from the costochondral margin to the pubic bone to create a smooth desirable abdominal contour. The bed is then flexed and two drains are placed exiting through inferolateral stab incisions. The Scarpa's fascia is then approximated with 0-Vicryl sutures and the dermis closed with buried deep dermal 3-0 Vicryl followed by a subcuticular 4-0 Monocryl and dermal glue.

- By this time, the mastectomy flap can be either clinically assessed or studies used to assess the viability of the mastectomy flaps. The lateral border of the breast can be recreated using dermal to fascia 3-0 Vicryl sutures. Puckering at this time is expected and will resolve. In cases of questionable flap viability, these areas may be excised or the flap inset delayed to allow further debridement of the flaps 3 to 5 days later. In cases where the mastectomy flap is viable, the TRAM flap is de-epithelialized in non–nipple-sparing cases except for the site of the nipple–areolar complex (NAC) or entirely in cases of nipple-sparing mastectomies (**FIG 11**). The flap is then secured medially and superiorly with Vicryl sutures to the pectoralis fascia. A drain is placed running along the IMF and exiting through a lateral stab incision (two drains are placed if axillary lymph node dissection has been performed) and the wound is closed with deep dermal 3-0 Vicryl sutures and a 4-0 Monocryl subcuticular suture followed by dermal glue (**FIG 12**).

FIG 12 ● Immediate tram reconstruction for left skin sparing mastectomy.

PEARLS AND PITFALLS

Preoperative planning	■ A thorough history and physical will identify high-risk factors. ■ Smoking cessation should be strongly encouraged. ■ High-risk patients should be considered for surgical delay. ■ A thorough discussion with the patient regarding goals and reasonable expectations is essential.
Patient marking	■ Careful marking of the patient in the standing and seating positions is essential to a successful TRAM flap.
Intraoperative technique	■ Use either bipolar or very low cautery to avoid injury to the medial and lateral rows of perforators. ■ Carefully assess the mastectomy flap viability. Excise any questionable areas or consider delaying the flap inset.

POSTOPERATIVE CARE

- Awaiting extubation and during transfer of the patient, the bed is kept in the flexed position.
- Routine postoperative care includes removal of the Foley catheter on the night of surgery, SCD boots, and subcutaneous deep vein thrombosis (DVT) prophylaxis beginning 6 hours after the procedure is completed and per the Caprini scale.
- Patients are moved to the chair and ambulated the afternoon of surgery or next morning.
- Incentive spirometry is encouraged hourly.
- No bra is initially placed to prevent compression of the pedicle, and a binder is placed when patient is ambulating but not while in the chair or sitting up in bed again to avoid compression of the pedicle. The binder is recommended for 6 to 8 weeks followed by use of compression undergarments for comfort. A surgical bra without underwire is placed in clinic on the first visit once the mastectomy flap has matured.
- No postoperative antibiotics are given after inset of the flap.
- Patients are discharged between 1 and 3 days after the procedure or on the day of inset if inset has been delayed.

COMPLICATIONS

- The most common complications related to breast reconstruction is mastectomy flap necrosis. Careful inspection and experience with your breast surgeon is critical.
- Partial flap loss or fat necrosis are also possible but have been limited by our requirements of smoking cessation and experience with surgical delay prior to TRAM. Complete flap loss is very unusual.
- Abdominal bulge, hernia, and back pain are also reported complications of TRAM patients.
- DVT and pulmonary embolus are life-threatening complications.

OUTCOMES

- In immediate breast reconstruction cases, common revisions include lateral abdominal dog ear scar revision. If the case was not nipple sparing, this can be performed under local anesthesia at the time of nipple reconstruction.
- Asymmetry can be improved also based on the patient's breast size goal and preoperative size, with contralateral breast reduction or mastopexy.
- Secondary revisions are more common in cases of delayed reconstruction. These can be performed to improve symmetry at the time of nipple reconstruction.
- In all cases, the superior pole may have a paucity of tissue and can be improved with autologous fat grafting. A common secondary procedure includes NAC reconstruction, dog ear revisions, and fat grafting to the superior pole.
- With these revisions, we have found patients to be very satisfied with their outcomes, with a few number of interventions (**FIG 13**).

Chapter 18

Free Transverse Rectus Abdominis Musculocutaneous Flap Reconstruction after Mastectomy

Maurice Y. Nahabedian   Ketan M. Patel

DEFINITION

- Breast reconstruction using free tissue transfer techniques have become routine procedures following mastectomy.
- The most common free flaps for breast reconstruction include the free transverse rectus abdominis musculocutaneous (TRAM) flap and the deep inferior epigastric perforator (DIEP) flap. Indications for these flaps are primarily based on the availability of sufficient skin and fat at the abdominal donor site.
- There are several decision points to be considered when determining candidacy for a free TRAM or DIEP flap. Many patients are now choosing to have bilateral mastectomy and reconstruction in the setting of unilateral breast cancer or for prevention of breast cancer.
- Once the decision to proceed with an abdominal free flap for breast reconstruction has been made, decisions relating to the type of abdominal flaps are considered and based on patient anatomy and surgical experience.
- Non–muscle-sparing free TRAM flaps are technically easier but are associated with increased donor site morbidity that includes contour abnormalities and weakness. These morbidities are increased when the continuity of the rectus abdominis muscle has been disrupted, such as with the traditional pedicle TRAM and the MS-0 (full width) free TRAM. For these reasons, the full-width free TRAM flap is rarely performed and will not be included in this review.
- Muscle-sparing free TRAM flaps and DIEP flaps are technically more challenging and require a better understanding and appreciation of perforator anatomy and dissection techniques. This chapter will focus on the free TRAM flap, whereas the DIEP flap is covered in Part 5, Chapter 19.
- Muscle-sparing TRAM flap classification[1] (**FIG 1** [top])
  - MS-0: no muscle preservation (traditional TRAM flap)
  - MS-1: medial *or* lateral muscle preservation
  - MS-2: medial *and* lateral muscle preservation (central muscle sacrificed)
  - MS-3: total muscle preservation (DIEP flap)

PATIENT HISTORY AND PHYSICAL FINDINGS

- Many women with moderate to excessive volume are interested in these options because of the abdominoplasty appearance of the abdomen that is usually obtained.
- In women that lack a suitable quantity of abdominal soft tissue, alternative donor site options such as the gluteal or medial thigh region are considered.
- Sufficient donor site volume must be assessed to deliver appropriate breast volume. In some cases of bilateral free flap reconstruction, a hemiabdominal flap may not provide adequate volume and adjuncts such as combining flaps with implants or autologous fat grafting may warrant consideration.
- Prior abdominal surgery or body habitus may necessitate the use of computerized tomographic angiography (CTA) or magnetic resonance angiography (MRA) to assess the patency and location of the perforators and deep inferior epigastric artery and vein.

SURGICAL MANAGEMENT

Preoperative Planning

- A thorough history should focus on comorbidities, smoking history, previous surgeries, and medications that can alter surgical management and affect microvascular reconstruction. (Examples include coagulopathies, previous cardiac bypass surgery, previous abdominal surgery, and antiplatelet medications.)
- Physical exam will uncover hernias and previous abdominal scars. In addition, an assessment of the anterior abdomen for thickness and dimensions will aid in estimating a reconstructed breast volume.
- General complications include bleeding, hematoma, seroma, infection, delayed healing, and injury to surrounding structures.
- Specific complications include a 1% to 3% total flap failure rate,[2] early revisional surgery for microsurgical anastomotic thrombosis, late revisional surgery for contour irregularities, breast asymmetry, poor cosmetic result, and donor site complications that include an abdominal bulge/hernia (3% to 5%),[3] complex scarring, lateral "dog ears," and prolonged pain.
- Average length of surgery can range from 4 to 8 hours for a unilateral reconstruction and 6 to 12 hours for a bilateral reconstruction. Appropriate deep vein thrombosis (DVT) prophylaxis and perioperative antibiotics are routinely used due to the length and extent of surgery.
- The decision to proceed with a free TRAM or DIEP flap is sometimes made preoperatively and other times intraoperatively. Patients with a high body mass index (BMI) (>35) who have an overriding pannus are usually scheduled preoperatively for a muscle-sparing free TRAM flap. In other patients, who are found to lack a dominant perforator intraoperatively, the decision to convert from a DIEP to a free TRAM is made. If one or two dominant perforators are found, a DIEP flap is performed.

Anatomy

- The lower abdominal skin is supplied by perforating vessels from the primary source vessels that include the superior and deep inferior epigastric system.

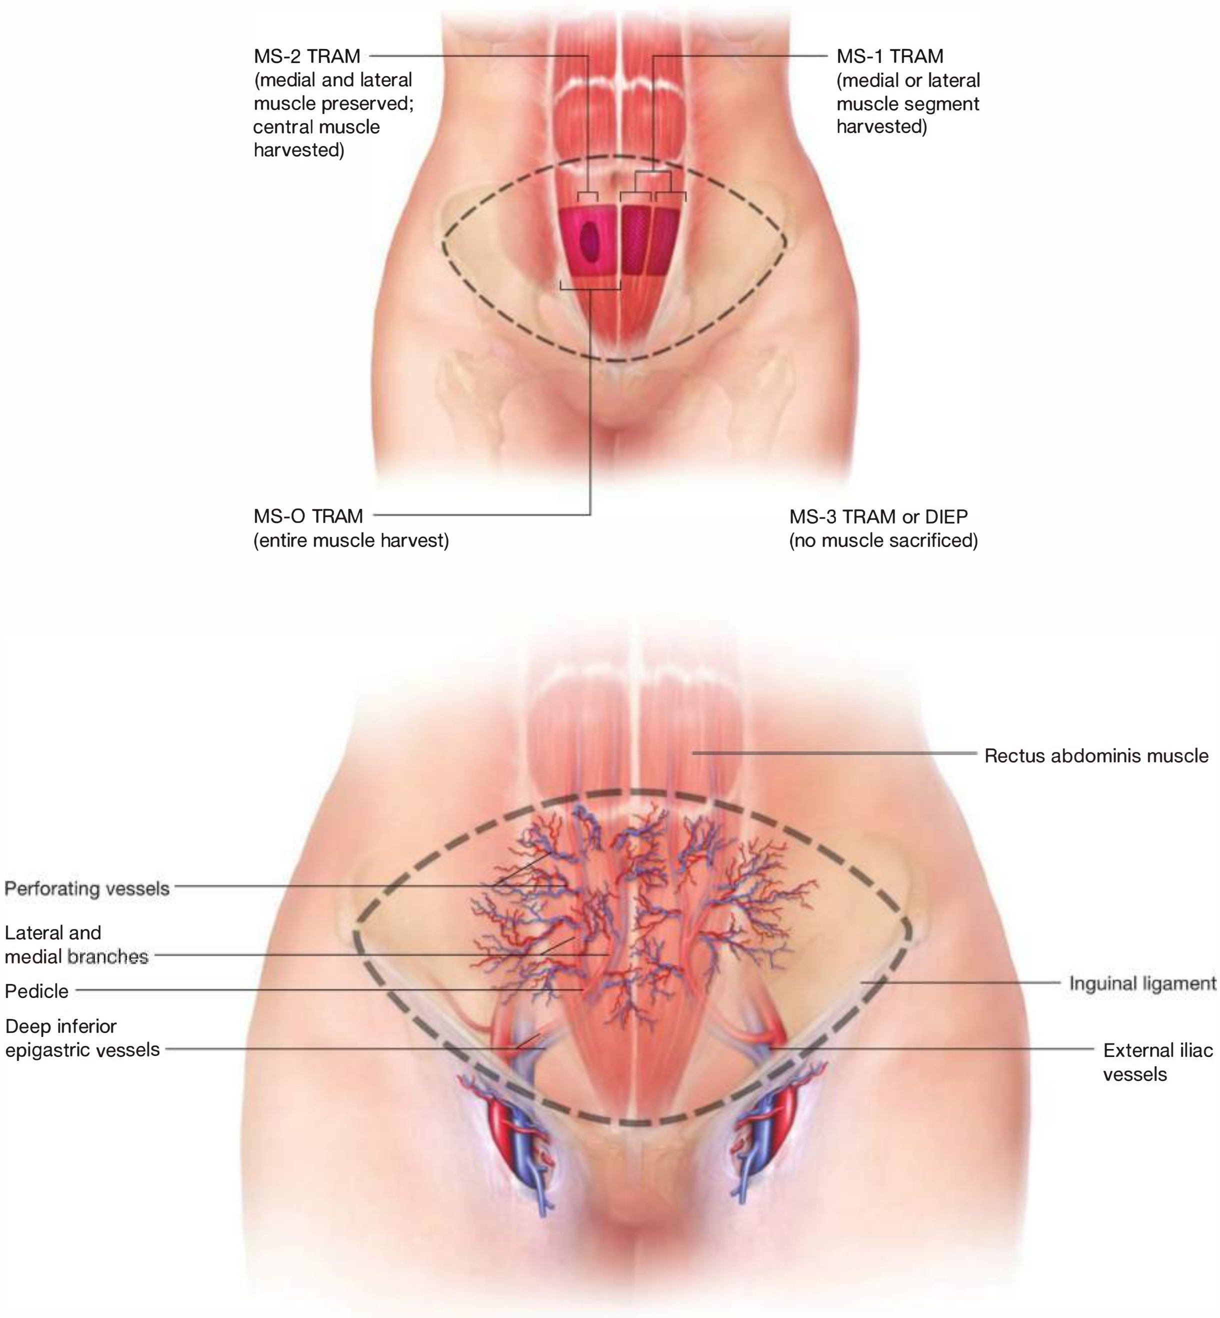

FIG 1 ● The variations of muscle preservation during abdominal flap harvest are shown. A traditional MS-0 represents the entire horizontal segment of rectus harvest. An MS-1 harvest can either spare the medial *or* lateral segments of rectus abdominis muscle as shown. Sparing of the lateral segment of muscle may result in an improved functional benefit as motor innervation to this segment is spared. MS-2 flap harvest spares the medial *and* lateral muscle segments with harvest of a central portion of the muscle. An MS-3 or DIEP flap spares the entire muscle and requires intramuscular perforator dissection.

- Source vessels travel vertically along the fibers of the rectus abdominis muscle on each side of the abdomen and send vertical perforating vessels to the overlying skin and subcutaneous tissue.
- The inferior epigastric system originates from the medial aspect of the external iliac system just superior to the inguinal ligament. The pedicle enters the rectus abdominis muscle on the undersurface from the inferolateral aspect of the muscle at the junction of the lateral and central third of the muscle.
- Two main intramuscular branches are identified: a lateral and medial branch. These branches then send perforating vessels to the overlying skin (**FIG 1** [bottom]).

ABDOMINAL FLAP HARVEST

- The patient is marked in the upright position (**FIG 2**). The anterior superior iliac spine (ASIS) is palpated and marked bilaterally. The upper extent of the abdominal flap is delineated, connecting the two ASIS marks across the abdomen and staying approximately 1 cm above the umbilicus. The lower abdominal line is an estimation that extends from the two ASIS markings in a curvilinear fashion. The inferior limit of this line is the pubic symphysis. The final inferior line is determined in the operating room after the upper skin flap is redraped. The markings for a free TRAM flap and a DIEP flap are identical (**FIG 3**).
- The initial incision is the upper abdominal ellipse. The incision extends to the anterior rectus sheath using electrocautery (**FIG 4**). The upper abdominal adipocutaneous flap is typically undermined to the midpoint between the umbilicus and the xiphoid process.
- The patient is flexed 10 to 30 degrees and the lower abdominal ellipse is definitively delineated and incised. The umbilicus is incised and preserved on its stalk.
- Flap elevation begins from a lateral to medial direction at the level of the anterior rectus sheath. The "safe zone" extends to the lateral edge of the linea semilunaris. Medial to the linea semilunaris, extreme precautions are taken to preserve and avoid injury to perforating vessels from the deep inferior epigastric system (**FIG 5**).
- A decision at this stage must be made to determine if a muscle-sparing free TRAM flap or DIEP flap will be performed. In either case, the lateral innervation to the rectus abdominis muscle is preserved.
- If bilateral free DIEP flaps are to be performed, medial to lateral and lateral to medial perforator dissection is performed (**FIG 6**). This is facilitated using bipolar cautery or monopolar cautery at very low current. Mosquito clamps are used to elevate and divide strands of muscle fibers without injury to the perforators or underlying vasculature.
- With the muscle-sparing free TRAM technique, an island of perforators is defined and the anterior rectus sheath surrounding the island of perforators is incised (**FIG 7**).

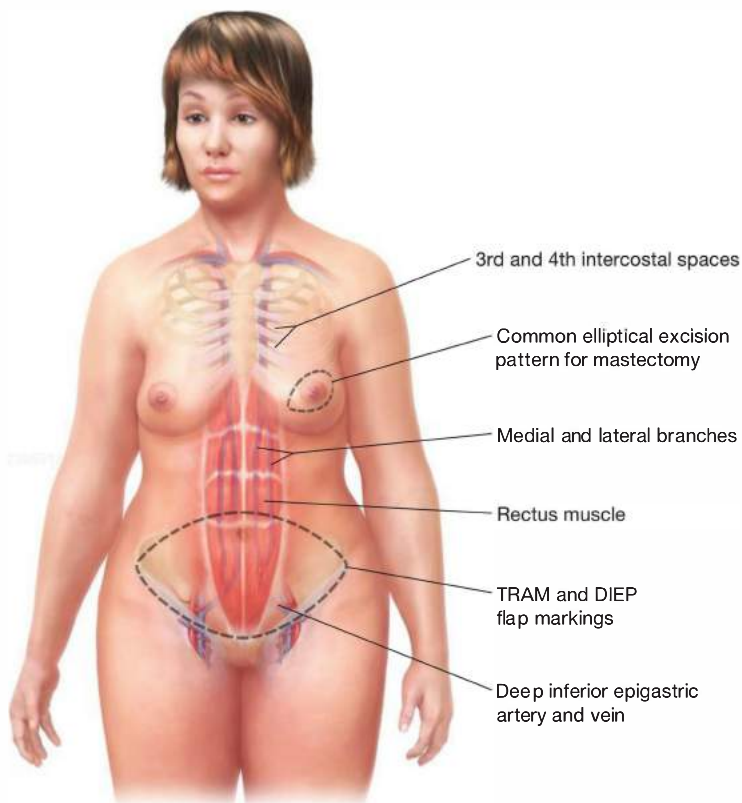

FIG 2 ● An oblique or horizontal ellipse is traditionally performed during a non–nipple-sparing mastectomy. Other configurations that can be used include a periareolar circular pattern or a vertically oriented pattern. Knowledge of the rib anatomy and intercostal spaces will aid in selecting a recipient site for microsurgical anastomosis. A large interspace, usually the 3rd or 4th intercostal space, is usually selected. The internal mammary vessels are located close to the sternocostal junction.

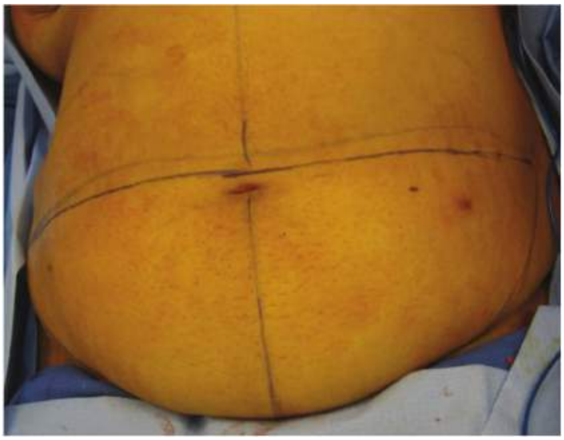

FIG 3 ● The abdomen in supine position is shown. The upper incision is usually located just above the umbilicus. The lower incision is placed in the lower abdominal crease or in a position to allow for donor site closure.

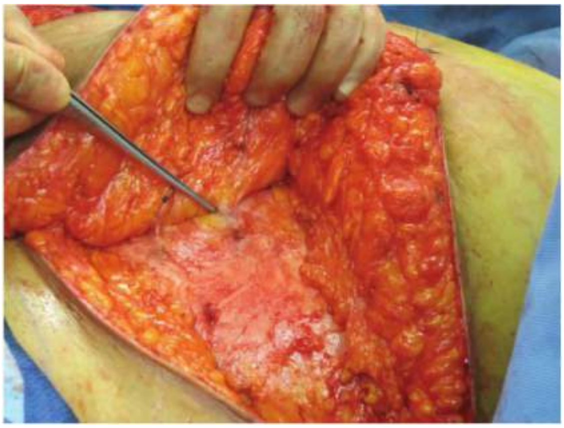

FIG 5 ● Flap elevation begins from the lateral edge. As the rectus sheath is encountered, lateral row perforators can be found piercing the fascia to perfuse the overlying skin and fat.

The medial and lateral sheath is elevated off the muscle and the retrorectus space is defined. The surrounding muscle is divided using monopolar or bipolar cautery.

- The superior portion of the rectus muscle is cauterized and the distal extent of the vascular pedicle is clipped. Palpation beneath the muscle will help identify the pulse and location of the pedicle to ensure that the pedicle is within the muscle segment (**FIG 8**).
- Once this is performed, the flap is solely based on the deep inferior epigastric system and elevated from distal to proximal. Cautery dissection proceeds at low current (**FIG 9**).
- The proximal portion of the pedicle can be visualized travelling toward the lateral edge of the rectus muscle and is dissected using sharp instruments. All side branches are clipped or ligated. Care must be taken to avoid injury to the vessels and intercostal nerves at this stage as diathermic injury may result in vessel thrombosis or neural injury (**FIG 10**).
- Pedicle dissection is continued proximally as deemed necessary for adequate pedicle length. Slightly increased caliber of the deep inferior epigastric artery (DIEA)/deep inferior epigastric vein (DIEV) is seen with more proximal dissection. Approximately 10 to 12 cm may be obtained if dissection is continued to the external iliac vessels.

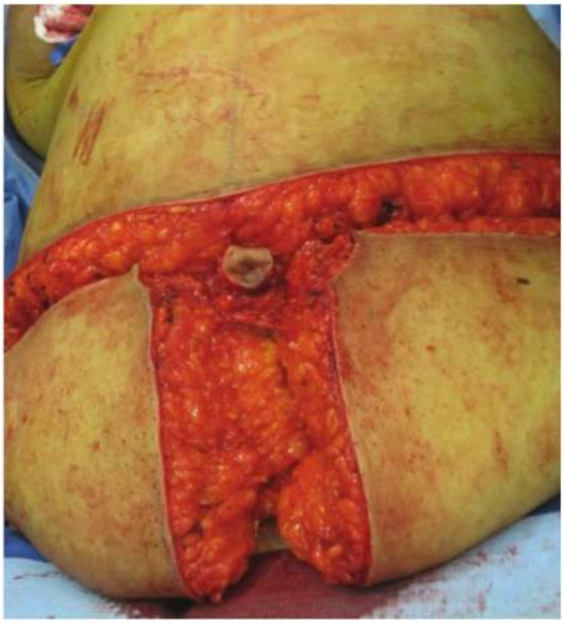

FIG 4 ● The upper incision is performed first. If bilateral reconstruction is being performed, the abdominal flap can be divided down the midline.

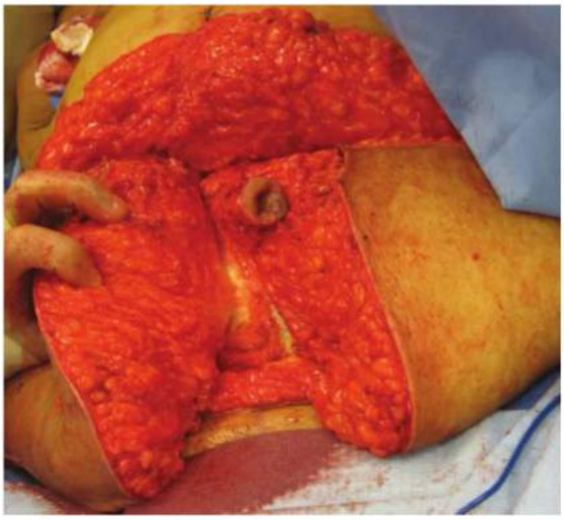

FIG 6 ● Dissection from the medial aspect of the flap is performed until medial row perforators are encountered and/or until safely over the rectus muscle.

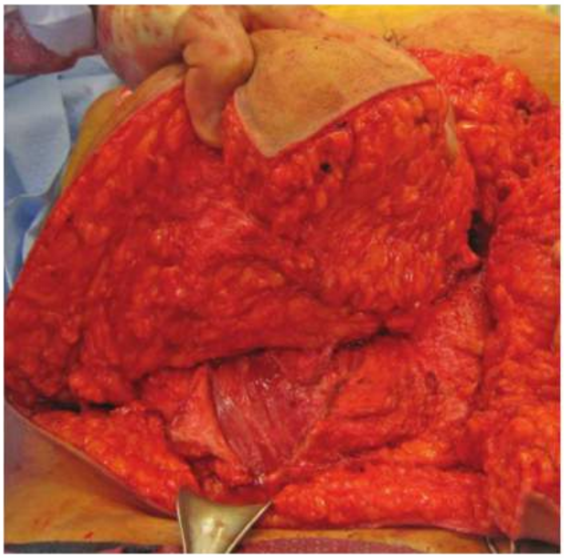

FIG 7 ● When harvesting a muscle-sparing TRAM flap, a fascial island is created around the perforators. The remaining fascia is elevated off of the surrounding muscle for better visualization and dissection.

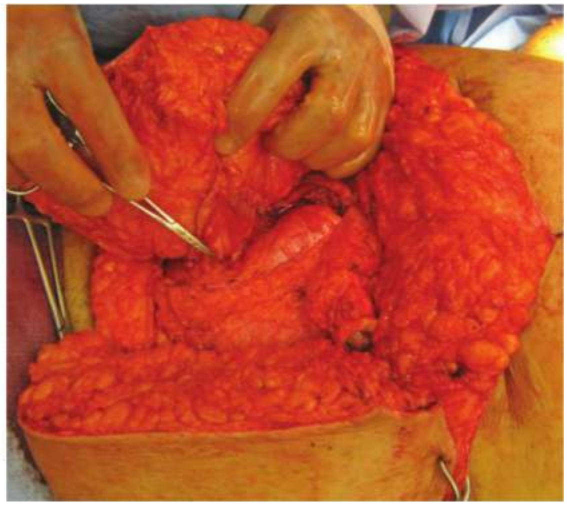

FIG 9 ● Once the muscle cuff is harvested, proximal dissection will reveal the pedicle vessels.

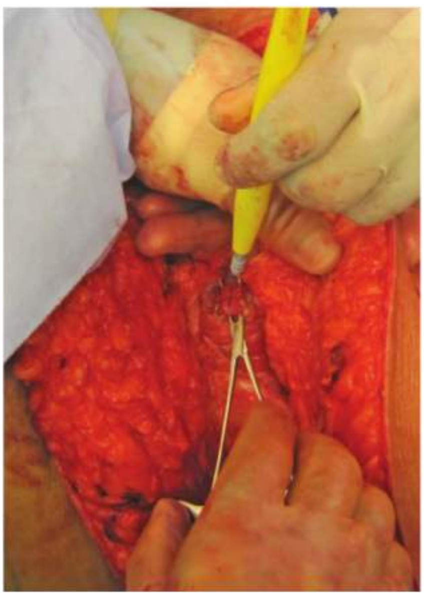

FIG 8 ● Careful dissection of the superior extent of the flap will allow for ligation of the distal pedicle to allow for distal to proximal flap harvest.

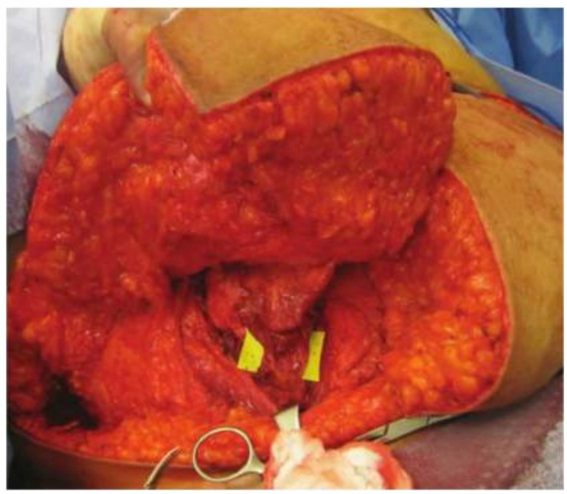

FIG 10 ● Care is taken to avoid injury to the pedicle during retrograde pedicle dissection.

RECIPIENT VESSEL DISSECTION

- The two sets of recipient vessels for free flap breast reconstruction include the internal mammary and thoracodorsal artery and vein. The most commonly used recipient vessels are the internal mammary system.
- The internal mammary vessels run paramedian to the sternum directly beneath the costal cartilage on the left and the right side. The thoracodorsal vessels are posterior in the axillary space and traverse along the anterior surface of the latissimus dorsi muscle.

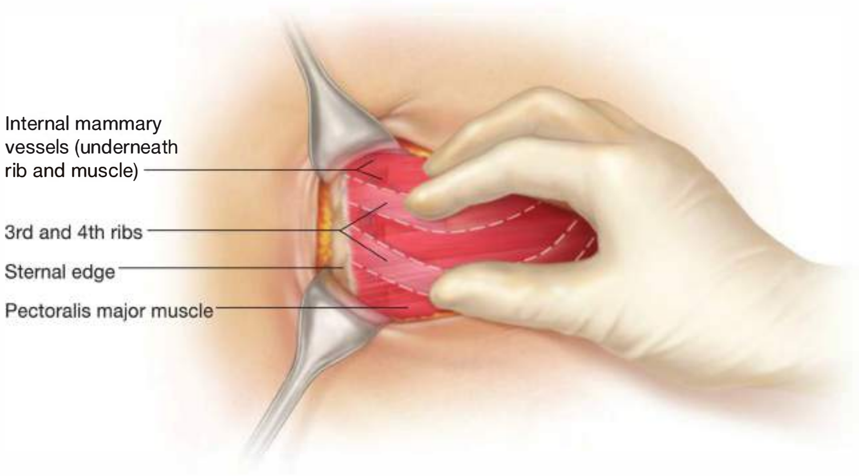

FIG 11 ● Selection of the interspace is usually performed intraoperatively with palpation of the intervening rib segments. Selection of a rib too low can result in a smaller caliber vein and a narrow interspace.

- The exposure technique described is for the internal mammary system. An appropriate intercostal space is chosen that will allow for adequate access for performing microsurgery. This is usually the 3rd or 4th interspace (**FIG 11**).
- The pectoralis major muscle overlying the desired rib is divided along the direction of the fibers using electrocautery. An adequate window is made, allowing for further rib and vessel dissection (**FIG 12**).
- The perichondrium is then removed overlying the costal portion of the rib and dissection proceeds in a subperichondrial fashion (**FIG 13**).
- Doyen surgical instruments are used to release the posterior perichondrium. Caution is taken in this dissection, as inadvertent passage through the posterior perichondrium can result in internal mammary artery and internal mammary vein (IMA/IMV) vessel injury or entry into the pleural space. A rib cutter is then used to isolate and remove a lateral segment of costal cartilage (**FIG 14**).
- Rib removal with a bone rongeur then proceeds from lateral to medial, again avoiding injury to the posterior perichondrium (**FIG 15**).
- Following complete removal of the costal cartilage segment, the posterior perichondrium is divided, elevated, and carefully excised using bipolar cautery and microdissection (**FIG 16**).
- The internal mammary artery and vein are visualized. The vein is usually the medial structure. Occasionally, a vena comitans is present. The recipient vessels are further dissected to clear the perivascular tissue using loupe magnification (**FIG 17**).

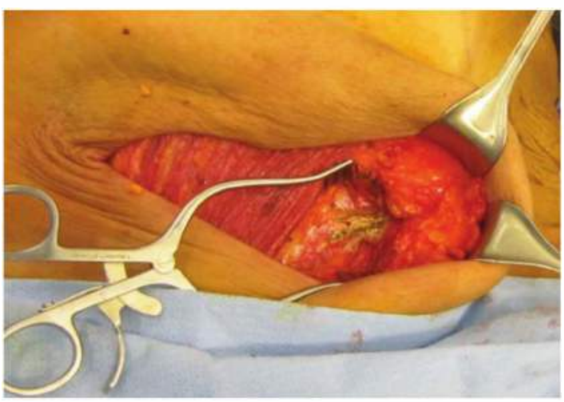

FIG 12 ● Division along the pectoralis major fibers will reveal the desired cartilaginous rib for resection.

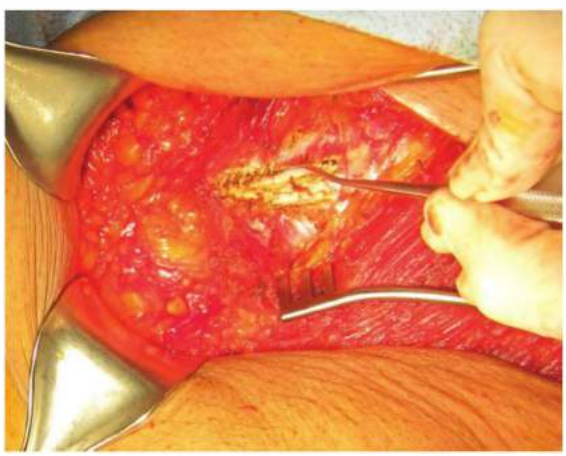

FIG 13 ● The perichondrium is incised and an elevator is used to circumferentially dissect around the rib segment.

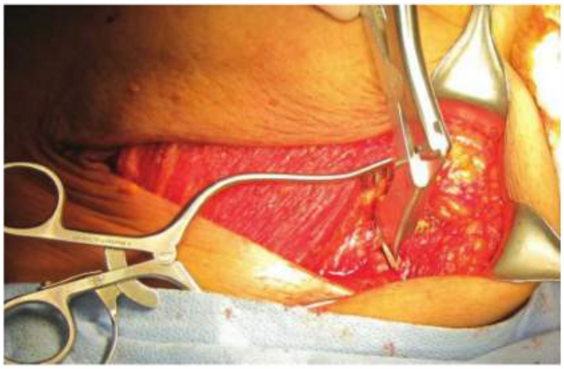

FIG 14 ● A rib cutter is used to remove the cartilaginous segment of rib.

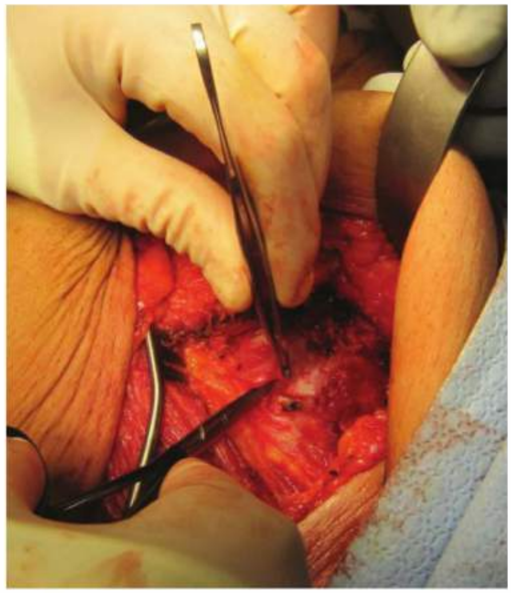

FIG 16 ● Careful dissection is performed to separate the posterior perichondrium from the underlying vessels.

FIG 15 ● A rongeur is used to finish the removal of the cartilaginous portion of rib. Care is taken to avoid injury to the posterior perichondrium as the internal mammary vessels lie deep to this structure.

FIG 17 ● Perivascular dissection is performed in order to prepare the vessels for microanastomosis.

MICROSURGICAL ANASTOMOSIS

- Intravenous heparin is usually administered prior to division of the inferior epigastric vessels.
- The harvested flap is positioned over the chest wall such that the inferior epigastric artery and vein are aligned with the internal mammary artery and vein.
- The medial anastomosis is usually performed first, which is typically the venous anastomosis. This is followed by the lateral or arterial anastomosis.
- The decision to use the vascular coupler (FIG 18) or to perform a hand-sewn anastomosis is based on surgeon preference. If a coupler is chosen, 2.0- to 3.0-mm ring is usually recommended. If a hand-sewn venous anastomosis is chosen, 8-0 or 9-0 sutures are used in an interrupted or continuous fashion. Avoidance of back-wall sutures is critical (FIG 19). Usually 8 to 10 sutures are needed to complete the artery (FIG 20).
- Following completion of the arterial and venous anastomoses, the vascular pedicle must be appropriately positioned on the chest wall to prevent twisting and kinking in order to minimize pedicle-related complications such as thrombosis.
- Positioning of the flap on the chest wall is an important step to recreate the breast contour and shape. Fortunately

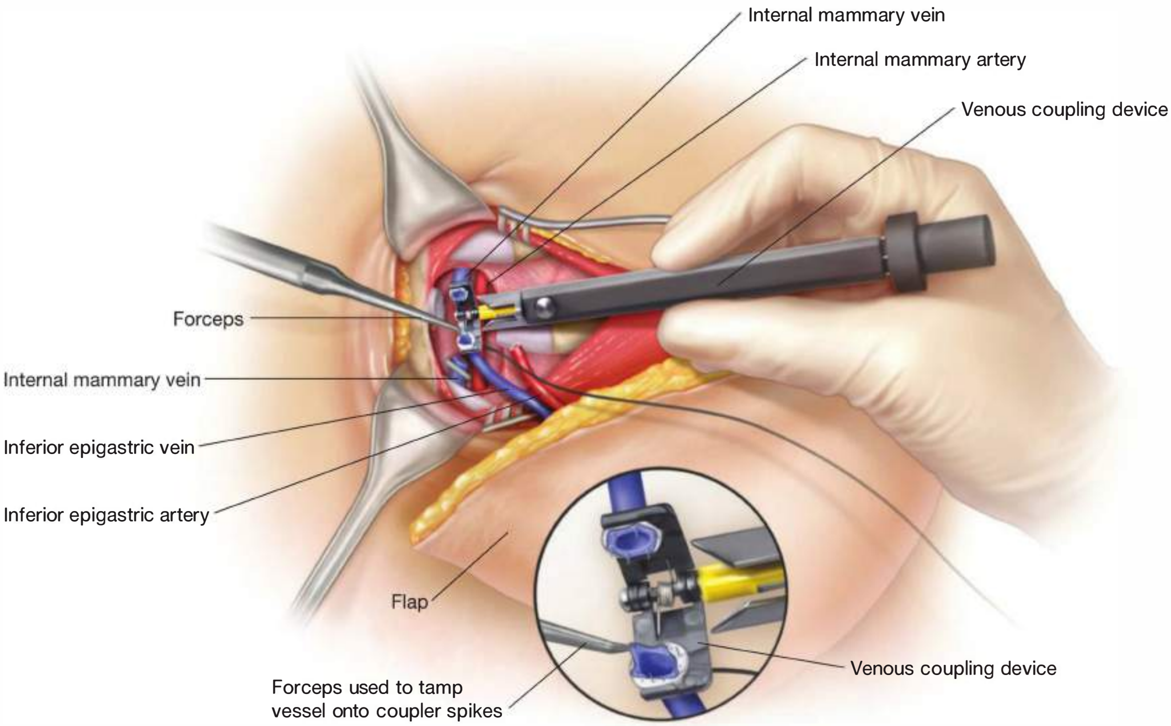

FIG 18 ● When the venous coupler is chosen to perform the venous anastomosis, proper orientation of the coupler device will ensure an efficient anastomosis. Performing the donor vein first will allow for reorientation of the device prior to performing the recipient side. The tamping forceps have a small central hole that allows correct positioning of the vein on the coupler spikes.

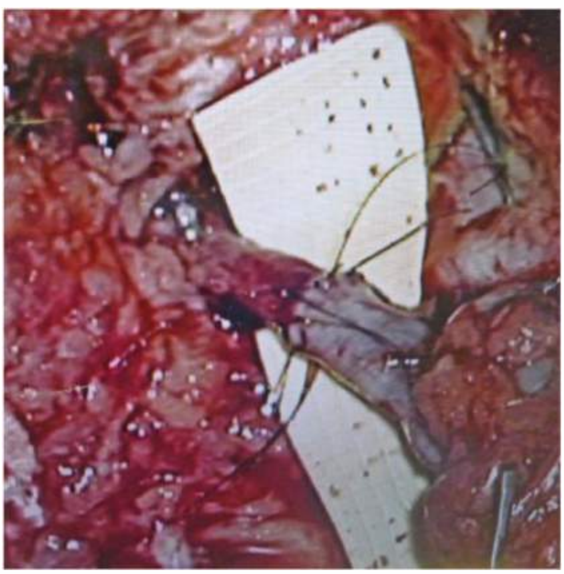

FIG 19 ● The medially located vein is usually anastomosed first with interrupted microsutures.

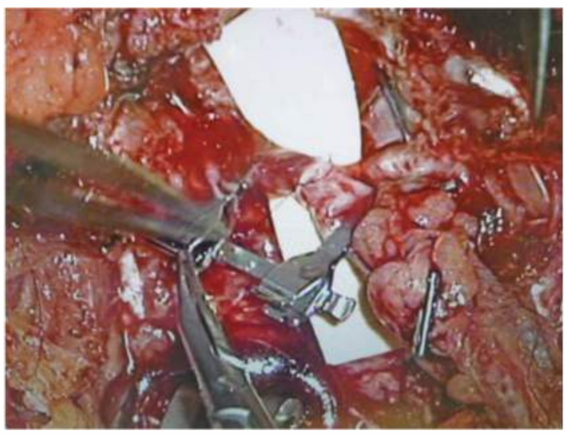

FIG 20 ● Arterial anastomosis is then performed using the same microanastomosis techniques.

with free flaps, there are no points that tether the flap and mobility of the flaps is maintained for optimal shaping.

- The abdominal donor site closure is an important phase of the breast reconstruction. With the DIEP flap, there is no muscle removed and usually no fascia; therefore, the closure consisted of a primary closure using a nonabsorbable monofilament. Reinforcement with a synthetic mesh is rarely necessary. With the muscle-sparing free TRAM, muscle and fascia are removed; therefore, it is sometimes necessary to replace the fascia with a synthetic or biologic mesh. This is more common with bilateral reconstructions compared to unilateral (**FIG 21**).
- Two drains are usually placed in the donor site and one drain in the reconstructed breast.

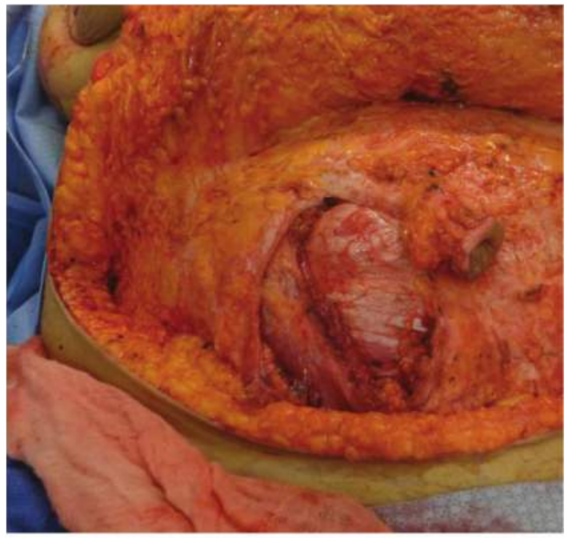

FIG 21 ● The donor defect is shown. When larger segments of anterior rectus sheath are harvested (such as in MS-0 and MS-1 TRAMs), mesh is used to either reinforce the anterior abdominal wall or to replace the anterior fascia.

PEARLS AND PITFALLS

Flap dissection	■ Finger palpation of the pedicle pulse is crucial during muscle-sparing harvest techniques. ■ A longer pedicle will allow for a larger vessel internal diameter that more closely matches the internal mammary vessel diameter.
Microanastomosis techniques	■ Secondary venous drainage may be helpful for larger flaps. ■ Radiated internal mammary vessels are less pliable and may tear more easily when using a venous coupler device.
Flap insetting	■ Excising radiated mastectomy flap skin may prevent tightness of the flap inset and later contour irregularities. ■ Suture tacks in the superior portion of the flap will maintain contour of the superior pole of the breast.

POSTOPERATIVE CARE

- Close flap monitoring occurs in the first 72 hours to ensure flap viability. A strict nursing flap check protocol includes frequent Doppler examination, color, and capillary refill assessments. Tissue oximetry is used on almost all flaps.
- Patients are maintained on postoperative antibiotic therapy for approximately 5 days and aspirin for 1 to 2 weeks to prevent anastomotic thrombosis.
- Ambulation is encouraged on postoperative day 1 or 2.
- Patients usually stay in the hospital for 3 to 4 days following surgery and are discharged home. They are encouraged to shower on postoperative day 3.

OUTCOMES

- The free TRAM reconstruction has been demonstrated to result in high levels of patient satisfaction and quality of life.[4] In long-term evaluation, autologous tissue reconstruction maintains a more natural-appearing breast as compared to implant-based reconstruction.[5]
- Abdominal donor site morbidity is relatively low.[6,7] Bulge/hernia formation may occur in approximately 3% to 5% of patients. In the event that surgical repair is necessary, this is usually achieved with fascial plication and reinforcement with a synthetic mesh.
- The free TRAM and DIEP flaps for breast reconstruction are valuable options for breast reconstruction following mastectomy.
- Free tissue transfer techniques are useful in complex situations such as prior radiation therapy, prosthetic failure, and in overweight and obese patients.
- Microsurgical expertise is necessary to obtain predictable outcomes and a low failure rate.
- Donor site morbidity rates are acceptable. Most women will achieve an "abdominoplasty" appearance of the abdomen following free TRAM and DIEP flap reconstruction.

COMPLICATIONS

- The most relevant complications following microvascular breast reconstruction include anastomotic thrombosis, hematoma, and flap failure. Postoperative flap monitoring is necessary to ensure prompt operative exploration in cases of vascular thrombosis. This is usually accomplished using tissue oximetry or Doppler analysis. Return to the operating room is necessary when there is a disruption in flow. Revision maneuvers include mechanical thrombectomy, tissue plasminogen activator (TPA), and redo anastomosis.

- Donor site morbidities are slightly more common and include contour abnormalities (hernia/bulge), incisional dehiscence, delayed healing, hematoma, and seroma. These complications can be managed conservatively but sometimes require operative intervention.

Chapter 19

Deep Inferior Epigastric Perforator Flap Breast Reconstruction after Mastectomy

Adeyiza O. Momoh

DEFINITION

- Autologous reconstruction techniques after mastectomy are well-established options for breast reconstruction. Although over the years multiple flap options for reconstruction have been described, abdominal-based flaps continue to be the workhorse for autologous breast reconstruction. Abdominal flaps provide distinct advantages over implant-based reconstruction including a natural contour, superior symmetry and appearance of the reconstructed breast mound, and higher patient satisfaction.[1,2] A secondary benefit of these flaps is the improvement they provide to the abdominal contour. Hartrampf et al.[3] first described the pedicled transverse rectus abdominis myocutaneous (TRAM) flap in 1982, with its benefits of providing a soft, ptotic, aesthetically pleasing reconstruction that closely approximates the natural breast. Technical advancements and the continued quest to improve on flap perfusion and minimize donor site morbidity led to the introduction of the deep inferior epigastric perforator (DIEP) flap by Koshima and Soeda[4] in 1989 with later popularization by Allen and Treece[5] in 1994. The DIEP flap has gained in popularity over the years, and the potential benefits it offers include less abdominal wall weakness, bulging, and hernias.[6–8]

ANATOMY

- The DIEP flap is an adipocutaneous flap based on intramuscular perforators from the deep inferior epigastric artery (DIEA) and deep inferior epigastric vein (DIEV).
- The DIEA and DIEV originate from the external iliac vessels in the groin and course superomedially toward the lateral border of the rectus abdominis muscle.
- Deep to the rectus abdominis muscle, the DIEA and DIEV most commonly bifurcate (type II branching pattern) in the vicinity of the arcuate line and join up with the superior epigastric vessels above the umbilicus.
- Other encountered branching patterns are the type I with no branching and type III with trifurcating vessels (**FIG 1**).
- Perforators to the lower abdominal skin and adipose tissue come off the pedicle at multiple levels and are referred to as medial or lateral rows of perforators, indicating their relative position within the rectus/entry point into the flap.
- Most perforators are found within a 10-cm radius from the umbilicus.
- Zones of perfusion based on fluorescent perfusion studies[9] are illustrated in **FIG 2**—illustration with zones transposed onto rectus/pedicle.
- In general, perfusion of the hemiabdominal flap ipsilateral to the perforators (zones I and II) is stronger than it is to the contralateral abdominal flap across the midline (zones III and IV).
- Medial row perforators have a greater likelihood of perfusing tissue across the midline than do lateral row perforators.
- In contrast, lateral row perforators have a greater likelihood of perfusing the most lateral extent of the ipsilateral hemiabdominal flap than do medial row perforators.
- Medial and lateral rows of perforators communicate via a subdermal plexus.
- There is also communication between DIEA and DIEV system and the superficial inferior epigastric artery (SIEA) and superficial inferior epigastric vein (SIEV) system.
- The SIEV is the dominant outflow vessel for the lower abdomen in many patients.

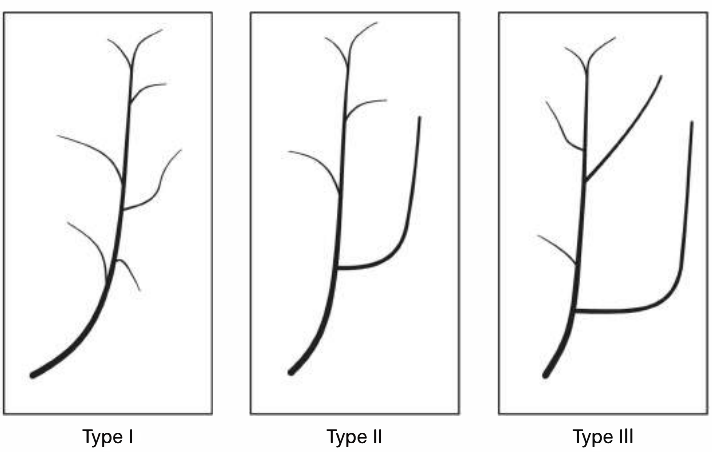

FIG 1 • Type I, type II, and type III vascular branching patterns.

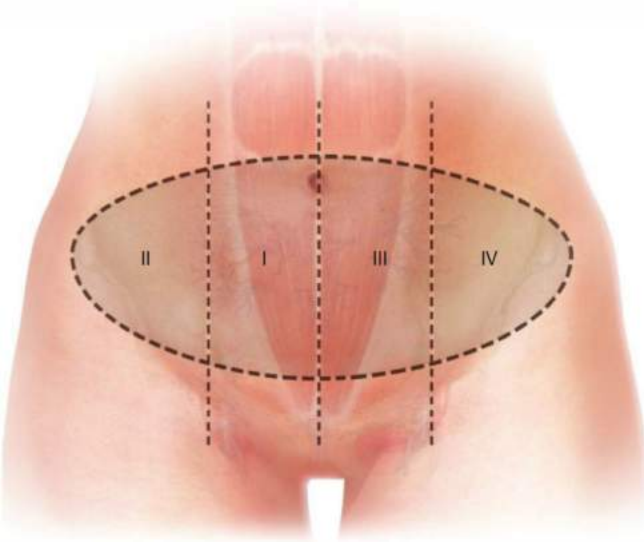

FIG 2 ● Zones of perfusion of the lower abdomen based on fluorescent perfusion studies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical examination are critical in preparing for reconstruction.
- Pertinent aspects of the history include previous abdominal or chest wall operations and medical conditions that would preclude patients from a lengthy operation under general anesthesia."
- A focused abdominal examination evaluating the amount of lower abdominal adipose tissue and the location of surgical scars if present
- A team-based approach involving surgeons, anesthesiologists, primary care physicians, and other specialists such as cardiologists, as needed, ensures that patients are evaluated as a whole and all key concerns are addressed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative computed tomography (CT) angiography of the donor site has been advocated in recent years. The preoperative scans provide a road map for flap perforators, with information on perforator location, size, and distribution (FIG 3).
- In patients with long low transverse abdominal incisions, the scans also allow for the assessment of continuity of the flap pedicle beyond the incision.
- Information gathered from scans has been shown to decrease operative times.[10] CT scans, however, are not an absolute requirement for preoperative planning.

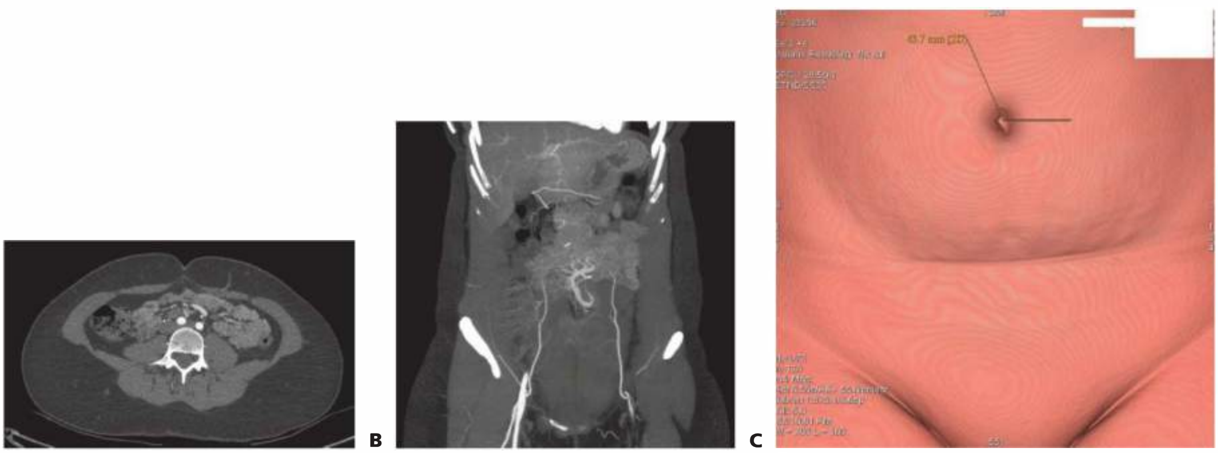

FIG 3 ● **A,B.** Preoperative CT angiography of the lower abdomen. **C.** A 3-D rendering of the abdominal soft tissue. Perforator locations based on axial cuts are transposed to the skin surface to enhance preoperative planning.

SURGICAL MANAGEMENT

- In consulting with patients, decisions about the timing of reconstruction (immediately after mastectomy or delayed) and the type of reconstruction are made, taking patient factors and tumor characteristics into consideration.
  - Patient factors of significance include the following:
    - Patient preference
    - Body habitus or the availability of abdominal donor tissue
    - Body mass index
    - Smoking history
    - History of previous abdominal operations that compromise the vascular pedicle or donor site
    - Medical comorbidities that would preclude patients from undergoing a lengthy operation
  - Tumor characteristics as they relate to the following:
    - The need for postmastectomy radiation therapy or
    - The need for close postmastectomy surveillance prior to reconstruction
    - In general, patients known to require postmastectomy radiation therapy are reconstructed in a delayed fashion to avoid the detrimental effects of radiation on flaps. A history of radiation therapy also serves as a relative indication for use of an autologous form of reconstruction, as implant reconstructions in the setting of radiation are prone to higher rates of complications and failure.

Preoperative Planning

- In addition to basic labs, patients should be type and screened, particularly in cases of bilateral reconstructions.
- All anticoagulant and antiplatelet medications should be stopped a week prior to the operation. Warfarin can be bridged with enoxaparin also a week prior.
- Smokers are required to quit for a minimum of 4 weeks prior.
- Patients receive preoperative antibiotics with intraoperative redosing.
- Patients receive deep vein thrombosis (DVT) prophylaxis with use of a pneumatic compression device and subcutaneous heparin at the beginning of the case.

Positioning

Marking/positioning

- Preoperative markings of the breast and abdomen are performed with the patient in the upright position.
- Key landmarks for the breast marked are the chest midline, inframammary fold, and a periareolar marking in the case of a skin-sparing mastectomy. The breast base width is also measured (**FIG 4A**).
- The upper marking for the abdominal flap is made at or just above the umbilicus with the location of perforators on preoperative imaging, providing some guidance. The breast base width is used to mark the potential vertical height/distance from the upper marking to the lower marking. The lower marking is then made to complete the elliptical pattern (**FIG 4B**).
- Patient positioning in the operating room (OR) is supine and the table is turned 180 degrees from the anesthesiologist, providing better access for two surgical teams (**FIG 5**).

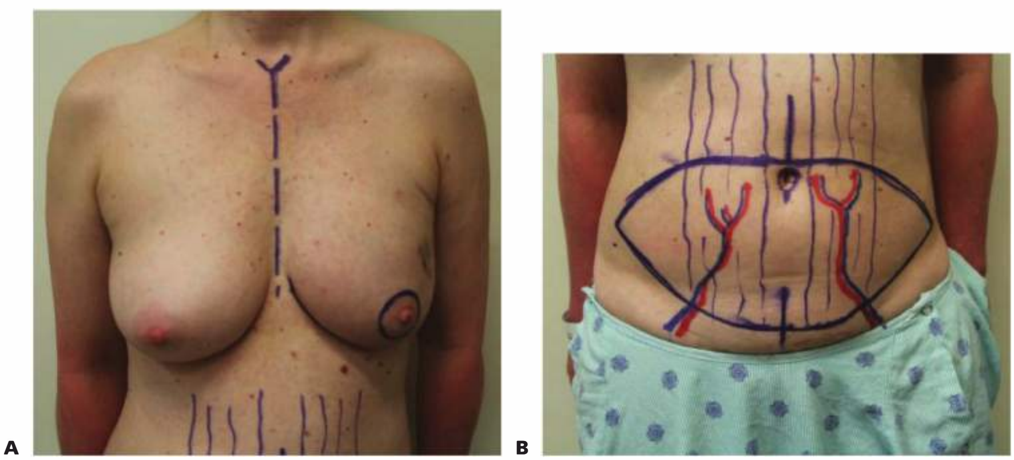

FIG 4 ● **A.** Breast preoperative marking. **B.** Abdominal preoperative marking.

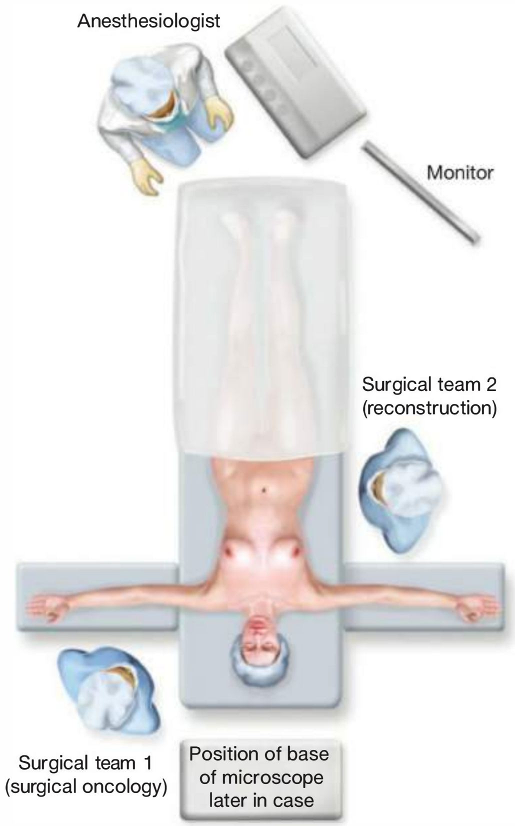

FIG 5 ● Patient positioning in the OR.

FLAP HARVEST

- Skin preparation with clipping is performed as needed.
- The breasts and abdomen are prepped and draped in a sterile fashion.
- The upper abdominal incision is made with a scalpel, and dissection through the adipose tissue down to anterior abdominal wall fascia is performed with electrocautery.
- An adipocutaneous flap is elevated cephalad with the electrocautery, ending at the xiphoid centrally and at the costal margins laterally. Less elevation may be needed in patients with ample skin laxity.
- The OR table is reflexed and the raised upper abdominal flap is transposed downward to assess the ability of this skin edge to meet the lower abdominal markings for closure. The lower abdominal markings are at this time adjusted as needed and the table returned to its original position.
- The lower abdominal incision is made superficially with a scalpel and careful dissection through the adipose tissue is performed, anticipating the presence of the SIEA and SIEV, typically above Scarpa's fascia (**FIG 6**).
- Once the superficial vessels are visualized, a Weitlaner retractor is introduced to provide further exposure and

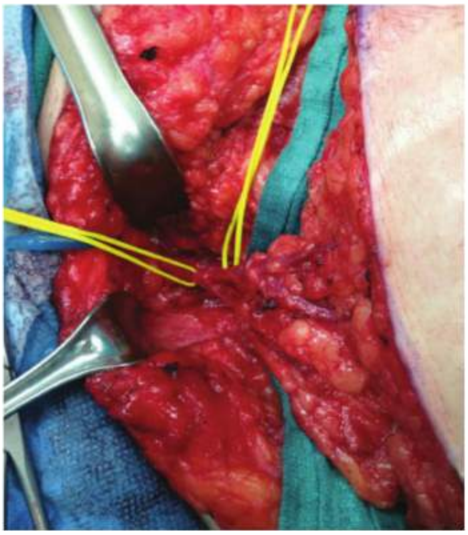

FIG 6 ● Dissection of the SIEV within the lower abdominal incision.

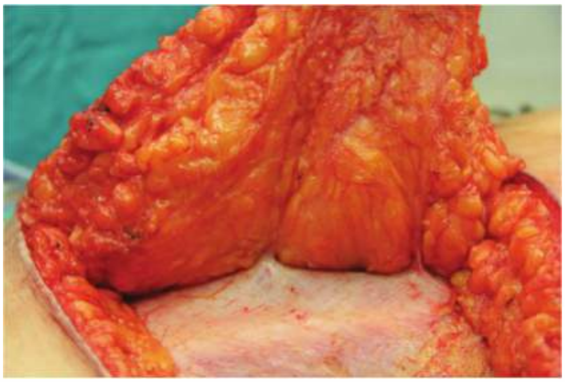

FIG 7 ● The lateral row of perforators visualized with suprafascial flap elevation.

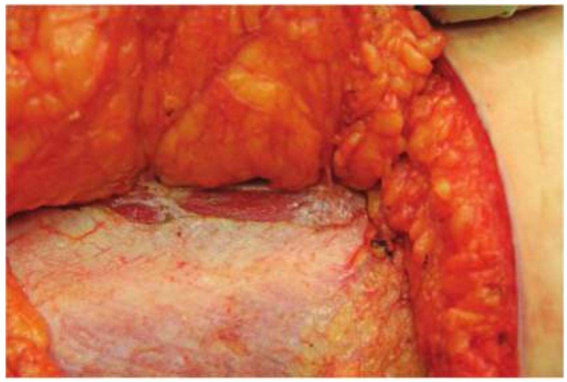

FIG 9 ● Subfascial exposure of flap perforators.

the vessels are dissected out toward the femoral vessels with use of tenotomy scissors and bipolar electrocautery. In patients who are not good candidates for the SIEA flap (SIEA) based on the absence of adequate-sized vessels, the vein is dissected to a length greater than or equal to 5 cm prior to ligating it with hemoclips and dividing it.

- Dissection down to the anterior abdominal wall fascia is then completed with electrocautery.
- Flap elevation is performed in the suprafascial plane from lateral to medial with electrocautery until the lateral row of perforators are encountered just medial to the edge of the rectus fascia (**FIG 7**).
- An incision is made around the umbilicus and along the midline of the flap in bilateral reconstruction cases or in cases with hemiabdominal flaps large enough for a unilateral reconstruction.
- The umbilical stalk is dissected out with blunt-tipped scissors and division of the flap down the midline is completed with electrocautery.
- In unilateral reconstructions that require use of portions of the flap that cross the midline, the umbilicus is dissected out without splitting the flap.
- Suprafascial elevation of the flap from its medial edge is performed with electrocautery until the medial row of perforators are encountered.

FIG 8 ● Perfusion map with laser-assisted indocyanine green fluorescent dye with dark areas indicating poor perfusion.

- Dissection around the perforators is performed with a low-energy electrocautery, and at this time, all perforators are assessed for their size and location within the flap.
- Small perforators (<1.5 mm in diameter) are ligated with hemoclips and one or more perforators within either the medial or lateral row are selected for use.
- Laser-assisted indocyanine green fluorescent dye can be employed at this point to assist with perforator selection. Appropriate-sized Acland clamps are placed on all perforators excluding the few selected and the dye is administered by the anesthesiologist intravenously. Within a few minutes of the dye administration, a real-time perfusion map of the flap is visualized (**FIG 8**).
- Alternatively, capillary refill can be assessed with the Acland clamps in place for a few minutes to determine adequacy of flap perfusion based on the few selected perforators.
- The anterior rectus fascia adjacent to the selected row of perforators is incised with electrocautery in a craniocaudal orientation (**FIG 9**).
- A millimeter cuff of fascia is cut with a tenotomy around the perforator, freeing it from the surrounding anterior rectus fascia.
- Two to 3 mL of heparinized saline is then injected into the rectus muscle adjacent to the individual perforators with an olive-tipped cannula. The heparinized saline used in this fashion hydrodissects the surrounding soft tissue away from the perforator and aids with visualization of the perforator course. This technique is repeated as needed throughout the course of the intramuscular dissection (**FIG 10**).
- The perforators are dissected through the rectus muscle with the aid of a bipolar electrocautery down to the larger deep inferior epigastric arterial and venous system that runs beneath the muscle.
- The continuation of the DIEA and DIEV system to the superior epigastric vessels is encountered above the most cephalad perforator and these vessels are ligated with

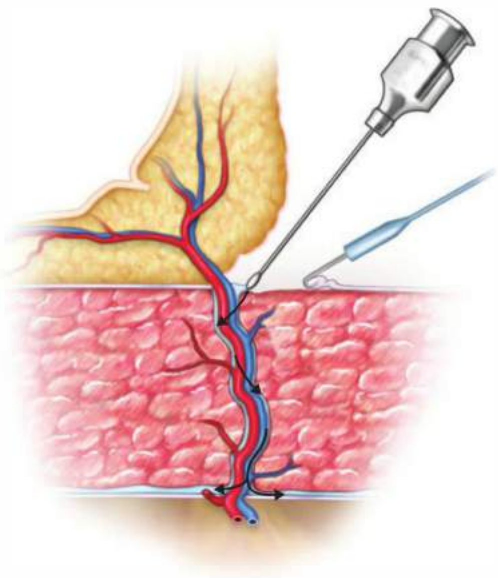

FIG 10 ● Hydrodissection technique for intramuscular perforator dissection illustrated. Heparinized saline is injected adjacent to the perforator and creates a dissection plane between the perforators and muscle. The *arrows* illustrate the course of the heparinized saline, which tracks along the perforator with each injection.

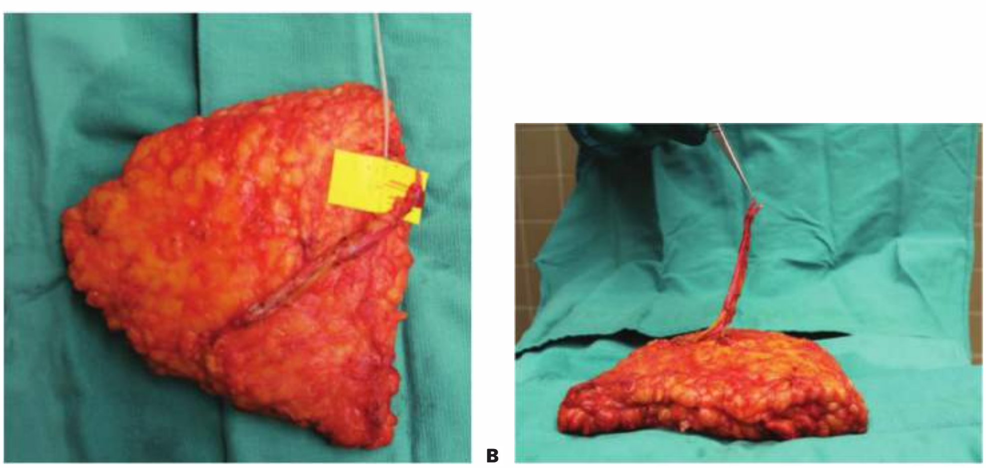
FIG 11 ● **A.** Intramuscular and submuscular dissection of perforators and vascular pedicle. **B.** DIEP flap pedicle prior to ligation.

appropriate-sized hemoclips 1 to 2 cm cephalad to the perforator.

- The submuscular dissection proceeds toward the external iliac vessels in the pelvis and is performed with the electrocautery, leaving a cuff of adipose tissue around the vessels.
- The DIEA and vein are dissected to a point where their length and size are appropriate for the recipient vessels in the chest (**FIG 11**).
- Once ready for transfer to the chest, the artery is first ligated distally with hemoclips followed by the vein(s).
- A tenotomy scissors is used to divide the vessels proximal to the clips.
- The harvested flap (**FIG 12**) is prepared on a back table by flushing the flap from its arterial end with heparinized saline until the venous outflow clears up and is less bloody.



A

B

FIG 12 ● **A,B.** Flap harvested and prepped on a back table.

RECIPIENT VESSEL EXPOSURE (INTERNAL MAMMARY)

- A common choice and the author's preference for recipient vessels are the internal mammary artery and vein. Alternatively, the thoracodorsal artery and vein can be used.
- Once the mastectomy is complete, the defect is irrigated and hemostasis with electrocautery is performed as needed.
- The medial cartilaginous aspect of the 3rd rib is palpated through the pectoralis major muscle. The muscle fibers over this medial aspect of the rib are split (ideally along the fibers) with electrocautery and a Weitlaner retractor is introduced between the muscle fibers to provide exposure. The muscle split is performed from the lateral edge of the sternum to a point approximately 6 cm lateral.
- The anterior costal perichondrium is scored along its length with the electrocautery and also perpendicular to the lengthwise incision at the medial and lateral extents of the exposed cartilage.
- A freer or narrow periosteal elevator is then used to elevate the perichondrium off the underlying cartilage circumferentially (**FIG 13**).
- The cartilage is then excised with a rongeur from lateral to medial, exposing the posterior perichondrium. The internal mammary artery and vein are sometimes visible through the posterior perichondrium at this point.
- A second Weitlaner is introduced perpendicular to the first using the lateral cut end of the rib as an anchor for one end of the retractor while the opposite end retracts the medial mastectomy flap out of the field.
- An incision is made laterally through the posterior perichondrium with a scalpel and a freer is then introduced underneath the perichondrium and used to push all soft tissue and vessel downward.
- The posterior perichondrium is then split from lateral to medial, exposing the underlying internal mammary artery (IMA) and internal mammary vein (IMV).
- The posterior perichondrium is bluntly dissected off the underlying vessels with a freer and excised completely to provide optimal exposure of the recipient vessels.
- The IMA and IMV are dissected circumferentially and a background mat with attached suction is placed beneath both vessels (**FIG 14**).

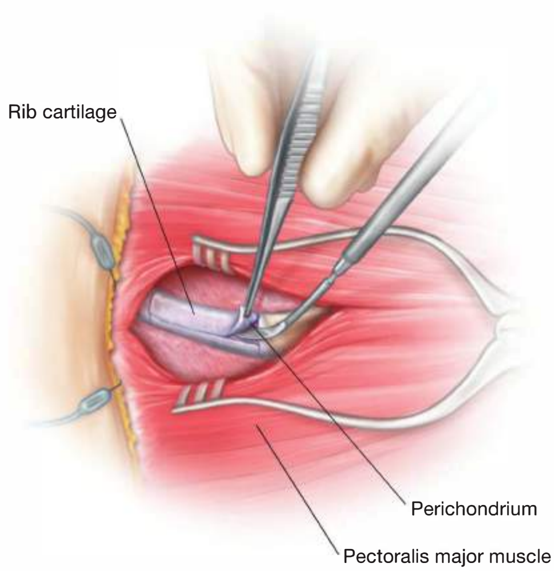


FIG 13 ● Elevation of the rib perichondrium.

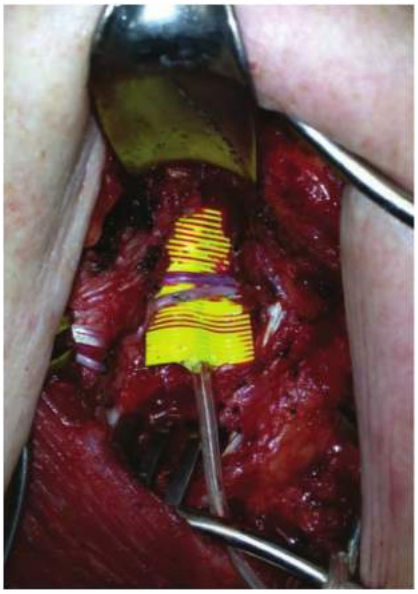

FIG 14 ● Exposed IMA and IMV with placement of a background mat with suction.

MICROVASCULAR ANASTOMOSIS

- The harvested DIEP flap is transferred to the chest and secured to the chest wall with sutures.
- With magnification from a microscope, the flap vessel ends are prepared, sharply cutting irregular vessel ends and loose adventitia.
- Similar preparation of the IMA and IMV are performed.
- Anastomosis of the arteries and veins can be performed in whichever order based on the surgeon's preference. The author preferentially couples the veins prior to the arterial anastomosis.
- An appropriate-sized single Acland clamp is placed proximally on the IMV and a hemoclip is applied distally prior to cutting the IMV with tenotomy scissors. The cut vessel end is then flushed with heparinized saline.
- A vessel sizer is used to determine the approximate vein diameter for both the flap vein and the IMV and the smaller of the two vessels determines the coupler size to be used.

- The flap vein is first placed in one end of the coupler followed by the IMV and the coupler is closed without placing tension on either vessel. The previously placed clamp is then taken off the IMV.
- One end of an appropriate-sized, double opposing Acland clamp is placed proximally on the IMA and hemoclips are applied distally prior to cutting the IMA. The flap artery is then introduced into the opposite end of the double-opposing Acland clamp.
- An end-to-end anastomosis of the arterial ends is performed with 8-0 or 9-0 nylon sutures in an interrupted or running fashion (**FIG 15**).
- Once the anastomosis is complete, the flap end of the clamp is taken off first prior to taking off the end on the IMA.
- With flow reestablished, papaverine is infiltrated into the adventitia of the arteries to prevent spasm.
- The flap and anastomosed vessels are warmed with warm saline and allowed to reperfuse for a few minutes.
- Doppler signals are identified on the flap skin and marked with sutures.
- Fat grafts obtained from either the abdominal donor site or flap edge are placed around the anastomosis to help secure the desired position of the vessels and reduce kinking.

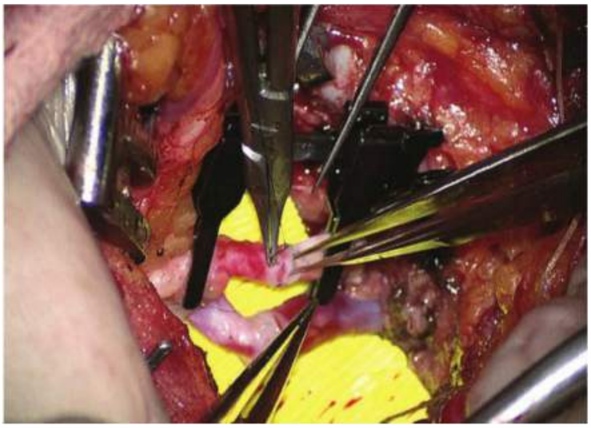

FIG 15 ● Microvascular anastomosis under an operating microscope. A double opposing Acland clamp holds the arterial ends in place and an end-to-end anastomosis is being performed with interrupted 8-0 nylon sutures. The DIEV has been coupled to the IMV in the background.

FLAP INSET/DONOR SITE CLOSURE

- Peripheral zones of the flap that may be less optimally perfused are excised.
- The flap is then placed within the mastectomy defect and interrupted absorbable sutures are used to secure the flap to the medial aspect of the chest wall.
- The pattern of the skin paddle is marked and all skin (epidermis and dermis) outside of the paddle is excised with electrocautery (**FIG 16**). De-epithelialization here is also an option.
- A drain is placed along the inferior aspect of the mastectomy defect and exits the skin along the anterior axillary line.
- Skin closure for the flap inset is performed in layers with absorbable interrupted deep dermal sutures and a running subcuticular suture.
- The OR table is reflexed; two drains are placed in the abdominal donor site; and closure of the defect is performed with approximation of Scarpa's fascia, the deep dermis, and subcuticular layer.
- The umbilicus is delivered through the skin flap above the horizontal abdominal closure along the midline by creating an appropriate-sized defect with a full-thickness excision. The umbilicus is then inset with a layered closure.
- Minimal dressings in the form of a skin glue product, Steri-Strips, or an ointment are then applied to all suture lines.

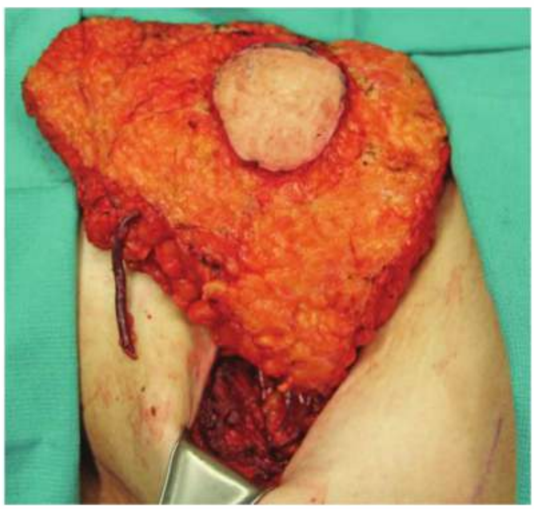

FIG 16 ● Flap with all skin outside of the skin paddle excised; preserved SIEV can be seen on the medial aspect of the flap.

PEARLS AND PITFALLS

Preoperative evaluation	■ Preoperative CT angiography is a useful tool to assist with perforator selection—It provides information on perforator location and size but does not give information on flow/perfusion. ■ Flap perfusion based on a few perforators is better assessed by laser-assisted indocyanine green fluorescents dye or by physical examination with occlusion of all perforators with the exception of the few selected perforators.
Patient positioning	■ With the patient in supine position, the table can be turned 180 degrees from the anesthesiologist, providing better access for two surgical teams.
Dissection of the vessels	■ Preserve as long a length of the SIEV (≥5 cm) as possible for use as an additional outflow vessel in flaps with venous congestion after elevation or transfer to the chest. ■ The hydrodissection technique used for the intramuscular perforator dissection simplifies this portion of the operation, creating dissection planes and allowing for better visualization of the perforators and small vascular branches.

POSTOPERATIVE CARE

- Patients can be transferred from the OR to a postanesthesia care unit (PACU) or directly to a unit with nursing capabilities for flap monitoring.
- Flaps are monitored by physical examinations (color, temperature, capillary refill, and handheld Doppler signals) performed every hour for the first 24 hours and then checks can be spaced out to every 2 hours and 4 hours over subsequent hospital days.
- Additional flap monitoring with continuous near-infrared spectroscopy (NIRS) tissue oximetry is employed for 72 hours postoperatively.
- DVT prophylaxis is the only form of anticoagulation used routinely.
- The patient's bed is kept in semi-Fowler's position at all times.
- Diet is advanced from clear liquids to regular on postoperative day (POD) 1 with restrictions to caffeine intake.
- Patients are assisted out of bed to a chair on POD 1 and they ambulate beginning on POD 2.
- Foley catheters and intravenous (IV) fluids are discontinued and IV medications/patient-controlled analgesias (PCAs) are converted to orals on POD 2.
- Patients are typically ready for discharge home from POD 3 to POD 5.
- Surgical drains are discontinued once the output is less than 30 mL for two consecutive days.
- Activities are limited and weight-lifting restrictions are in place for 6 weeks postoperatively.
- The first postoperative visit is at 1 week following discharge.
- Preoperative photographs of a patient with a left breast invasive cancer who opted for DIEP flap reconstructions are presented in **FIG 17A,B**.

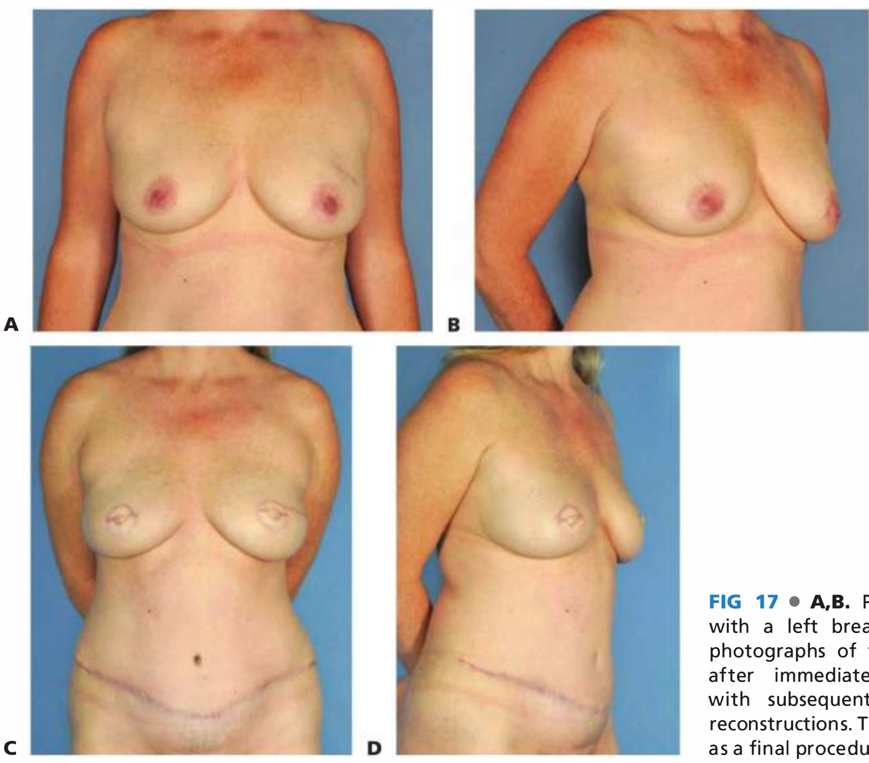

FIG 17 ● **A,B.** Preoperative photographs of a patient with a left breast invasive cancer. **C,D.** Postoperative photographs of the breasts and abdominal donor site after immediate bilateral DIEP flap reconstruction with subsequent revisions including bilateral nipple reconstructions. The patient will undergo nipple tattooing as a final procedure.

- The same patient's postoperative results after immediate bilateral DIEP flap breast reconstruction and subsequent revisions are presented in FIG 17C,D.

OUTCOMES

- The goals of breast reconstruction are to create breast mounds that are aesthetically pleasing, symmetric, and similar to the natural breast in appearance and feel.
- Patient satisfaction is of great importance in assessing outcomes of reconstruction.
- Breast reconstruction patients are typically satisfied in the short term (<5 years) with their choice of reconstruction across implant-based to autologous forms of reconstruction.[11]
- Over the long term (>8 years), satisfaction with abdominal-based flap reconstruction is maintained, whereas satisfaction with implant-based techniques tends to depreciate.[11]
- Studies have also shown greater satisfaction with autologous reconstruction in patients requiring unilateral reconstructions.[12] This is likely the result of better symmetry with the natural contralateral breast.
- Patient satisfaction in bilateral reconstructions has been found to be similar across all techniques provided that the same technique is used on both sides,[12] highlighting again the importance of symmetry.

COMPLICATIONS

Flap-Related Complications

- Infections—Surgical site infections are rare as these are clean cases and the autologous tissue transferred to the chest offer greater resistance to infection than do prostheses.
- Delayed wound healing—This complication typically occurs at the interface between the mastectomy flap and DIEP flap skin paddle. It often is a result of marginal mastectomy flap necrosis from poor skin perfusion, which is more likely in smokers and in the previously radiated breast skin.
- Fat necrosis—Varying degrees of fat necrosis are encountered in 10% to 15% of reconstructions; it occurs in small segments of flap adipose tissue with poor perfusion. This complication is apparent within a few weeks of the operation and presents as a firm palpable nodule, which occasionally causes some discomfort. These areas of necrosis can be directly excised or managed with liposuction (ultrasound assisted or suction assisted) during revision procedures.
- Partial flap loss—an uncommon complication that is also related to poor perfusion. Here, a segment of the flap is lost. It can be the result of poor perforator selection or thrombosis of one or more of the selected perforators. An excision of the necrotic segment is usually required.
- Total flap loss—This is one of the most devastating complications encountered and it occurs in less than 2% of reconstructions. The ultimate cause of flap loss is a thrombosis of the vascular pedicle, which could be brought about by a variety factors ranging from technical problems to hypercoagulable conditions. Early detection of thrombosis with a return to the OR and correction of the inciting problem leads to flap salvage in most cases.

Donor Site Complications

- Hernias/bulges—the result of abdominal wall weakness; this complication is seen with much less frequency when compared to the TRAM flap, which by definition takes muscle and fascia as part of the flap harvest. The incidence of this complication has been shown to decrease with use of mesh reinforcement in TRAM flap harvests.
- Delayed wound healing—Wound healing problems are encountered often in morbidly obese patients, diabetics, and smokers. Perfusion to the infraumbilical portion of the abdominal donor site is marginal in some patients; fat necrosis occurs in this area and ultimately results in a wound dehiscence. These wounds are managed by debridement and dressing changes with healing by secondary intention.

Chapter 20 Nipple–Areolar Reconstruction

Anita R. Kulkarni Amy K. Alderman Andrea L. Pusic

DEFINITION

- Nipple–areolar reconstruction (NAR) is typically performed as the final stage of breast reconstruction after mastectomy. The nipple is reconstructed to give three-dimensional projection, and the areola is reconstructed separately to mimic a natural nipple–areolar complex (NAC).

PATIENT HISTORY AND PHYSICAL FINDINGS

- NAR is an elective stage of breast reconstruction that can be performed after any type of primary breast mound reconstruction. Published studies indicate that approximately 50% of breast reconstruction patients elect to undergo NAR.[1,2]
- NAR is performed at least 3 months after breast reconstruction is complete. This allows the final breast shape and position to be obtained prior to placement of the NAC.
- NAR can also be performed in a delayed fashion at any time a patient decides, including months or years after breast mound reconstruction.

SURGICAL MANAGEMENT

- There are many described techniques for nipple reconstruction, including nipple sharing, local flaps, cartilage grafts, dermal grafts, and prostheses.[3] Local flaps are the most popular option and are described in detail in this chapter.
- Reconstructed nipples lack the rigid ductal and smooth muscle elements of a natural nipple; therefore, the long-term maintenance of nipple projection continues to be the most challenging aspect of NAR.[4]
- Multiple autologous and prosthetic materials (auricular cartilage, rib cartilage, toe pulp, acellular dermal matrix, calcium hydroxylapatite, polytetrafluoroethylene implants, etc.) have been attempted to give permanent rigidity to the nipple; however, no single technique has demonstrated definitive superiority.[3]
- Areolar reconstruction is primarily done by skin grafting, tattoo, or both.
- The first described technique in this chapter is a skate flap for nipple reconstruction with a full-thickness skin graft for areolar reconstruction. This procedure is typically done in the operating room under sedation or general anesthesia.
- The second described technique is a C-V flap for nipple reconstruction, which can be used in combination with a tattoo for areolar reconstruction. This procedure can be done in the office under local anesthesia.

Preoperative Planning

- In unilateral NAR, the position, size, and shape of the opposite nipple are taken into consideration to design the reconstruction in addition to anatomic landmarks. In bilateral NAR, anatomic landmarks and standard measurements are used to position and design the NAC.
- Anatomically, the NAC is located at the anterior-most projecting part of the breast mound at the level of the inframammary fold, centered on the reconstructed breast mound.
- The nipple has an average projection of 5 mm and the areola has an average diameter of 35 to 45 mm.

POSITIONING

- In the operating room, patients are positioned supine with arms at 90 degrees secured to arm boards. Both breasts are prepped into the field to allow for evaluation of symmetry. Patients are secured to the operating table to allow upright evaluation intraoperatively.
- In the clinic, patients are positioned supine with arms at sides.

Skate Flap (Nipple) and Full-Thickness Skin Graft (Areola)

- The patient is placed in supine position with arms abducted at 90 degrees. Arms are secured on arm boards.
- The NAC position is selected at the anterior-most projecting part of the reconstructed breast with the patient in an upright position. In unilateral nipple reconstruction, the NAC is placed symmetrically to the opposite side (**FIG 1**).
- A donor site is chosen for the full-thickness skin graft, which will be used to reconstruct the areola. Commonly used sites include the lateral edge of the mastectomy scar, the lower abdomen, and the groin crease. Additionally, the areolar graft can be taken adjacent to any of the patient's existing scars.
- A 38- or 42-mm nipple sizer is used to mark the areolar skin graft. An ellipse is drawn tangent to the areolar graft to allow linear closure of the donor site.
- The areolar skin graft is scored with a knife prior to harvest. The ellipse is then excised as a full-thickness skin graft (**FIG 2**).
- The areolar graft is aggressively defatted with a small sharp scissor, leaving only full-thickness skin behind (**FIG 3**).
- The skate flap is designed at the previously marked site (**FIG 4**).
  - A 1- to 1.5-cm circle is drawn at the planned location of the nipple.

FIG 1 ● Nipple position is selected symmetrically to the native nipple.

FIG 2 ● Areolar skin graft is marked with a 38-mm nipple sizer. An ellipse is drawn tangentially to facilitate linear closure.

  - A 38- or 42-mm nipple sizer is used to mark the areola centered around the nipple.
  - A horizontal line is drawn across the circle at the superior edge of the marked nipple.
  - The upper portion of the circle is crosshatched to mark the area that will be de-epithelialized.
  - The lower portion of the circle will be raised as the "skate flap" to create the new nipple.
- The epidermis is scored along all incisions.
- The crosshatched semicircle is de-epithelialized (**FIG 5**).
- The flap is then raised from the edges at the level of the mid-dermis. The deepest layer of dermis is left down in order to provide a vascularized bed for the areolar skin graft (**FIG 6**).
- The flap remains attached to the deep dermis at the marked nipple. The flap is raised in a slightly deeper plane at the center in order to include some fat with the flap to provide bulk (**FIG 7**).
- The corners of the flap are centralized and sutured to the underlying dermis using 5-0 Vicryl Rapide (**FIG 8**).
- The edges of the flap are sutured together using interrupted 5-0 Rapide (**FIG 9**).
- The cap is sutured down to close off the nipple (**FIG 10**).
- The full-thickness skin areolar skin graft is sutured to the bed using 4-0 chromic half-buried horizontal mattress sutures. The buried portion of suture is placed along the native breast skin to avoid scarring on the breast (**FIG 11**).
- A 1-cm hole is cut in the center of the areolar graft to expose the nipple (**FIG 12**).

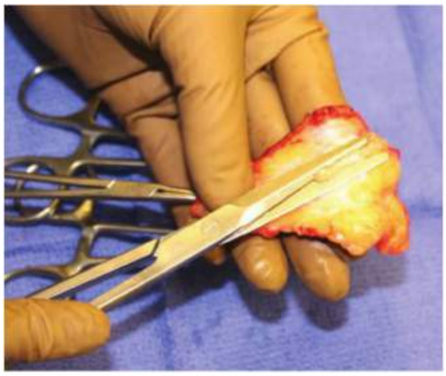

FIG 3 ● Areolar skin graft is aggressively defatted.

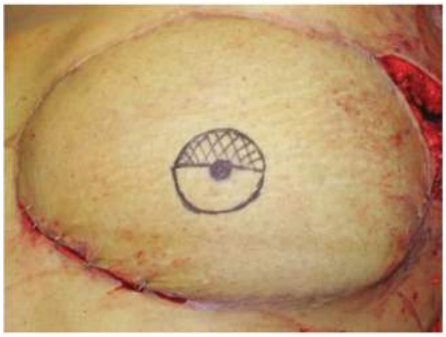

FIG 4 ● Skate flap design.

FIG 5 ● Crosshatched area is de-epithelialized.

FIG 6 ● Skate flap is raised in the middermal plane, leaving central pedicle attached.

FIG 7 ● Skate flap is shown raised.

FIG 8 ● Edges of skate flap are brought together centrally to recreate nipple.

- The graft is secured to the nipple using interrupted 5-0 chromic sutures.
- 4-0 chromic tacking sutures and piecrust incisions are placed in the areolar graft (**FIG 13**).
- A protective dressing is applied using Mastisol on the native breast, crisscrossed Steri-Strips, 2 × 2 fluffed gauze, and foam tape (**FIG 14A–D**). The goal of the dressing is to protect the NAR without putting any pressure on the skate flap.
- The dressing is kept in place for 5 to 7 days after surgery, at which time it is removed in clinic.

C-V Flap

- This procedure can be performed under local anesthesia with the patient awake.
- With the patient in a seated upright position, the NAC position is marked at the anterior-most projecting part of the breast (**FIG 15**).

FIG 9 ● Edges are sutured together in midline.

FIG 10 ● Open end of nipple is sutured down as a cap.

FIG 11 ● Areolar skin graft is sutured to skin edges.

FIG 12 ● Central hole is cut in areolar skin graft to allow nipple to protrude.

FIG 13 ● Tacking sutures and piecrust incisions are placed in areolar skin graft.

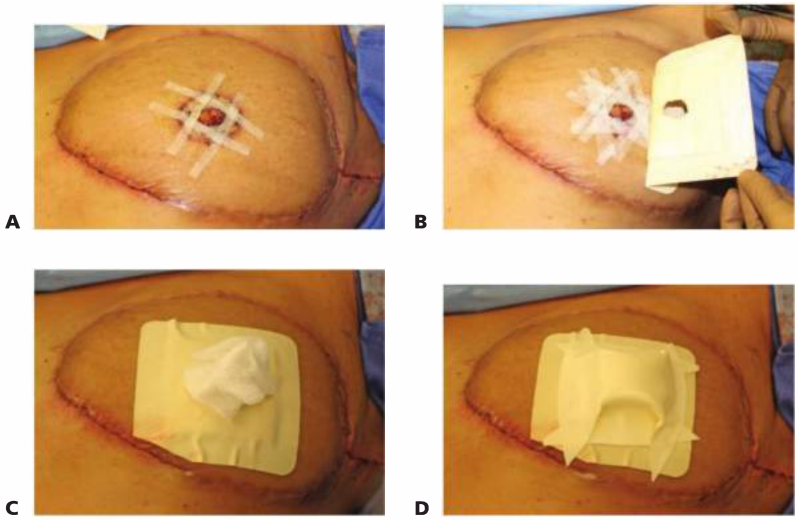

FIG 14 ● Bolster dressing. **A.** Mastisol is applied to surrounding breast skin, followed by tightly adherent Steri-Strips placed in crosswise fashion to apply pressure to graft. **B.** Foam tape dressing with a central hole for nipple is placed over crosswise Steri-Strips. **C.** 2 × 2 fluffed gauze is placed over the nipple. **D.** Additional foam tape is tented over the fluffed gauze without putting any pressure on nipple reconstruction.

- C-V flap is drawn as shown. The length of the flap is approximately 5 cm (*A* to *F*), and the width is approximately 1.5 cm. The width of the flap (*BD* to *CE*) determines the projection of the nipple (**FIG 16**).
- The subcutaneous tissue is infiltrated with 1% lidocaine with 1:100,000 epinephrine (**FIG 17**).
- Incisions are made along all edges *except* points *B* to *D* at the base of the nipple. This area is left attached and serves as the blood supply to the flap (**FIG 18**).
- The flap is raised from both sides in the midsubcutaneous fat plane (**FIG 19A,B**).
- The incision is closed from point *B* to *C* and *D* to *E* (**FIG 20**).
- One flap edge (point *A*) is brought to the center and sutured in place with 5-0 Vicryl Rapide (**FIG 21**).
- The opposite flap edge (point *F*) is brought to the center and sutured to the first flap edge (**FIG 22**).
- The cap is sutured down to close the top of the nipple and the remainder of the incision is closed with 4-0 Vicryl deep and 4-0 Monocryl running subcuticular (**FIG 23**).
- Nipple projection is shown with both reconstructions complete (**FIG 24**).

FIG 15 ● Bilateral nipple position marked at the anterior-most projecting part of breast mounds adjacent to mastectomy scars.

FIG 16 ● Markings for C-V flap. Length from *A* to *F* is approximately 5 cm, width from *BD* to *CE* is approximately 1.5 cm.

FIG 17 ● 1% lidocaine with 1:100,000 epinephrine is injected subcutaneously.

FIG 18 ● C-V flap is incised through to midfat level along all incisions except *B* to *D*.

A

B

FIG 19 • **A.** C-V flap is raised in the midfat plane. **B.** C-V flap is shown raised.

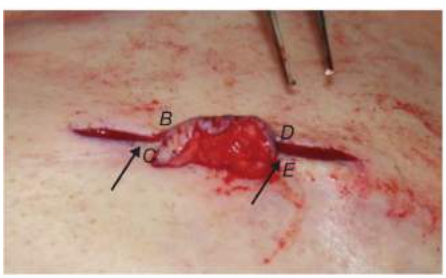

FIG 20 • Incision is closed (point *B* to *C* and *D* to *E*).

FIG 21 • One flap edge (point *A*) is centralized and sutured to the deep surface.

FIG 22 • Opposite flap edge (point *F*) is centralized and sutured to point *A*.

FIG 23 • Cap is sutured down to close off nipple, and all incisions are closed with interrupted sutures.

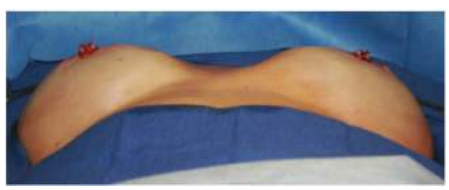

FIG 24 • Final result showing projection of bilateral C-V flaps.

PEARLS AND PITFALLS

Indications	■ Nipple–areolar reconstruction should be deferred until the final breast mound shape is obtained.
Placement of incision	■ Flaps should be based adjacent to the mastectomy scar whenever possible to avoid additional scarring.
Projection	■ Nipple projection will decrease by 50% in the first year; therefore, projection should be overestimated at the time of reconstruction. ■ Projection can be increased later with dermal fillers such as collagen or hyaluronic acid.
Areola	■ Areolar tattoo is often used as an addition to skin grafting or as a primary modality for areolar reconstruction. ■ Tattoos often need more than one application spaced over several months in order to achieve the final desired color.

POSTOPERATIVE CARE

- After nipple reconstruction, a protective dressing should be applied and maintained in place for 1 week postoperatively. Brassieres should be avoided for the first 6 weeks to prevent pressure on the nipple flap.
- If no skin graft is used, patients may shower after the dressing is removed 1 week postoperatively.
- If a skin graft is used for areolar reconstruction, the bolster is removed 1 week postoperatively in the clinic, and daily Xeroform dressing changes are performed for 1 week. After 2 weeks, patients may shower and apply moisturizer to the graft.

OUTCOMES

- All modes of nipple reconstruction result in some degree of loss of projection over time, up to 50%.[5] Most loss of projection occurs within the first 3 months, and final nipple shape and size is typically achieved by 1 year.[6] C-V flaps tend to lose more projection than skate flaps over time.
- Dermal fillers such as collagen and hyaluronic acid can be injected into the nipple to increase projection.

COMPLICATIONS

- Loss of nipple projection
- Partial or complete flap necrosis
- Partial or complete loss of areolar skin graft
- Infection

Chapter 21

Reduction Mammoplasty

Sebastian Winocour Valerie Lemaine

DEFINITION

- Reduction mammoplasty is defined by the removal of expendable breast skin and parenchyma, and repositioning the nipple–areolar complex (NAC) in patients who suffer from breast hypertrophy. The goal is to achieve an overall reduction in breast volume in an aesthetic manner without sacrificing breast sensation or function. Other terms for reduction mammoplasty include breast reduction and reduction mammoplasty.

DIFFERENTIAL DIAGNOSIS

- The differential diagnoses of breast hypertrophy include breast carcinoma, phyllodes tumors, benign breast masses (including fibroadenomas, neurofibromas, lymphangiomas, and breast cysts), hematomas, ectopic tumors producing sex steroids, pregnancy, lactation, and virginal hypertrophy. It is of paramount importance to distinguish benign breast hypertrophy from breast carcinoma, which is much less common, tends to be unilateral, is usually eccentric with respect to the NAC and typically presents as a defined lesion firm to touch.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be performed prior to treatment, identifying physical, functional, and psychological symptoms. It is also important to obtain a detailed past medical and surgical history, reproductive history, family history, social history, and current medications and allergies from the patient.[1]
- Physical and functional problems associated with macromastia include pain (neck, back, and shoulder), mastodynia, shoulder grooving, intertriginous rashes and/or infections, physical activity restriction, and difficulty fitting into clothing. Patients often suffer from psychological symptoms related to breast size, including feelings of physical unattractiveness and embarrassment in both private and social settings.[2,3]
- Past medical history should screen for any diseases that would impact the patient's ability to recover from the reduction mammoplasty, such as heart or lung disease, or impact the viability of the NAC postoperatively, such as collagen vascular diseases.[1] A history of previous benign or malignant breast masses should also be elicited. Obtaining a thorough past surgical history should identify any previous breast or chest wall incisions that may influence planning of either the skin pattern incision or the pedicle to the NAC.[1]
- Because childbearing can affect the size and shape of a woman's breasts, the reproductive history of the patient is important to understand and anticipate the effect reduction mammoplasty will have on the future breast.[1] Inquiring about plans for future pregnancies and breastfeeding is important to inform patients of the risks of the procedure. Finally, in patients who have recently given birth and who may be currently breastfeeding, it is important to discuss timing of surgery because it is ideal to delay surgery for at least 1 year after completing either.
- Obtaining a thorough family history is important to identify patients at increased risk for breast carcinoma. Younger patients with a family history of breast cancer, in addition to any patient older than the age of 40 years, should undergo a preoperative mammogram in order to identify any suspicious lesions prior to surgery.[2] Some surgeons routinely obtain a bilateral mammogram in all patients considering reduction mammoplasty.
- Smokers are at increased risk of compromise of the blood supply to the NAC and for poor wound healing.[1] Therefore, eliciting a smoking history may alter the timing of surgery. Current recommendations indicate that a period of at least 4 weeks of smoking cessation prior to surgery is ideal for best outcomes.
- Macromastia can present at different periods in a woman's life and therefore surgical timing is important. When present during adolescence, the timing of reduction mammoplasty needs to be balanced with the effects of macromastia on self-esteem and physical activity restriction with ongoing pubertal breast development and potential future childbearing.[4] In older patients who have encountered recent significant changes in overall weight, it is prudent to delay surgery for at least 1 year until their weight has stabilized, as this can translate into disproportionate changes in breast volume.
- A bilateral breast examination should be performed in every patient, including examination of the axillary and supraclavicular lymph node basins. The patient's height, weight, body mass index, and body surface area, as well as appropriate breast measurements should be taken, including breast width, sternal notch/clavicle to nipple distance, midline inframammary fold to nipple distance, and the dimensions of each areola.[2] In addition, breast characteristics should be noted including symmetry, upper pole contour and fullness, presence of breast ptosis, skin quality including presence of striae, and breast tissue density (**FIG 1**).[1]

FIG 1 • A typical patient suffering from macromastia.

- A discussion of patient's desires and expectations following surgery is essential to avoid dissatisfaction and misunderstandings. In addition, the patient should be informed about possible complications associated with reduction mammoplasty, including changes in nipple sensation, asymmetry, unappealing breast size or shape, scarring, fat necrosis, NAC loss, inability to breastfeed, hematoma, and infection.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The American Cancer Society recommends screening mammograms starting at age 40 years in patients with average risk of developing breast cancer.[5] These patients, and younger patients at increased risk of breast cancer, should therefore undergo a preoperative mammogram prior to reduction mammoplasty. Many plastic surgeons routinely perform a preoperative screening mammogram in all patients undergoing this procedure.

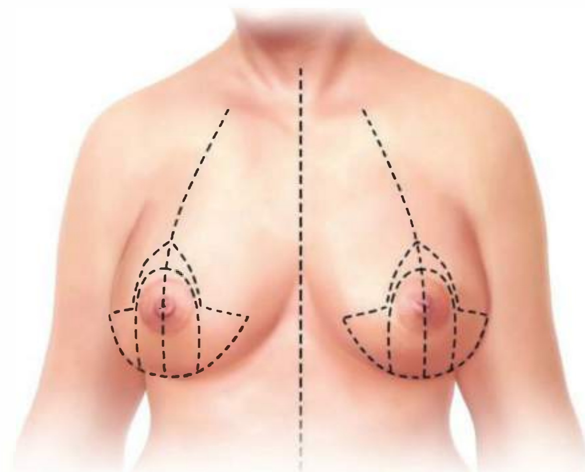
SURGICAL MANAGEMENT

- There are multiple surgical approaches to reduction mammoplasty; however, all must deal with the following four considerations: (1) reduction in the parenchymal volume of the breast, (2) creation of the NAC pedicle, (3) reduction of expendable skin followed by redraping, and (4) repositioning of the NAC.[3] This chapter will describe the most commonly practiced Wise pattern (inverted T) technique, which reduces the medial, lateral, and superior breast parenchymal volume and maintains blood supply to the NAC by an inferior pedicle. Other techniques include the superior medial breast reduction,[3] short scar periareolar inferior pedicle reduction (SPAIR),[1] and the liposuction breast reduction,[6] among others.
- Advantages to the Wise pattern technique include its reproducibility, popularity, and applicability to a wide range of breast shapes and sizes, whereas disadvantages include longer scars and a tendency toward developing breast ptosis over the long term.

Preoperative Planning

- Preoperative markings with a permanent marker should be performed in the upright position in the preoperative holding area on the day of surgery.
- The chest midline, breast meridian, and inframammary creases are initially marked. The inframammary crease should then be transposed onto the anterior breast to mark the desired new nipple position.[7] The distance from the sternal notch/clavicle to this point is measured and transposed symmetrically to the other breast. Eight-centimeter obliquely vertical limbs are then drawn medially and laterally from this point. They should be separated by a distance of 8 to 10 cm between their inferiormost points, depending on the desired breast width reduction. The bases of the vertical limbs are subsequently connected medially and laterally with a curvilinear line that joins the inframammary crease. Minor adjustments are made to account for breast asymmetry and minimize the appearance of standing cones (**FIG 2**).

A



B

FIG 2 ● **A,B.** Preoperative markings are made with the patient in the standing position prior to surgery.

- Although there is limited data to support the use of preoperative antibiotics for reduction mammoplasty, the general consensus among plastic surgeons is that prophylactic antibiotics covering skin flora should be administered at least 30 minutes prior to skin incision.[8] Data can be also be extrapolated from several general surgery mastectomy studies demonstrating that antibiotic prophylaxis reduces the incidence of postoperative wound infections.[9]

Positioning

- Reduction mammoplasty is performed under general endotracheal anesthesia.
- Because the procedure requires intraoperative assessment of breast symmetry, shape, and contour in the semi-upright position, the patient should be placed in the supine position with the bed break at the hips. The patient's arms should be securely padded on adjustable arm boards, ready for repositioning.
- Sequential compression devices are applied to the lower extremities and a Foley catheter is inserted.

PREINCISION INFILTRATION AND MARKINGS

- The breast bases and planned incisions may initially be infiltrated with 1% Xylocaine with 1:100,000 epinephrine. Then, an 8- to 10-cm–wide inferiorly based dermal pedicle is marked on the skin of each breast, extending in a circular fashion above the NAC all the way down to the chest wall. Using a cookie cutter centered on the nipple, a 40- to 44-mm circular marking is made with the breast skin under minimal to no tension to reduce the diameter of the NAC (**FIG 3**). Tourniquets may then be placed around each breast base to assist with hemostasis (**FIG 4**). After the skin incisions and de-epithelialization of the dermal pedicles are completed, the tourniquets are removed.

Initial Incisions

- The markings of the NAC and dermal pedicle are initially scored with the scalpel. The skin of the inferior pedicle is then de-epithelialized down to the inframammary line, leaving the NAC intact. The dermis between the vertical limbs is preserved to maintain the dermal and subdermal plexus blood supply to the NAC. Incisions are made around the neo-NAC and along the vertical limbs down to the subcutaneous tissue isolating the inferior pedicle from the surrounding breast parenchyma (**FIG 5**).

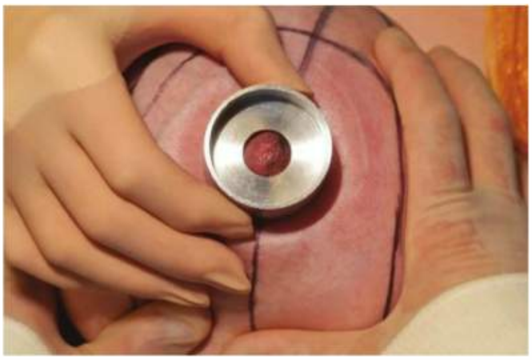


FIG 3 ● A 40- to 44-mm cookie cutter is centered on the nipple with the breast skin under minimal to no tension to mark the neo-NAC.

FIG 4 ● Tourniquets are placed around each breast base to minimize blood loss and are removed after skin incisions and de-epithelialization of the dermal pedicles.

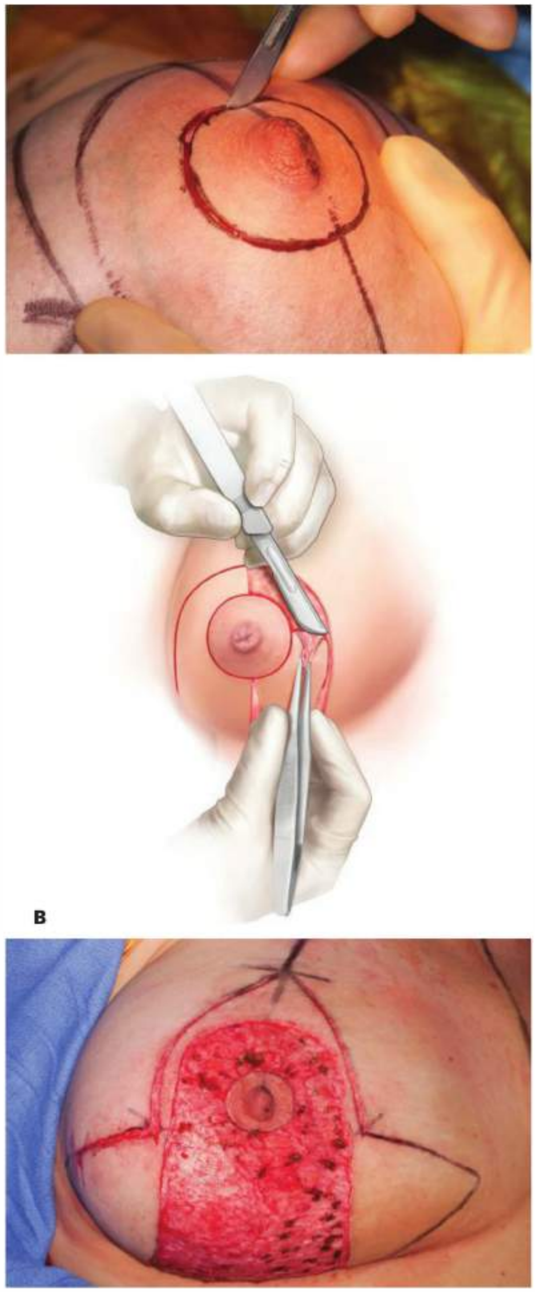

FIG 5 ● **A–C.** The skin markings are scored with the scalpel after which the inferior pedicle is de-epithelialized down to the inframammary line, leaving the neo-NAC intact.

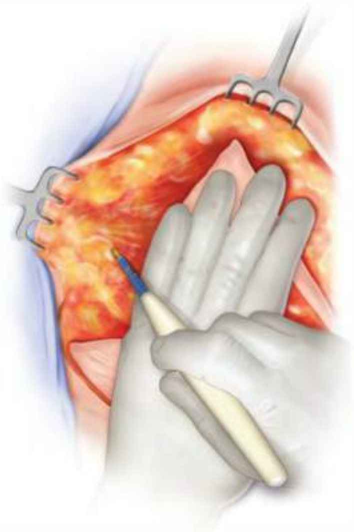
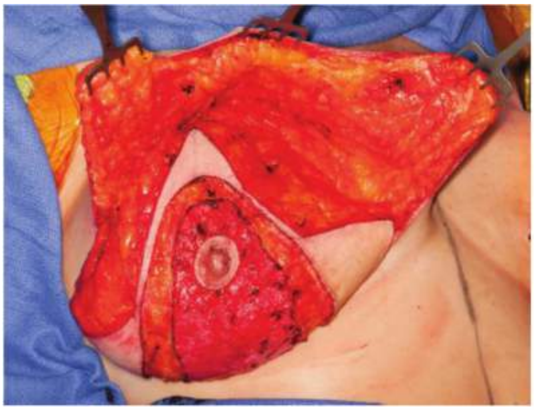


A



B

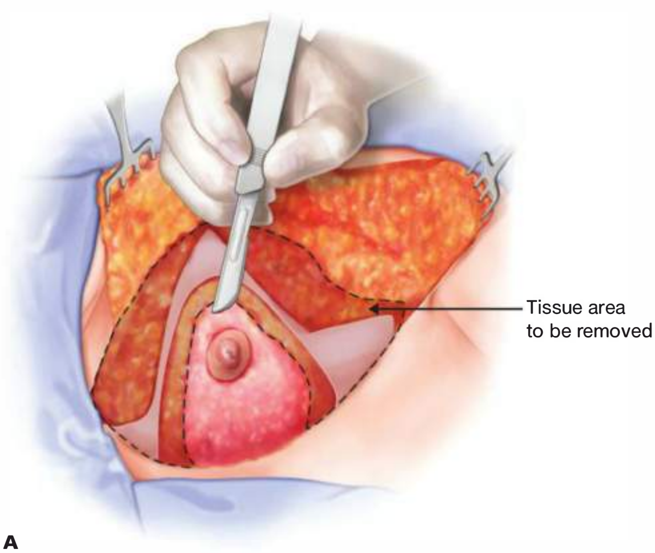
FIG 6 ● **A,B.** Skin flaps are raised medially, laterally, and superiorly around the pedicle.

Creation of Skin Flaps

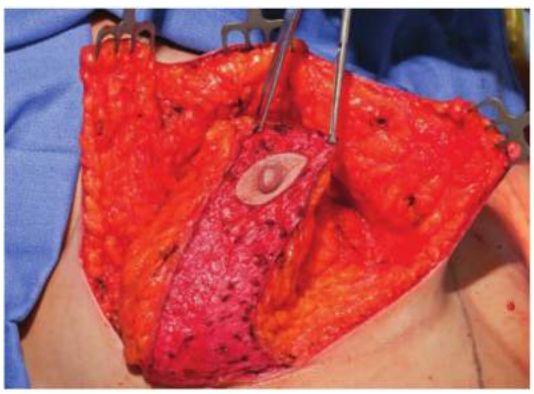
- Medially, laterally, and superiorly based skin flaps are then raised to separate the skin from the breast parenchyma. The flaps are designed to gradually increase in thickness as one approaches the chest wall to ensure a smooth breast contour when the skin is eventually redraped over the breast. They should measure 1 to 2 cm in thickness (**FIG 6**).[1]

Creation of the Nipple–Areolar Complex Pedicle and Parenchymal Excision

- The inferior pedicle is then created without undermining the blood supply to the NAC. The excess breast parenchyma is systematically excised medially, laterally, and superiorly. Superiorly, breast tissue is removed down to the chest wall extending up to the level of the clavicle, whereas medially, it is removed down to the pectoral fascia but stopping short of midline. Finally, a layer of breast tissue is left on the chest wall laterally in an attempt to preserve the innervation to the NAC (**FIG 7**). Wound irrigation and meticulous hemostasis is achieved prior to proceeding.
- All breast parenchyma removed from the breast is initially weighed and subsequently sent to pathology for evaluation (**FIG 8**).



A



B

FIG 7 ● **A,B.** The inferior pedicle is created without compromising the blood supply to the NAC by excising breast parenchyma in the medial, lateral, and superior quadrants.

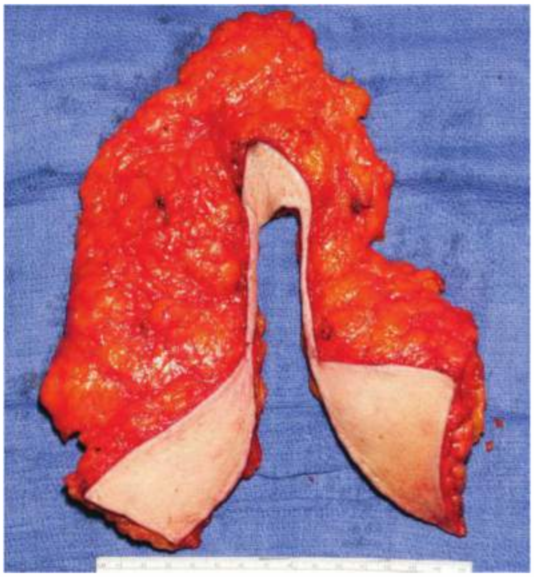


FIG 8 ● The excised specimen includes skin and parenchyma and should be weighed prior to having it sent to pathology.

- The same procedure is repeated on the opposite breast with the goal of achieving breast symmetry in shape and size.

Skin Reduction and Redraping

- The skin flaps are redraped over the breast and temporarily approximated using staples (**FIG 9**). The patient is then placed in the sitting position and minor adjustments can be made to skin approximation to achieve symmetry and improve aesthetics. The final markings for the medial and lateral inframammary margins can then be made; after which, the skin is excised as needed.
- Once symmetry is achieved, and with the patient still in a sitting position, the final NAC position is determined with a 38- to 42-mm cookie cutter and marked on the breast (**FIG 10**). The skin is then excised and the NAC is exteriorized (**FIG 11**).

Repositioning of the Nipple–Areolar Complex

- Once the NAC is exteriorized, the position and orientation of the inferior pedicle is verified to ensure that it is not distorted. A Gillies suture using absorbable monofilament may be placed at the inverted T junction, which is the point of maximal tension. The NAC is then secured in its correct orientation with buried dermal absorbable monofilament sutures in four quadrants. All incisions are then closed in layers with deep dermal interrupted absorbable monofilament sutures, followed by an absorbable running subcuticular monofilament suture (**FIG 12**). A dry dressing is applied to all wounds.
- Bulb suction drains may be left prior to closure.

FIG 9 ● The breast skin flaps are redraped over the pedicle and secured with staples.

FIG 10 ● The final NAC position is chosen and marked with a 38- to 42-mm cookie cutter.

FIG 11 ● The NAC is exteriorized by incising the circular marking and removing the circular paddle of skin and soft tissue. Care is taken not to injure the underlying NAC.

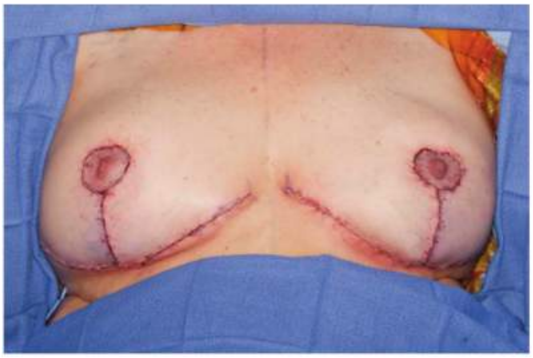

FIG 12 ● The final result after all skin incisions are closed.

PEARLS AND PITFALLS

Preincision infiltration	■ A spinal needle is helpful for thorough infiltration of the breast bases with anesthetic and epinephrine solution.
Initial incisions	■ Only the dermis of the vertical limbs should initially be incised to allow for better traction during de-epithelialization. ■ De-epithelialization can be more efficiently performed with Kaye scissors as compared to a scalpel blade.
Creation of skin flaps	■ Appropriate flap thickness is critical for good blood supply to the skin and to maintain smooth breast contour. The skin flaps should gradually increase in thickness as one approaches the chest wall.
Creation of the NAC pedicle and parenchymal excision	■ Avoid dissection below the inframammary fold medial and lateral to the NAC pedicle to prevent inferior migration of tissue and breast ptosis postoperatively.
Skin reduction and redraping	■ Staples can be an effective alternative to skin approximation clamps when redraping the skin flaps over the breast. ■ Crosshatched orientation marks can be placed after the skin is redraped to ensure skin segments are accurately approximated when staples are removed.
Repositioning of the NAC	■ Verify that the pedicle is not distorted prior to skin closure to avoid ischemia to the NAC due to unusual positioning.

POSTOPERATIVE CARE

- After reduction mammoplasty, the patient should be placed in either a breast binder/wrap or supportive brassiere that should be worn regularly for 2 to 4 weeks after surgery. This maintains pressure on the breasts, minimizing hematoma and seroma formation, and also relieves tension on the skin incisions, preventing wound dehiscence and unfavorable scarring (**FIG 13**).

OUTCOMES

- Outcomes following reduction mammoplasty are excellent with high overall patient satisfaction rates.[8] The complications most frequently reported are (1) symptomatic scarring (6%), (2) wound dehiscence (5%), and (3) infection (1.2%).[10] Patients also report high reduction or resolution of common preoperative symptoms including neck pain (91%), back pain (96%), shoulder grooving (100%), as well as a subjective improvement in perception of self-image (92%).[10]

COMPLICATIONS

- Undesirable scarring
- Wound dehiscence
- Infection (cellulitis or abscess)
- Decreased NAC sensation
- Breast asymmetry
- Unappealing size and/or shape
- Fat necrosis
- NAC loss
- Difficulty or impossibility to breastfeed
- Hematoma

Chapter 22

Wide Excision of Primary Cutaneous Melanoma

Russell S. Berman   Jeffrey E. Gershenwald

DEFINITION

- Wide excision (WE) of a primary cutaneous melanoma is the term used to describe the definitive surgical management of the primary melanoma site. It is defined as the surgical removal of the primary tumor and/or the biopsy site that includes a defined radial margin of normal-appearing skin and underlying subcutaneous tissue. The appropriate margin of resection is determined by the Breslow thickness as discussed in this chapter.
- Depending on primary tumor characteristics and clinical nodal status, WE may be performed concomitantly with either intraoperative lymphatic mapping and sentinel lymph node biopsy (SNB) (for patients with clinically negative nodes and a primary tumor suggesting sufficient risk of occult regional node metastasis) or regional lymphadenectomy (for patients with clinically involved regional lymph nodes without distant metastasis)[1] (refer to Part 5, Chapters 31, 32, and 34).
- The main function of the WE is to remove the primary tumor along with any nearby microscopic melanoma cells. In addition to following oncologic principles, the surgeon should also aim to simultaneously minimize dysfunction or disfigurement. This procedure is also known as a wide local excision.

DIFFERENTIAL DIAGNOSIS

- A WE should not be performed unless a definitive pathologic diagnosis of melanoma has been obtained.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A patient with newly diagnosed melanoma should undergo a comprehensive history that includes assessment of age, gender, personal or family history of melanoma or other malignancy as well as history of any nevus syndromes. The patient should also be assessed for any other significant medical and surgical history or issues, medications used, and allergies.
- History of sun exposure and use of tanning beds, if any, should also be obtained. A thorough history may also provide clinical clues as to the extent of disease present at diagnosis. Symptoms such as worsening headaches or abdominal cramps may suggest distant metastatic disease and warrant additional workup.
- A physical examination is extremely important in the newly diagnosed patient with melanoma. If a biopsy has been performed, the anatomic site and orientation of the biopsy should be documented along with the presence or absence of any residual pigmented lesion.
- Skin and soft tissue between the primary site and draining regional nodal basin(s) should be examined for any signs of satellite metastases or in-transit disease. Melanoma most commonly metastasizes via regional lymphatics to regional lymph nodes. Nonetheless, because melanoma may metastasize to both regional and distant nodes, all palpable lymph nodes should be carefully examined in the new melanoma patient, including cervical, supraclavicular, axillary, epitrochlear, inguinal, and popliteal nodes. For patients with a melanoma in a region of ambiguous drainage (typically considered to be the head and neck and trunk regions), multiple nodal basin drainage is possible. Given the importance of the lymphatics in melanoma, meticulous attention to the lymphatic exam is essential. Evidence of lymphedema in the melanoma-bearing extremity may also suggest regional nodal disease.
- It is imperative to confirm the specific site(s) of any primary melanoma to be treated. Although this may seem obvious, many patients have had concomitant and/or prior skin biopsies, and further clarification with source information, including pre-biopsy photographs and/or direct consultation with the referring clinician, may be necessary. Because biopsy sites may heal prior to treatment, photographic images are often obtained to document location(s) of all biopsy sites for which treatment is/may be planned.
- The clinician should document the presence of any lymphadenopathy along with details such as firm, fixed, or matted nodes. Clinically suspicious lymph nodes should be evaluated by fine needle aspiration biopsy (often performed with ultrasound guidance) and cytologic analysis. Biopsy-proven regional metastasis renders a sentinel node biopsy (SNB) procedure unnecessary to diagnose stage III disease in the involved basin.
- Importantly, palpable "reactive" lymphadenopathy may sometimes develop following biopsy of the primary melanoma, thus highlighting the importance of pathologic confirmation of metastatic melanoma before definitive treatment of the basin—for example, lymphadenectomy—is considered.
- Newly diagnosed melanoma patients should also undergo a head-to-toe skin examination to identify the presence of other suspicious skin lesions. Although it is beyond the scope of this section to review biopsy techniques in detail, an appropriate biopsy should include the epidermis, dermis, and at least a cuff of subdermal fat. This allows the dermatopathologist to accurately report the essential components of primary melanoma tumor histopathologic microstaging, including, at a minimum, Breslow thickness (in millimeters), presence or absence of ulceration, mitotic rate, Clark level, status of peripheral and deep margins, and presence or absence of satellite lesions.
- When signs and/or symptoms are suggestive of additional disease, a well-performed physical examination may raise suspicion for distant metastasis. Particular attention should be paid to the neurologic examination, assessing for any localizing symptoms or mental status changes. The finding of hepatomegaly, abdominal mass, or a rectal exam significant for mass or occult blood should prompt further workup. Finally, distant dermal or subcutaneous nodules or distant adenopathy also warrant investigation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Treatment planning for patients with primary melanoma is based largely on primary tumor histologic microstaging.
- In the absence of symptoms, the use of imaging studies as part of a staging workup has not been shown to significantly impact survival or the treatment algorithm of the newly diagnosed, clinically node-negative melanoma patient. For asymptomatic preoperative stages I and II melanoma patients, preoperative cross-sectional imaging has a very low yield.[2] In one study, only 1 of 344 (0.3%) studies correlated with confirmed melanoma metastasis; no significant impact on proposed surgical management or staging was noted.[3]
- Even among asymptomatic microscopic stage III patients (i.e., sentinel-node positive), cross-sectional imaging studies infrequently identify distant metastatic melanoma.[4] Although positron emission tomography (PET)/computed tomography (CT) generally includes images of the extremities, regions not typically imaged during standard CT or magnetic resonance imaging (MRI), a benefit for routine use of PET/CT has yet to be demonstrated in this patient population.
- In the otherwise asymptomatic patient with clinically palpable adenopathy, the detection rate of asymptomatic distant metastasis is higher and baseline imaging for staging (CT, PET/CT, MRI) is recommended.[5]
- There is no specific tumor marker or biochemical parameter that has been validated and employed for melanoma screening or recurrence. Elevated serum lactate dehydrogenase (LDH) level is an adverse prognostic factor in patients with distant metastatic melanoma and is included in the American Joint Committee on Cancer (AJCC) staging system for stage IV disease. Patients with elevated serum LDH levels LDH levels are classified as M1c regardless of distant anatomic site(s) involved.[6]

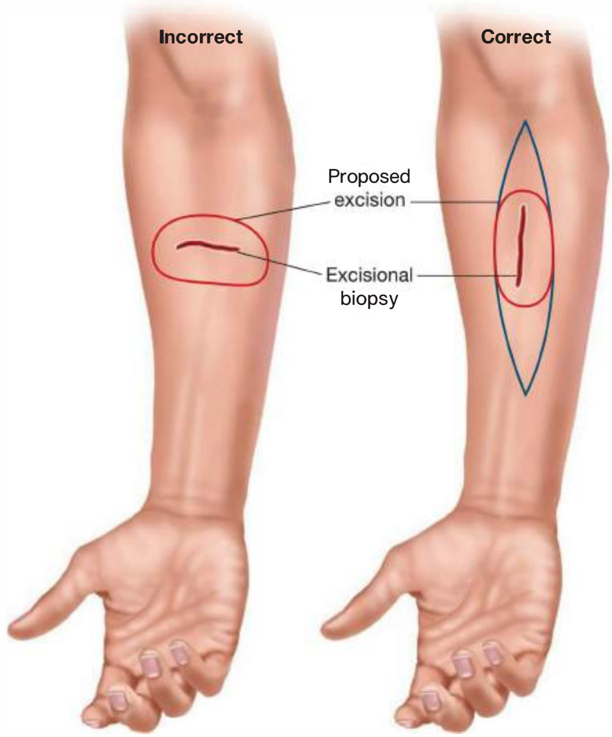

FIG 1 ● Importance of orientation of excisional biopsy. An excisional biopsy of the extremity is typically oriented parallel to the long axis of the extremity (right panel). In this example, incorrect orientation (left panel), would likely result in the need for skin graft closure, while primary closure could be likely be achieved if the biopsy had been correctly orientated (right panel). Note the in the right panel example, the overall excision has been extended to accommodate primary closure. It is always important to consider next steps when performing a biopsy.

SURGICAL MANAGEMENT

Preoperative Planning

Biopsy

- Most cutaneous lesions suspicious for melanoma have been biopsied by a dermatologist or other health care provider prior to treatment referral.
- If the biopsy of a lesion suspicious for melanoma has not yet been performed, the surgeon should plan and perform a biopsy: to establish a definitive histologic diagnosis, to obtain appropriate microstaging of the lesion (if melanoma is confirmed), and to maximize the potential for primary closure of the subsequent WE.
- An excisional biopsy should include a narrow margin of normal-appearing skin around the suspicious lesion along with a cuff of underlying subcutaneous fat to provide the dermatopathologist with sufficient material to fully diagnose and, if melanoma, to histologically microstage the primary tumor.
- An excisional biopsy of the extremities is typically oriented parallel to the long axis of the extremity (**FIG 1**). On the trunk and head and neck, the orientation of the biopsy should ideally follow the lymphatic drainage of the involved skin while also being mindful of the lines of tension for optimal closure.
- Incisional biopsies are sometimes necessary for large lesions, especially in cosmetically sensitive areas. Such a biopsy approach does not always reflect the full primary tumor microstaging of the lesion, including margin assessment, and such limitations need to be considered during definitive treatment.
- Shave biopsies are not generally recommended when a cutaneous lesion is suspicious for melanoma, because the full extent of the lesion (especially Breslow thickness) may not be included in the biopsy and the approach may limit accurate microstaging of the primary tumor.
- Confirmation of the melanoma biopsy site(s) must be performed prior to any planned definitive treatment.

Histopathologic microstaging of primary melanoma

- In order to determine the appropriate extent of surgery for a patient with a primary melanoma—including WE margin and whether to offer/perform intraoperative lymphatic mapping and SNB—assessment of several of the primary tumor's histopathologic features is essential.

- Breslow thickness (in millimeters), mitotic rate (expressed in mitoses/mm^2), presence or absence of primary tumor ulceration, and the biopsy margin status (peripheral and deep margins) are all essential to define T stage and to guide appropriate surgical therapy; they should be assessed by a dermatopathologist. Additional primary tumor information that may be useful to the operative surgeon includes the presence or absence of lymphovascular invasion, neurovascular invasion, regression, extent of tumor-infiltrating lymphocytes, histologic subtype, and Clark level.

Margins of excision

- WE includes a radial margin of skin and underlying subcutaneous tissue, with margins appropriate for tumor thickness.
- The radial margin chosen for the WE is based on the primary tumor (Breslow) thickness. At least five prospective randomized trials conducted over the past three decades informed an evidence-based approach. Although detailed discussion is beyond the scope of this section, the recommendations from the National Comprehensive Cancer Network (NCCN) for the radial margin are as follows:[5]
  - Melanoma in situ: 0.5-cm margin (Note: For large diameter melanoma in situ, for example, lentigo maligna type, margins >0.5 cm may sometimes be considered to adequately treat occult early invasive disease).
  - Less than or equal to 1.0 mm: 1.0 cm
  - 1.01 to 2.0 mm: 1.0 to 2.0 cm
  - 2.01 to 4.0 mm: 2.0 cm
  - Greater than 4.0: 2.0 cm

Positioning

General positioning strategies

- Depending on primary tumor characteristics and other considerations, lymphatic mapping and SNB are most often performed in the same operative setting as a WE. For this reason, proper patient positioning should account for both the location of the primary melanoma and the location(s) of draining regional nodal basins. This may become challenging when the primary melanoma drains to multiple nodal basins and/or to interval, ectopic, and/or in-transit sites. Skin graft donor sites or other reconstructive issues must also be considered when positioning the patient.

Proximal extremity

- For proximal upper extremity lesions, a supine position is generally appropriate for WE and SNB. For more posterior lesions near the shoulder, a modified supine position using a shoulder roll or a lateral decubitus position provides easy access for WE and closure. The arm, prepped circumferentially, should be supported to prevent injury to the brachial plexus and/or shoulder.
- For proximal lower extremity lesions, the supine position provides excellent exposure of anterior or lateral sites, allowing both WE and SNB. When the melanoma is on the posterior proximal leg or the buttock, the WE may be performed with the patient in the lateral or prone position. Pressure points need to be padded and axillary and chest rolls need to be appropriately positioned. Some surgeons are comfortable performing both WE and inguinal SNB in the lateral position; a potential advantage is that repositioning is not required. Alternately, SNB can be performed in the supine position, and the patient repositioned for the WE.

Distal extremity

- In general, a supine position is appropriate for most distal extremity lesions. If SNB is also to be performed, access to the axillary, epitrochlear, and inguinal nodal basins is readily achieved. If a patient's melanoma drains to the popliteal nodal basin, then an alternative position other than the supine approach should be used. The prone position is sometimes used so as to allow the sentinel node to be removed through an incision that could be incorporated into a full popliteal node dissection incision if evidence of metastasis were to be identified.
- Heel melanomas not only have the potential to drain to the popliteal basin but may also require specialized reconstructive approaches (e.g., wound vac device, rotational flaps, and/or vascularized free flaps). In this situation, use of a beanbag on the operating room table allows for repositioning as indicated.

Truncal sites

- When an SNB is performed with WE of a truncal melanoma, the possibility of multiple nodal basin drainage patterns must be considered when devising an operating room positioning strategy. A preoperative lymphoscintigraphy will demonstrate afferent lymphatic drainage patterns to major and unusually situated (e.g., ectopic, interval) nodal basins.
- For most anterior truncal melanomas (e.g., chest and abdomen), the supine position allows for access to the primary and draining regional nodal basins. For lateral truncal melanomas, ideal positioning for the WE may include placing the patient in a partial or formal lateral position (with appropriate padding and brachial plexus protection).
- When performing a WE only (e.g., for a thin melanoma without adverse risk features), back melanomas may be performed in the prone (e.g., for medial lesions) or lateral (e.g., for most back lesions) position at the discretion of the surgeon. Appropriate padding and brachial nerve protection must be employed and airway protection is essential. If SNB is being performed in the same operative setting, patient positioning must foster access to draining nodal basins including multiple and/or unusually situated nodal basins. It may be necessary to reposition the patient after the SNB and before the WE (**FIGS 2** and **3**).

Head and neck sites

- Head and neck melanoma patients must also be carefully positioned with consideration of the WE, reconstructive requirements, and in continuity access to draining regional nodal basins if SNB is to be performed. Whether in a supine, prone, or lateral position, the head and neck must be appropriately supported and padded. Additionally, the airway, eyes, and ears must be protected.

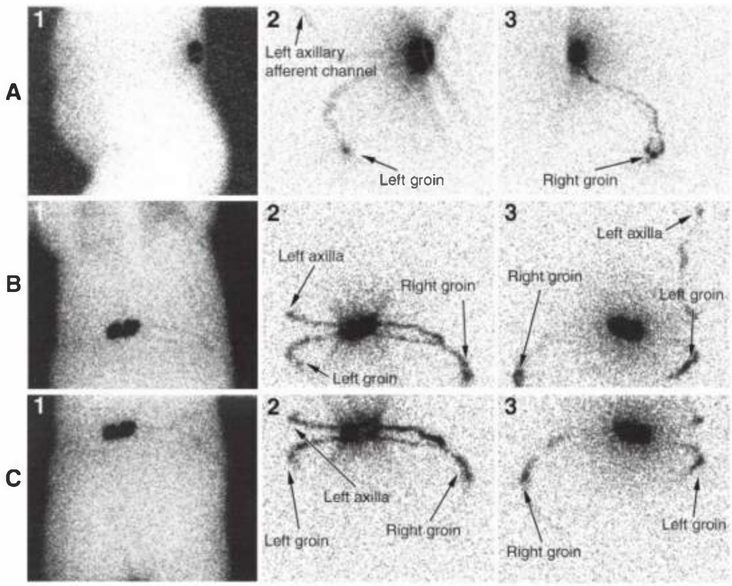

FIG 2 ● Lymphoscintigraphic images of a patient with a primary cutaneous melanoma of the midline mid back demonstrates radiotracer uptake activity in the bilateral groins and the left axilla.

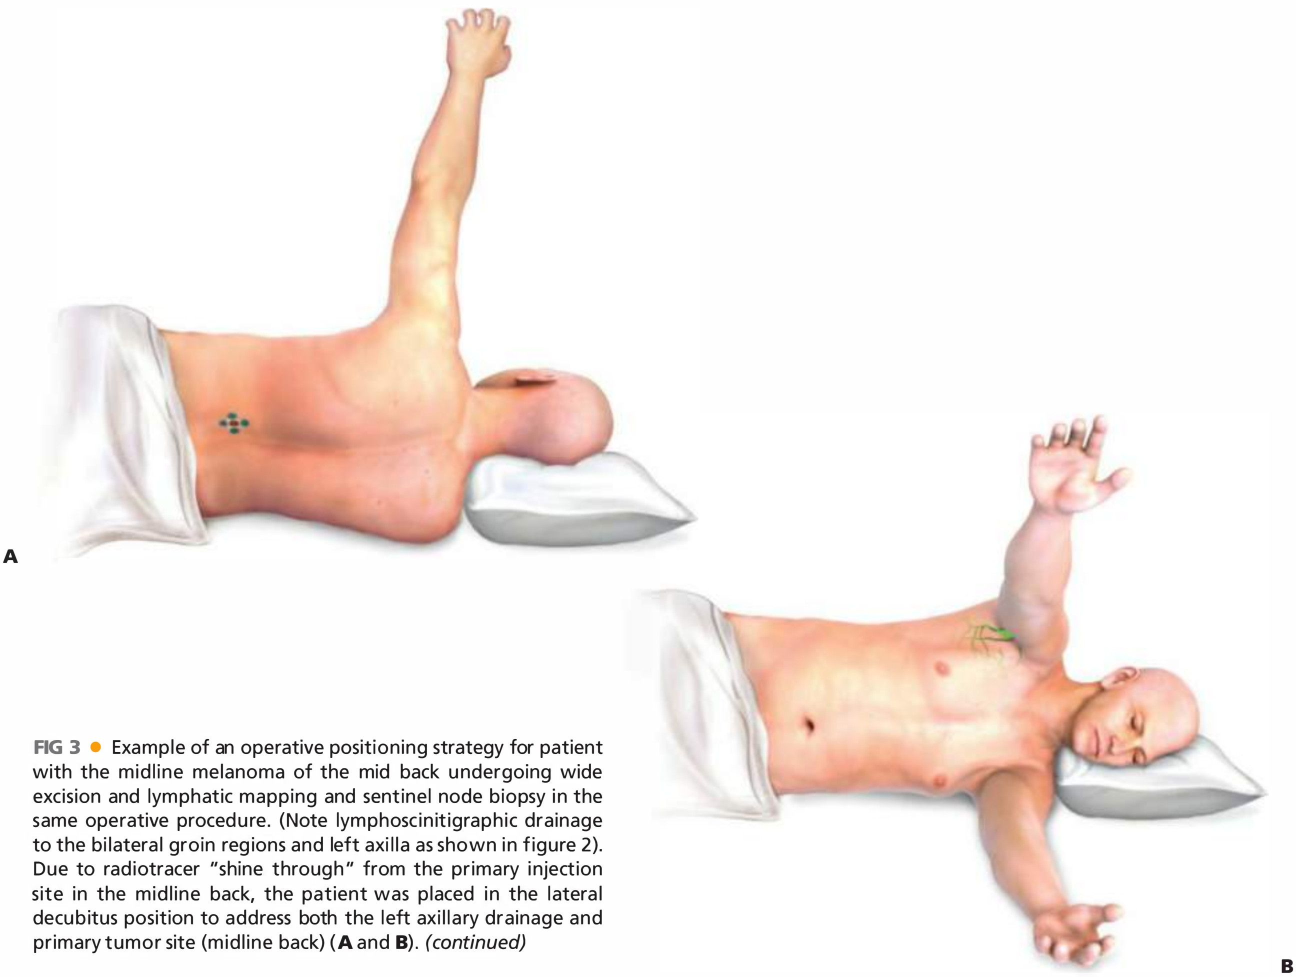

FIG 3 ● Example of an operative positioning strategy for patient with the midline melanoma of the mid back undergoing wide excision and lymphatic mapping and sentinel node biopsy in the same operative procedure. (Note lymphoscinitigraphic drainage to the bilateral groin regions and left axilla as shown in figure 2). Due to radiotracer "shine through" from the primary injection site in the midline back, the patient was placed in the lateral decubitus position to address both the left axillary drainage and primary tumor site (midline back) (**A** and **B**). *(continued)*

C

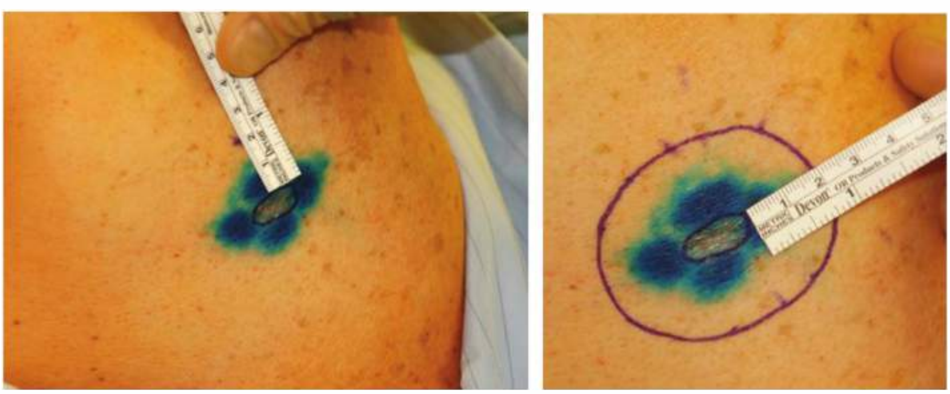
FIG 3 ● *(continued)* The patient was then repositioned to supine to perform bilateral inguinal sentinel node biopsies **(C)**. Note that if radiotracer shine through was not a problem, then the patient could have been initially positioned in the supine position (after injection of both isosulfan blue dye and radiocolloid) to address the bilateral inguinal nodal basins as well as left axillary nodal basin and then repositioned into the lateral decubitus position to perform the wide excision of the back melanoma. Regardless of approach, it is important to scan intervening regions with the gamma probe.

WIDE EXCISION MARGIN

- The planned margin of excision of the primary melanoma is based on the Breslow tumor thickness as described above and refers to the radial margin of normal-appearing skin to be resected. If the primary melanoma is entirely or partially intact, the margin should be measured from the periphery of the visible lesion. When the entire pigmented lesion has been excised by the previous biopsy, the margin should be measured from the periphery of the biopsy scar.

PLACEMENT AND ORIENTATION OF INCISION

- Proper planning of the incision is critical. The surgeon must consider the required radial margin (i.e., margin of excision), the specific anatomic primary site involved, as well as the quality and quantity of local soft tissue.
- Because the resulting final incision may be significantly longer than what the patient might have otherwise anticipated, based on the usually "small" biopsy site, we strongly recommend that this theme be integrated into the surgical consultation and preoperative visits: a "scale" drawing presented to the patient at the time of initial and/or preoperative visit is often very instructive.
- The recommended margin of excision is based on primary tumor thickness (described above) and is measured from either the edge of the intact melanoma or biopsy scar, generally resulting in the proposed circular or oval defect marked on the skin (**FIG 4A,B**). When a primary closure is planned, the circle or oval can be modified into



A B

FIG 4 ● **A,B.** In this example, the patient has already been injected with both Tc-99 sulfur colloid and isosulfan blue intradermally around the biopsy site for a lymphatic mapping and sentinel biopsy procedure at the time of wide excision in the same operative setting. The recommended margin of excision is based on primary tumor thickness and is measured from either the edge of the intact melanoma or biopsy scar, generally resulting in the proposed circular or oval defect marked on the skin.

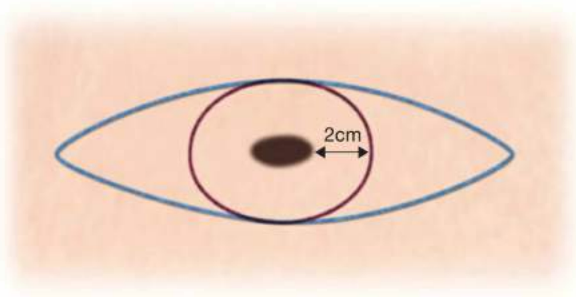


FIG 5 ● When a primary closure as planned, the circle or oval is generally fashioned into an ellipse prior to wide excision to improve cosmetic outcome and facilitate primary closure.

an ellipse prior to WE to improve cosmetic outcome and facilitate primary closure (**FIG 5**). Excision of an ellipse of tissue results in a more gradual transition in wound contour and minimizes "dog ears" at the poles of the incision.

- Creation of an ellipse three to four times as long as it is wide has often been recommended in textbooks; cosmetically acceptable closure can sometimes be achieved with a smaller ratio and should be individualized.
- Alternatively, tissue that may contribute to dog ears can be resected after the oncologic portion of the WE. Depending on the lines of tension of the skin, a modified ellipse such as lazy S or "hurricane"-type (**FIG 6**) incision may facilitate closure, generally as triangular-shaped segments of skin and underlying subcutaneous tissue.
- When feasible, the incision should be oriented to facilitate primary closure. On the extremities, for example, the WE incision is usually oriented parallel to the long axis of the limb. This facilitates primary closure, results in greater excision of lymphatics that are at risk for melanoma tumor cell emboli, and may decrease subsequent lymphedema.
- Breast—Primary cutaneous melanoma of the skin of the breast should be managed with similar principles as cutaneous melanoma elsewhere. A mastectomy is not required to achieve oncologic control.
- Hand, foot, and digits—General margin guidelines for cutaneous melanoma should be followed and consideration for preservation of function should be maximized. As a general principle, it is not usually necessary to remove bone to obtain oncologic control of the primary melanoma. However, amputation is usually necessary if standard WE for subungual or distal digit invasive cutaneous melanoma leaves insufficient soft tissue to maintain a functional digit without partial phalanx bony resection. Phalanx-preserving approaches can sometimes be employed for distal digit/subungual melanoma in situ.
- Perianal skin melanomas should be treated as cutaneous melanomas.

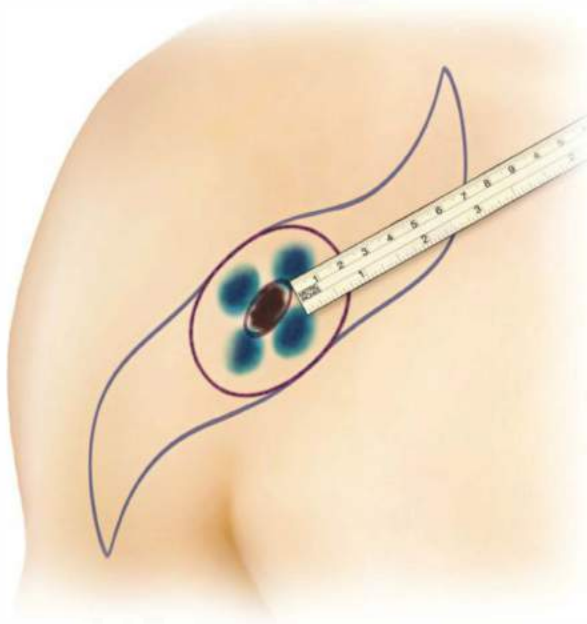

FIG 6 ● Depending on the lines of tension of the skin, a modified ellipse such as lazy S or hurricane-type incision may facilitate closure.

SKIN INCISION

- The skin incision is typically made with a no. 10 or 15 blade scalpel, initially to the level of the deep dermis. The remainder of the dermis can be divided either using the electrocautery on cutting mode or by using a scalpel. Care is required to avoid cautery to the skin edges, as this may result in wound healing issues.
- The excision continues by deepening the initial incision into the subcutaneous tissue to the level of the muscular fascia; care must be taken to maintain an angle of attack through the subcutaneous tissue that is perpendicular to the skin surface. The actual depth of excision will vary according to the anatomic location of the primary melanoma. It is rarely necessary to include fascia with WE[5]; an exception is when prior surgery at the site included or abutted the fascia such that clear margin cannot be achieved or in the case of obvious tumor involvement at the fascia.

EXCISION OF SPECIMEN

- Once the depth of the resection has reached the underlying muscular fascia, the WE is completed by dissecting skin and soft tissue from the underlying fascia using the electrocautery (**FIG 7**).
- WE specimens are almost always submitted for permanent section analysis; intraoperative frozen section analysis is the exception. When reconstruction may be significantly impacted by an involved margin, "rush" permanent pathology (turnaround about 24 to 48 hours) may be coordinated with the pathology team (see also "Delayed Wound Closure" later in this chapter).
- It is important to properly orient the specimen in the event that final margins are involved and an additional resection (usually as a separate operative procedure) is required (**FIG 8**).

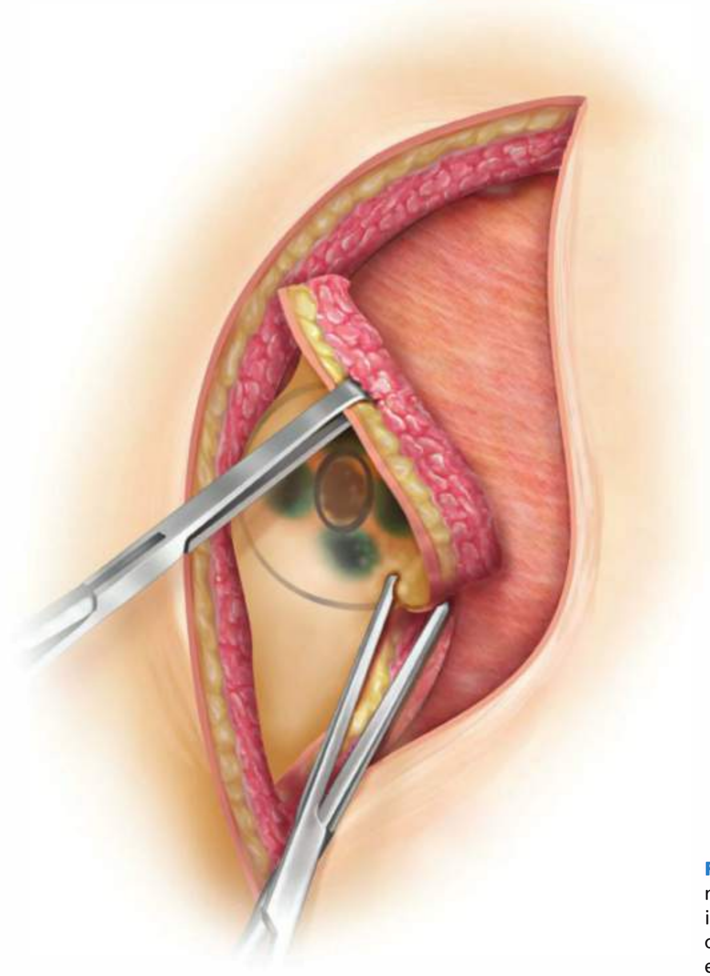

FIG 7 ● The depth of wide excision down to the muscular fascia is demonstrated. Once this depth is reached, the skin and soft tissue is dissected off the underlying fascia, completing the wide excision.

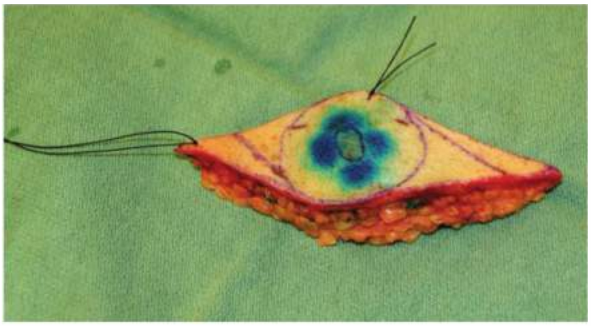

FIG 8 ● The resected specimen is carefully oriented to ensure accurate margin assessment by the pathologist. It is also important to orient in such a fashion that re-excision of involved margins can be accurately mapped back to the patient.

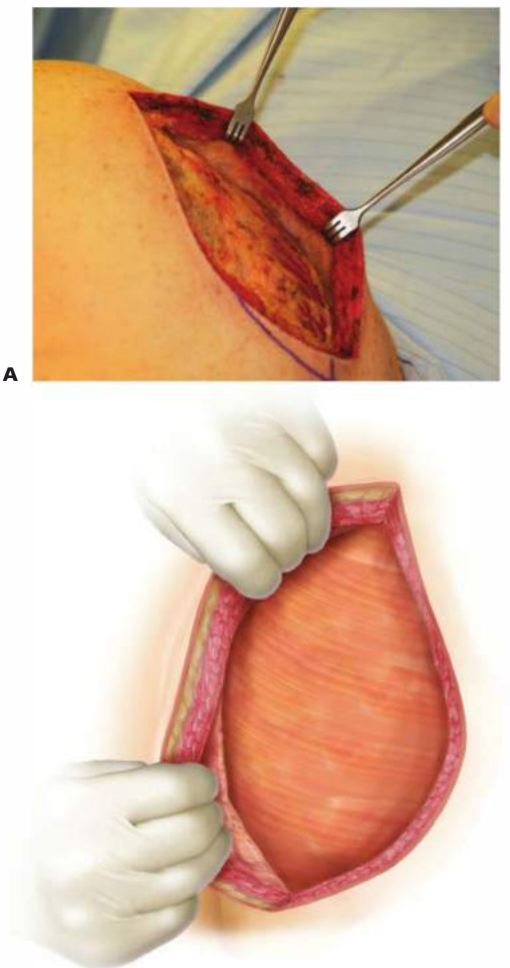
CLOSURE

- The majority of 1-cm margin defects and many 2-cm margin defects can be closed primarily. Recruitment of adjacent tissue by fashioning local flaps often facilitates primary closure and is dependent on the primary tumor location, margin, and the laxity of adjacent skin. Surgical defects may often be closed by mobilizing tissue flaps that have been created by undermining in a suprafascial plane and include full-thickness skin and underlying subcutaneous fat (**FIG 9A,B**).
- Complex closure of a WE defect involves placement of one or two layers of deep absorbable sutures (**FIG 10**), followed by placement of an intradermal layer of a buried absorbable suture. Skin closure can be carried out using a number of techniques, depending on the tissue tension, anatomic location, mobility, and surgeon preference. A subcuticular skin closure may be performed using an absorbable monofilament suture or a nonabsorbable pull-through suture that requires removal. Interrupted or running nonabsorbable sutures and skin staples may also be used as per surgeon preference (**FIG 11**). Dermal adhesives or adhesive bands may be used to directly cover the skin.

FIG 10 ● Photo demonstrating placement of deep absorbable sutures to facilitate complex primary closure of a WE. Typically one or two layers of deep absorbable sutures are used.



A

B

FIG 9 ● Photo **(A)** and illustration **(B)** demonstrating the mobilization of tissue flaps by undermining the full thickness of skin and subcutaneous fat at a level just superficial to the muscular fascia.

FIG 11 ● After reapproximation of deep layer(s), the skin may be closed using a number of different techniques and sutures depending on location, tension, and surgeon preference. In this photograph, interrupted vertical mattress sutures were used.

- At the discretion of the surgeon, closed suction drainage may be used when extensive undermining or large flaps are necessary or when considerable dead space persists after layered closure. If a drain is used, the exit site should be placed in line with the incision so that any potential recurrence can be reexcised without jeopardizing subsequent wound closure. Alternatively, suture plication of the more superficial tissue to the underlying fascia may sometimes be used and obviate the need for drainage, even when larger flaps are used.

RECONSTRUCTION

- When primary closure is not feasible, consideration should be given to skin grafts or local tissue flaps. The advantage of a skin graft is that it is a relatively straightforward procedure that minimizes adjacent tissue manipulation, allows for easy long-term monitoring of the primary melanoma site, and does not disrupt lymphatic drainage pathways. Skin grafts, however, are insensate, provide little protection to underlying tissue, and may result in a more pronounced contour defect. Furthermore, compared to local tissue flaps, skin grafts may result in more disfigurement and prolonged healing. Skin grafts are discussed in detail in Part 5, Chapter 24.
- Typically, split-thickness skin grafts are harvested from the posterior or proximal lateral thigh. Of note, when a lower extremity melanoma requires a skin graft closure, the graft should be harvested from the contralateral extremity.
- Full-thickness skin grafts can be harvested from multiple locations, allowing for better skin color and texture matching to skin adjacent to the melanoma excision. Full-thickness skin grafts may be harvested from the inguinal groin crease, the lower neck region overlying the clavicle, or behind the ear. After an appropriately sized ellipse of skin is excised down into the subcutaneous fat, the donor site is primarily closed, resulting in less morbidity than the typical split-thickness skin graft donor site. The full-thickness harvested skin is de-fatted and prepared as a skin graft.
- The decision to proceed with a local tissue or rotational flap should be made after careful consideration of the features of the local tumor, including risk of satellite or in-transit metastases, the potential benefit to the patient from the functional and cosmetic perspective, the comorbidities of the patient, and the local tissue options available. The advantages of local flaps include durable, sensate, similar thickness, and textured skin. Disadvantages include rearrangement of regional soft tissue at risk for in-transit/satellite metastatic disease. Advancement and rotational flaps are discussed in detail in Part 5, Chapter 23.

DELAYED WOUND CLOSURE

- The majority of WE defects are closed or reconstructed during the same operation as the WE. There are circumstances, however, when delayed reconstruction is the most appropriate course of action. These situations may include delaying reconstruction in the setting of large diameter or poorly defined melanomas where margins are clinically equivocal at time of WE. Unlike its common use for assessment of margins for nonmelanoma skin cancer, intraoperative frozen section margin assessment is infrequently employed for intraoperative margin assessment of melanoma WE.
- Delayed reconstruction may also be beneficial when time is needed for a granulation bed to form in order to facilitate grafting, such as after excision of a heel melanoma where skin grafting onto a granulating bed is often performed in such a fashion (**FIG 12**).
- When wound closure is delayed, options for wound coverage include temporary wound dressings with routine dressing changes or a vacuum-assisted sponge dressing device (e.g., vacuum-assisted closure [VAC] device). VAC devices are sometimes not available until negative margins are confirmed.
- In some situations, a request for rush permanent pathology of the WE specimen may be coordinated in advance with the pathology team, thus facilitating advance surgical planning (often at 48 hours postoperative) both in terms of operating room space and collaboration with the reconstructive team. In such cases, a temporary occlusive dressing is often used to protect the WE site until final margins are available.

FIG 12 ● Photographs demonstrating use of delayed reconstruction for a large heel melanoma **(A)**. Upon completion of the WE **(B)**, a vacuum- assisted sponge dressing device is placed intraoperatively **(C)**. The recipient granulation bed, shown here after use of a vacuum-assisted device for approximately 3 weeks, is now optimized for skin grafting **(D)**.

PEARLS AND PITFALLS

Preoperative strategies	■ Orientation of biopsy is important whenever performed. ■ Healing of biopsy—Photo document biopsy site for later site confirmation whenever it may be possible that site will be healed prior to definitive WE. ■ Complete history and physical essential to identify additional suspicious primary lesions as well as potential sites of in-transit metastasis, satellites, and clinical nodal disease.
Operative positioning	■ Pad all pressure points. ■ Include potential interval and/or in-transit drainage sites within operative field if SNB is to be performed. ■ Do not harvest skin grafts from in-transit region (i.e., between primary tumor and draining nodal basin); as a practical approach, it is generally not prudent to harvest skin grafts from ipsilateral extremity.
Placement of incision	■ Extremities—Incision is generally oriented parallel to the long axis of extremity. ■ Always consider reconstructive options when placing and planning incision for WE. ■ Use radial margins appropriate for tumor thickness. ■ Be aware of superficial (subcutaneous) motor nerves (e.g., superficial peroneal and portion of spinal accessory)
Intraoperative considerations	■ Excision should be performed to, but not include, level of the underlying muscular fascia, unless the fascia itself is involved with tumor or the prior biopsy procedure. ■ Maintain perpendicular orientation through subcutaneous tissue. ■ Frozen section margin analysis is rarely employed. ■ Proper orientation of WE specimen is essential to facilitate reexcision of involved margins when necessary.
Closure	■ Consider overall risks of locoregional and other metastases with any extensive reconstruction option employed. ■ Consider closing dead space where appropriate to reduce likelihood of seroma formation.

POSTOPERATIVE CARE

- Specific postoperative care is dependent on the type of closure, the use of absorbable or permanent suture material, the extent of tension on the wound, and the presence or absence of a drain.
- In general, the patient can shower in 24 to 48 hours unless skin grafts are used.
- Drains (if used) usually stay in place until collected volumes remain 30 mL or less for 2 consecutive days.
- Specific restrictions may apply depending on anatomic location (e.g., restrictions on weight bearing for melanomas on the plantar surface of foot) and type of closure (e.g., skin graft).
- Progressive increase in activity, weight bearing, or lifting over a 4- to 6-week period

OUTCOMES

- After an appropriate WE based on tumor thickness, true local melanoma recurrences are uncommon and likely represent lymphatic tumor emboli. Some “local recurrences” are a result of an incompletely or inadequately excised primary melanoma.
- Functional outcome is critical and early use of physical therapy is encouraged when appropriate.

COMPLICATIONS

- Infection (cellulitis or abscess)
- Seroma
- Hematoma/ bleeding
- Wound dehiscence or separation
- Failure of take of skin graft or flap
- Poor functional or cosmetic outcome
- Numbness and/or hyperesthesia and/or pain
- Edema/lymphedema

Chapter 23 Advancement and Rotational Flaps

Jeffrey H. Kozlow

DEFINITION

- Advancement and rotational flaps are tissue transfer techniques used in reconstructive surgery for the closure of acquired defects.
- A flap is an area of tissue designed for movement to another area while remaining vascularized. This is in contrast to a graft, which is transferred in a nonvascularized fashion and becomes revascularized only with local incorporation and vascular neogenesis.
- Advancement and rotation flaps are both considered local flaps because they borrow from the tissue adjacent to the defect. Distant flaps use tissue from areas away from the defect, and free flaps involve the transfer of tissue from a distant site by means of a microsurgical anastomosis.
- Local flaps can be defined by their vascularity. Random flaps are based on blood flow through the subdermal plexus to provide vascularity to the distal end of the flap (**FIG 1**). Axial flaps are based on a longitudinal blood vessel incorporated into the flap design that can extend the effective length of a flap (**FIG 2**). Perforator flaps are based on underlying septocutaneous or musculocutaneous perforators into the central area of the flap (**FIG 3**).
- Local flaps can also be defined by the geometry of the incisions used with example of common designs shown in the following text.
- Flap design includes evaluation of tissue laxity, optimization of scar position, and management of standing cutaneous deformities.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The choice and design of local flaps is dependent on multiple factors including the region on the body for reconstruction, local and regional soft tissue laxity, relationships with underlying critical anatomy, relaxed lines of skin tension for scarring, and underlying flap vascularity.
- Poor quality of tissue adjacent to the defect may preclude the use of local flaps.
- Local radiation damage will often limit the pliability of tissues for transfer and inhibit the healing potential of tissue.
- Each patient is different and flap choice must be tailored to the individual, the size of the defect, and the location of the defect.
- There are often multiple different flaps that will adequately reconstruct a defect; there is no "one right answer" for any given case.
- Flap design should also consider potential oncologic implications including the need for recurrence monitoring, secondary reconstruction techniques, and margin management when reconstruction is done immediately after resection and margin status cannot be confirmed.
- For patients with lower extremity defects, an evaluation of arterial status and venous insufficiency should be considered.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- In general, local flaps do not require preoperative imaging or diagnostic studies.
- Doppler can be used to identify either axial or perforating blood vessels if clinically indicated.

SURGICAL MANAGEMENT

Preoperative Planning

- A reconstructive plan can only be made after the resection is designed. In cases that may require a plastic and reconstructive surgeon for advanced reconstructive techniques, it is always best to plan accordingly ahead of time and not consult intraoperatively.

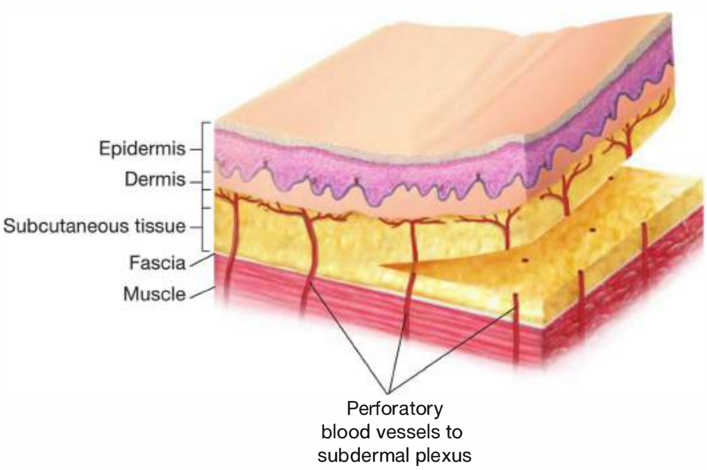

FIG 1 • Demonstration of a "random" pattern flap based on the subdermal plexus—The distal aspect of the flap remains vascularized through the small vessels running underneath the dermis only. As the length of the flap increases, the blood flow through the subdermal plexus decreases.

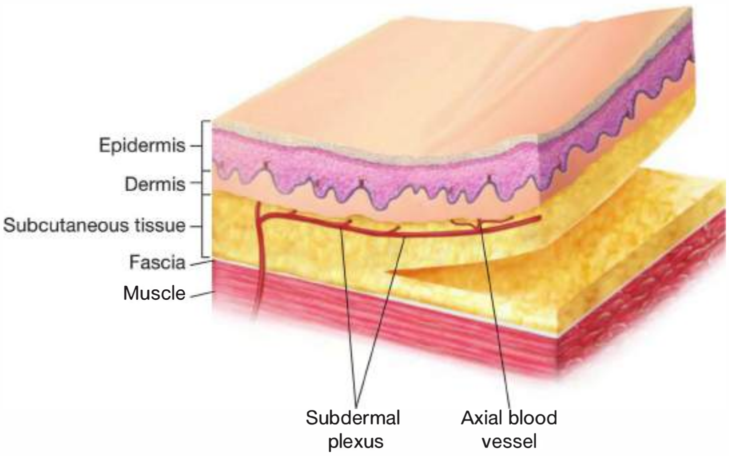

FIG 2 ● Demonstration of an axial pattern flap—The flap design incorporates a named arterial supply along the length of the flap, which increases perfusion to the distal aspect of the flap compared to a random pattern flap.

- Preoperative markings may include important regional anatomic landmarks (such as facial rhytids) that may be obscured with the injection of local anesthetic intraoperatively.

Positioning

- Patients should be positioned to optimize not only surgical access for tumor resection but also for access to any local areas potentially usable for the subsequent reconstruction.
- All areas should be prepped widely to allow for access to all local and regional flap option. All extremities should be prepped and draped circumferentially. For areas where symmetry is important (such as the face or breasts), it is important to have the contralateral side in the operative field as well.

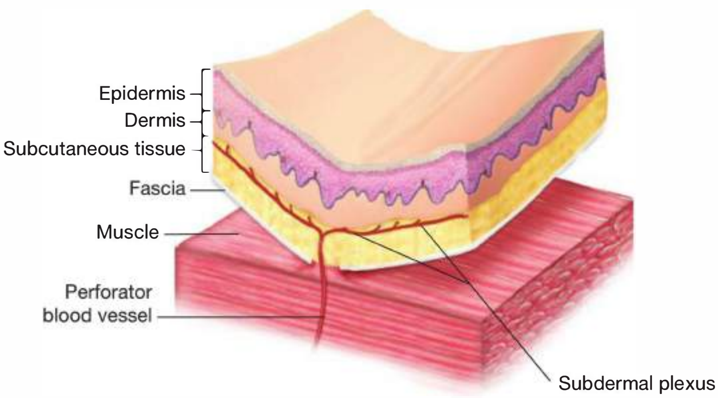

FIG 3 ● Demonstration of a perforator-based flap—The flap is centered around a single blood vessel, which perforates through the fascial layer from the underlying muscle or muscular septa to then supply the subdermal plexus.

- There are multiple local flaps that are available for use in reconstruction. Not all of them can be highlighted in this text; however, the most common flaps for general reconstruction are described in the following text. In some cases, multiple local flaps are required and techniques can be combined to achieve closure of the defect.
- In most flaps, the area is often infiltrated with local anesthesia including 1:100,000 to 1:200,000 parts epinephrine to help with hemostasis and minimize electrocautery injury to dermal edges. However, overinjection of local anesthesia can result in tissue edema that decreases flap mobility.
- Skin hooks are used on the margins of a flap for handling; the use of forceps is discouraged due to injury to the flap edges from overzealous pressure.
- Drains are typically not used unless flaps are large.
- Flaps designed around joints should be inset under the greatest tension of the joint to avoid postoperative dehiscence.

SIMPLE ADVANCEMENT FLAPS

Flap Design

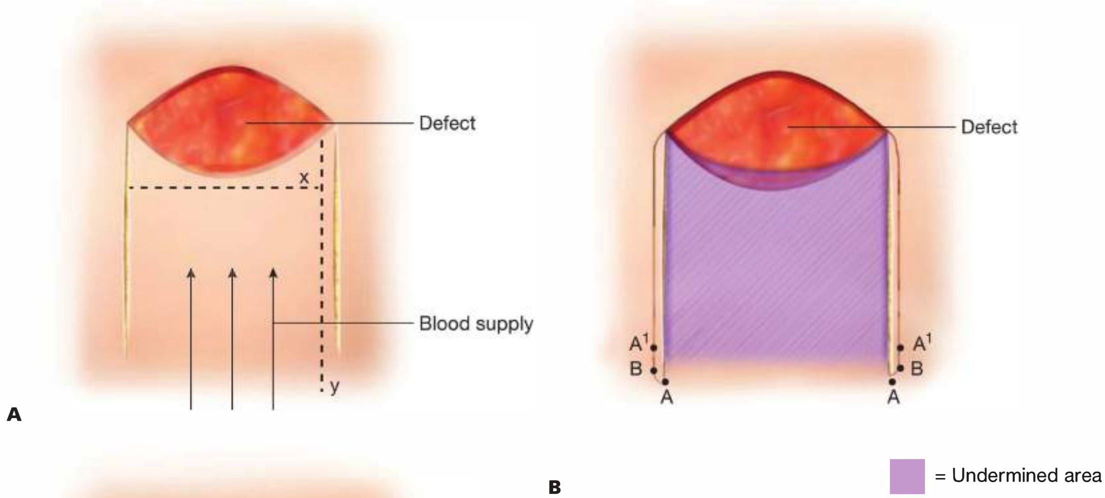
- Based on either the subdermal plexus as a vascular supply from the base of the flap to the distal end or can include an axial vessel for additional length and degrees of freedom
- Incisions are designed in a parallel fashion equal to the dimensions of the defect (**FIGS 4A** and **5A**); choice of direction is based on local tissue laxity.
- Classic teaching is that a maximum 3:1 ratio of length to width can be used when the flap is based on the subdermal plexus.

Flap Elevation

- Incisions are made extending from the defect in a parallel fashion toward base of flap.
- Dissection is carried down to the depth of defect or deeper in order to match volumetric dimensions of reconstruction.
- The central portion of the flap is undermined either in the deep subcutaneous level or below the fascia, depending on flap design and reliance on subdermal only versus axial-based blood supply (**FIGS 4B** and **5B**).

Defect Closure

- Careful hemostasis is assured after flap elevation; hematomas under the flap can compromise vascularity and overall outcome.
- Once flap has adequate advancement to fill defect, closure often occurs from the base of the flap to help "push" the flap into the defect, which can help alleviate tension over the distal closure (**FIG 4C**).
- Standing cutaneous deformities can occur as the base is advanced. These areas can be resected with a scar perpendicular to the direction of the flap.
- Dermal closure is performed using an absorbable suture followed by either a subcuticular or simple external suture (**FIG 5C**).



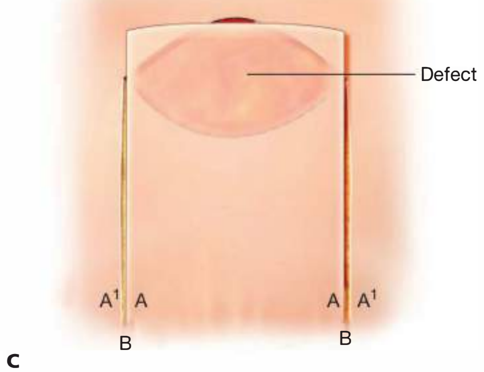


FIG 4 ● The design of an advancement flap is based on subdermal blood supply from the base of the flap. The initial parallel incisions are drawn from the wound edges **(A)**. The advancement flap is undermined toward the base, leaving only the subdermal blood supply to vascularize the distal tip **(B)**. The flap is then advanced forward and pushed into the defect. The previous base corner of the flap (point *A*) has been pushed forward and is approximated to point A^1 **(C)**.

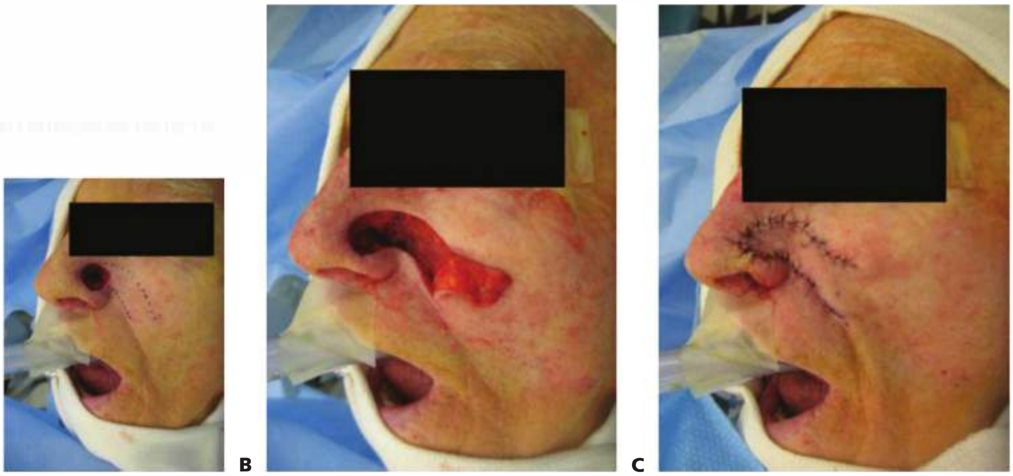


A B C

FIG 5 ● **A.** In this case, an axial-based advancement flap for nasal reconstruction is designed to incorporate the angular artery for additional length. This undermining is seen in **B** as the flap is fold back toward its base prior to advancement. The final advancement and closure of the advancement flap is demonstrated in **C**.

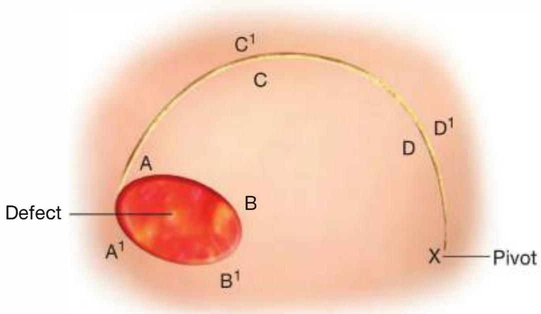
ROTATIONAL/TRANSPOSITION FLAPS

Flap Design

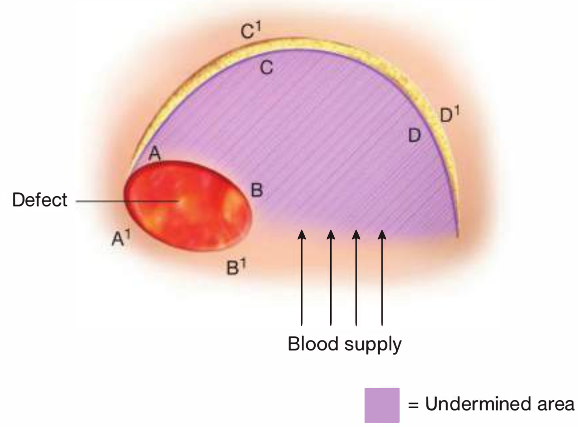
- Designed as a semicircle extending from one corner of the defect (FIGS 6A and 7A)
- Direction and orientation of flap is based on local areas of laxity.
- Based on a pivot point at "base" of flap that determines amount of rotation available

Flap Elevation

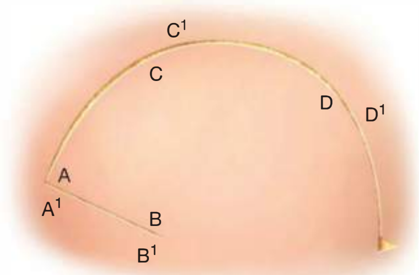
- Incision is made through skin and subcutaneous tissues to depth of defect or greater.
- Flap is undermined in same or deeper plan up to the base (FIG 6B).
- Careful hemostasis is assured in undermined area to avoid a hematoma that may compromise flap.



A

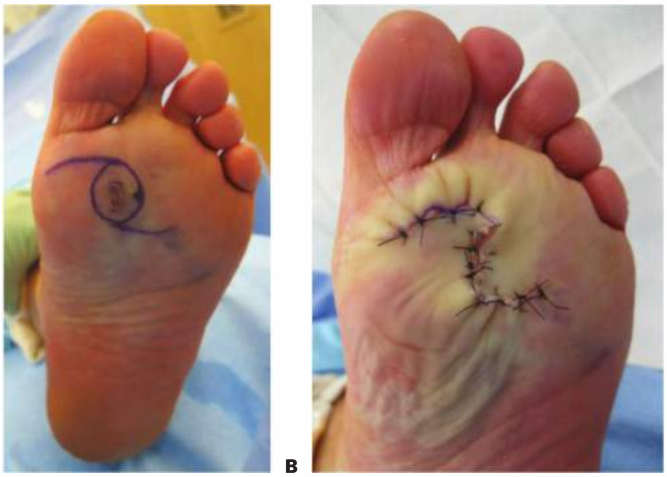


B



C

FIG 6 ● The semicircular markings for a rotation flap are demonstrated. The subsequent advancement of the flap is demonstrated by the movement of points *A*, *B*, *C*, and *D* to A^1, B^1, C^1, and D^1, respectively **(A)**. The rotation flap is undermined back toward the base leaving the distal portion of the tissue perfused through the subdermal plexus. Additional back-cuts across the base should be done judicious to not compromise vascularity of the flap **(B)**. The rotation flap is rotated into the defect for closure. The movement of the flap relative to the adjacent skin is noted by the changed alignment of the *C* and *D* marks to the C^1 and D^1 marks, respectively. **C.** A small standing cutaneous deformity at the base of the flap may require excision.



A B

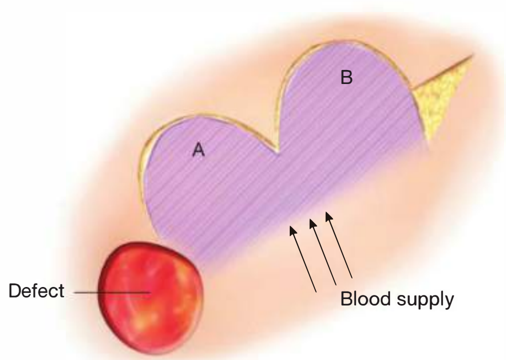
FIG 7 ● A. In this clinical case, opposing advancement flaps have been designed for reconstruction of a plantar foot wound. B. In this case, the opposing flaps have both been advanced to reconstruct the defect.

Defect Closure

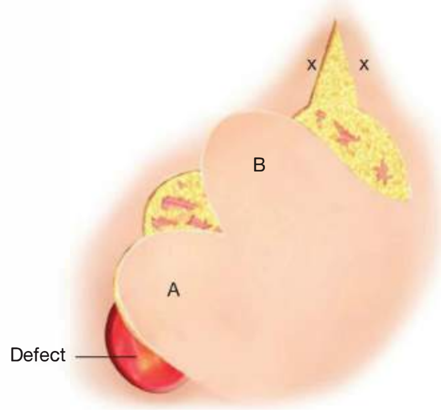
- Flap is advanced and rotated into defect with closure often starting at base of defect to help push and rotate flap into defect (FIG 6C).
- Dermal closure is performed using an absorbable suture followed by either a subcuticular or simple external suture (FIG 7B).
- Excision of standing cutaneous deformities should be away from the base of the flap to avoid decreasing flap vascularity.

Additional Designs

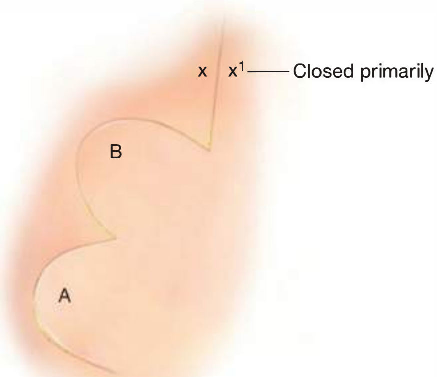
- Multiple variations in flap design are commonly used but based on the same principle as earlier. For example
  - A bilobed flap uses two adjacent rotation/transposition flaps. The flap directly adjacent to the defect is used to close the primary defect and the other flap is then used to close the donor site for the first flap (FIG 8A–C).
  - A rhomboid flap is designed along the longer edge of a defect and transposes skin from an area of laxity to the defect, allowing for primary closure of the donor site (FIG 9A–C).



A

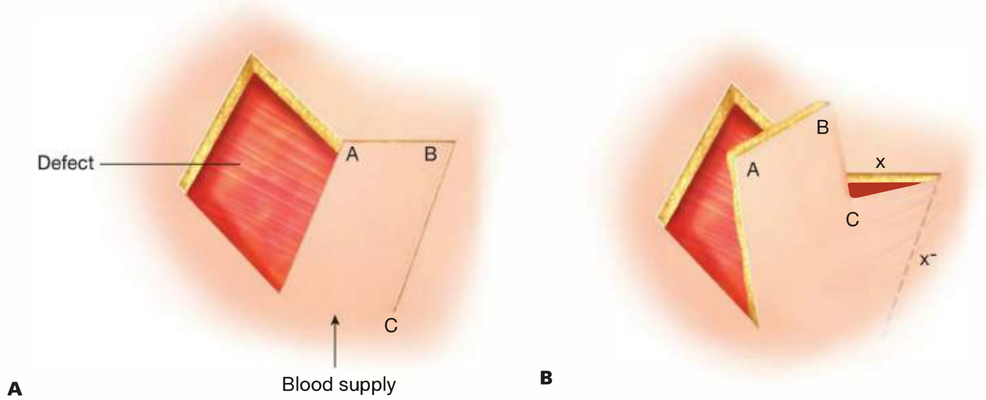


B



C

FIG 8 ● The bilobed flap uses two rotation-transposition flaps for closure of a defect. **A.** *Flap A* is used to close the primary defect and *flap B* is used to close the donor site from *flap A*. **B.** The flap is elevated in the subcutaneous tissues leaving blood supply from the subdermal plexus at the base of the both "lobes" of the flap. **C.** The flaps are then transposed with primary closure of the donor site for *flap B* by reapproximation of x to x^1.



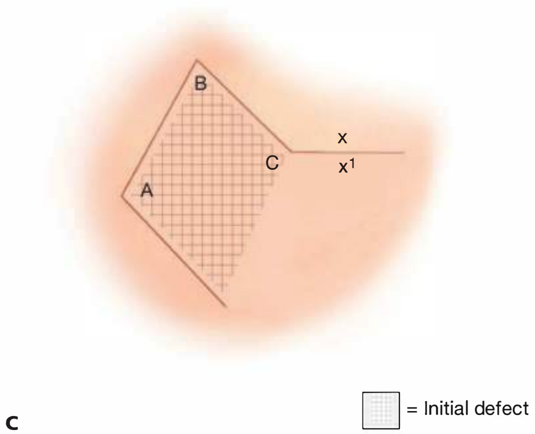


FIG 9 ● The rhomboid flap is another variation on the rotation-transposition flap and works well with elliptical- or rhomboid-shaped defects. The flap is designed off the "oblique" angle of the defect directly perpendicular to the defect. An additional incision designed parallel to the side of the defect is used to create a mirror image of the defect through the shared border of the flap and the defect **(A)**. The flap is then elevated in the subcutaneous tissues leaving blood supply from the subdermal plexus **(B)**. The flap is then rotated and transposed to fill the defect with the flap donor site closed primarily with approximation of *x* to x^1 **(C)**.

V-Y ADVANCEMENT FLAP

Flap Design

- The vascularity of the V-Y advancement flap is based on the central perforating vessels.
- Orientation is designed on areas of local laxity and mobility.
- Incisions are designed from wide part of defect and then gently tapered into a triangle perpendicular to wound edge (**FIG 10A** and **FIG 11A**).
- Care is taken to design large enough flap to allow for some undermining at base of flap for additional advancement while still leaving enough central contact with deeper tissues for vascularity.

Flap Elevation

- Incisions are made through skin and subcutaneous tissues. Dissection through the subcutaneous tissues should be beveled away from the flap in order to increase the area for capture of underlying perforators into the central flap.
- The fascia can also be divided to allow for additional flap mobility.
- Can undermine the distal and proximal one-fourth of flap to allow for additional advancement but must *not* undermine centrally because this area is key to vascularity (**FIG 10B**). This is often done by spreading with a scissors vertically to preserve any potential blood vessels entering the flap.

Defect Closure

- Careful hemostasis is assured after flap elevation; hematomas under the flap can compromise vascularity and overall outcome.
- Closure starts at the "point" of the triangle where the donor site is closed primarily to form the vertical limb of the "Y." This also helps push the flap forward into the defect (**FIG 10C**).
- The flap is then pushed forward into the defect by closure of the sides of the triangle (**FIG 11B**).

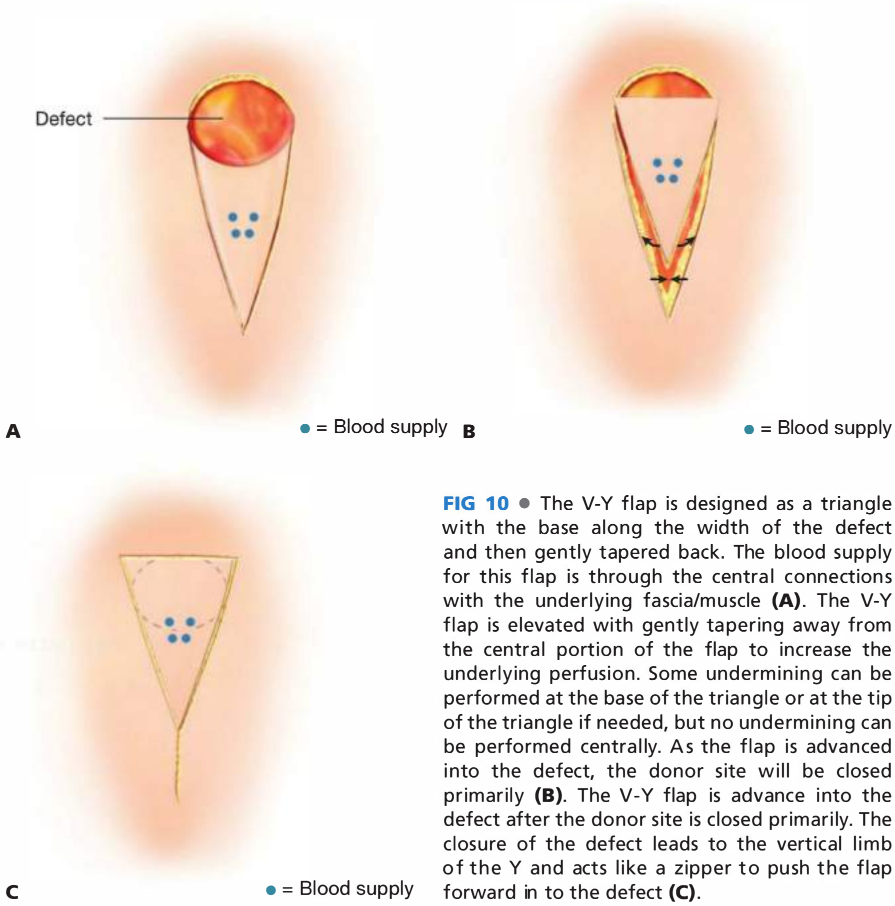

FIG 10 ● The V-Y flap is designed as a triangle with the base along the width of the defect and then gently tapered back. The blood supply for this flap is through the central connections with the underlying fascia/muscle **(A)**. The V-Y flap is elevated with gently tapering away from the central portion of the flap to increase the underlying perfusion. Some undermining can be performed at the base of the triangle or at the tip of the triangle if needed, but no undermining can be performed centrally. As the flap is advanced into the defect, the donor site will be closed primarily **(B)**. The V-Y flap is advance into the defect after the donor site is closed primarily. The closure of the defect leads to the vertical limb of the Y and acts like a zipper to push the flap forward in to the defect **(C)**.

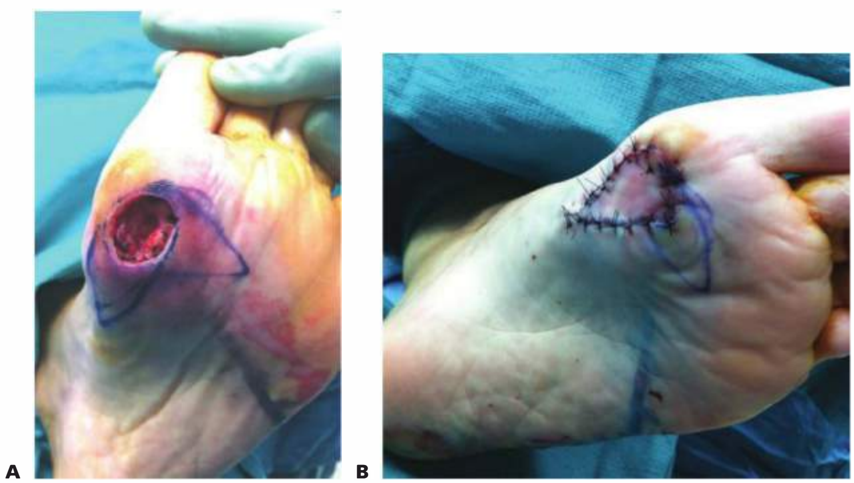

FIG 11 ● **A.** In this clinical case, two potential options for a V-Y flap have been designed with the decision to use the flap designed back toward the heel selected due to the relative laxity of that donor site compared to the flap running transversely across the plantar foot. **B.** In this case, the flap has been nicely advanced into the defect with the resultant Y closure demonstrated.

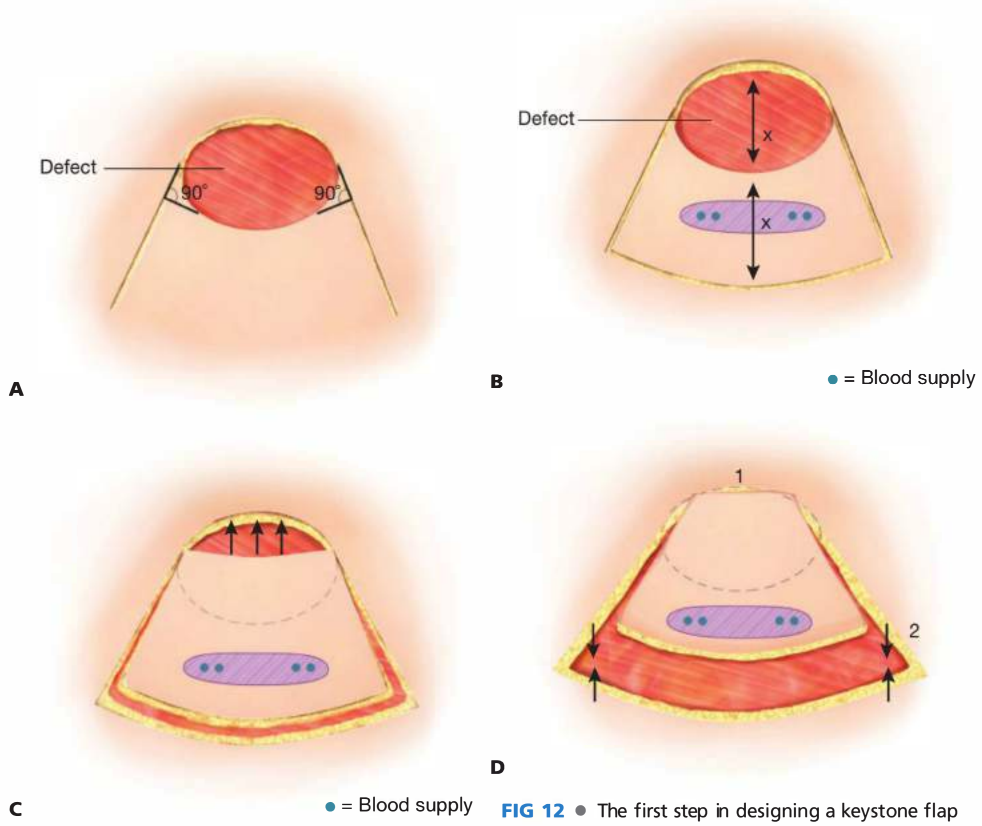
KEYSTONE FLAP

Flap Design

- Flap design is based on central perforators and use of "V-Y" closures to gain local tissue for advancement into the defect.
- A handheld Doppler can be used to identify specific large central perforators for preservation if additional mobilization is expected.
- The flap is most often designed from the longer border of a defect by first marking out the lateral borders of the flap at a 90-degree angle to the defect (**FIG 12A**).
- The flap width is then determined to be at least the width of the defect if not large. The flap is designed to remain this width along the entire length to each of the lateral borders (**FIGS 12B** and **13A**).

Flap Elevation

- Incisions are made through skin and subcutaneous tissues. This dissection is carried perpendicular to the skin with minimal beveling.
- The underlying fascia may also be divided for additional mobility and can be especially helpful in larger flaps.
- A small amount of subcutaneous or subfascial undermining can be performed, but this must be done judiciously unless large perforators have been knowingly included in the flap design.



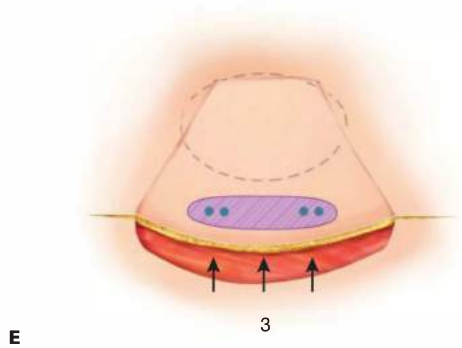


FIG 12 ● The first step in designing a keystone flap is to plan incisions from the corners of the defect perpendicular to the defect **(A)**. Next, the flap is designed to be at least the width of the defect with the central blood supply from the underlying tissue providing the vascularity to the flap **(B)**. The flap is elevated by incising through the skin, subcutaneous tissues, and fascia. The flap is then advanced into the defect and closure occurs first in this area of maximal tension **(C)**. After the flap has been advanced into the defect, the corners of the donor site are closed in a V-Y fashion, which also help push the flap into the defect and transitions the flap into a rounder shape **(D)**. The incision along the flap border opposite the initial defect is then closed by advancing the adjacent skin flap, which is often undermined **(E)**.

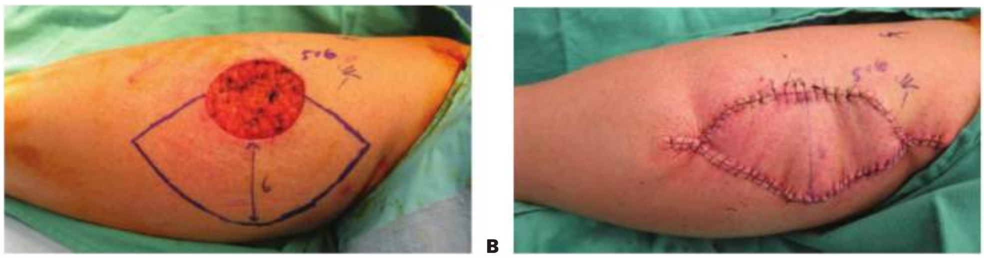
Defect Closure

- The leading edge of flap is advanced into the defect with deep dermal sutures. In situations where this may be initially under significant tension, one can start away from this area and work from peripheral to central, helping push the flap toward the defect (**FIG 12C**).
- The defect tissue margin opposite the flap can also be undermined to provide some advancement. Alternatively, an opposing keystone flap may also be designed along this border to provide additional tissue laxity.
- The lateral ends of flap donor site are then closed in a V-Y fashion to help recruit additional tissue centrally as the flap transitions from a hemi-arc shape to an ellipse (**FIG 12D**).
- Finally, the trailing edge of the flap opposite the defect is sutured back the edge of the donor site. This may require undermining of adjacent skin flaps to ease the overall tension on the closure (**FIGS 12E** and **13B**)



A B

FIG 13 ● In this case, a 6-cm wide flap has been designed to match the 6-cm width of the defect **(A)**. In this case, the flap has been advanced and reconstructed the defect. The corners of the flap donor site have been closed in a V-Y fashion and the flap shape has changed from a "keystone" or semi-arc shape to a more round shape **(B)**.

PEARLS AND PITFALLS

Flap selection	■ Flaps that are not undermined (e.g., keystone flaps) should be considered when margin status is unknown.
Flap design	■ Flaps should be large enough for readvancement if necessary.
Flap elevation	■ Care must be taken with perforator-based flaps to avoid central undermining because the subdermal plexus is transected circumferentially around the flap.
Defect closure	■ Care must be taken to avoid hematomas or infections, which can compromise a flap. ■ Postoperative immobilization should be considered for flaps around movable areas. ■ Excision of residual standing cutaneous deformities should be done judiciously to avoid compromise of flap vascularity and can be done at a later operative date if necessary.

POSTOPERATIVE CARE

- Flaps near joints should be immobilized with splinting to prevent mechanical dehiscence.
- Elevation for flaps on the extremities is critical for postoperative edema control.

COMPLICATIONS

- Marginal flap ischemia
- Delayed wound healing
- Infection (cellulitis or abscess)
- Hematoma
- Poor cosmetic outcome
- Flap failure/loss

OUTCOMES

- Outcome data for cutaneous reconstruction are quite heterogeneous due to the multiple body areas, flap techniques, and individual surgeon preferences.
- In general, the average incidence of a major complication is low but increases with the size of the defect and reconstruction. Minor complications include delayed wound healing, nonoperative infections, and need for secondary revision surgery.[1–3]
- The incidence of total flap failure is low when appropriate reconstructive principles are followed.

Chapter 24 Skin Grafts

David L. Brown

DEFINITION

- A graft, unlike a flap, does not bring an independent blood supply with its tissue to the recipient site. Skin grafts can be defined based on their origin: autograft (same individual), allograft/homograft (another individual of the same species), or xenograft (from another species).
- Skin grafts represent a rung on the proverbial reconstructive ladder above those of primary closure and healing by secondary intention and below local flaps (**FIG 1**).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Skin grafting should only be considered once a viable recipient bed is obtained. This includes debridement of nonviable tissues, elimination of active infection, assurance of good vascularization to the wound bed, lack of significant fluid efflux from the wound (i.e., edema or bleeding), and coverage of vital structures (exposed bone, vessels, tendons, nerves, etc.).
- Indications include inability to perform primary closure or insufficient tissues for local skin flap coverage, uncertainty of tumor clearance, and comorbid conditions.
- Contraindications include active infection (i.e., bacterial counts $>10^5$ CFU/g via quantitative culture), poor vascularity of recipient bed (i.e., history of radiation to the area), and anticipation of further underlying reconstruction (i.e., nerve or tendon grafting).

The Reconstructive Ladder

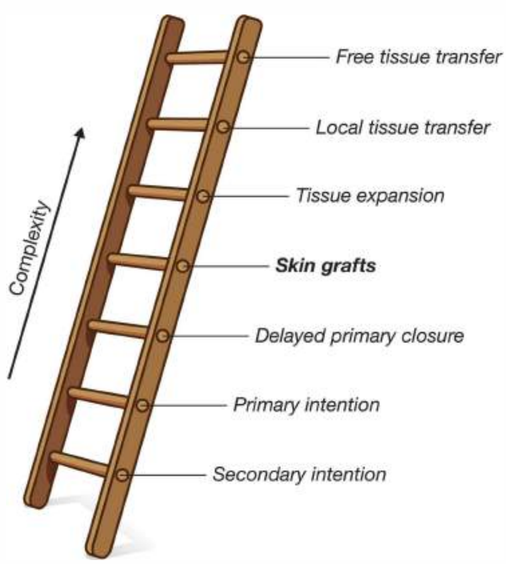

FIG 1 ● The reconstructive ladder. Skin grafts occupy an intermediate position in the heirarchy of complexity of closure technique.

- Relative contraindications: comorbidities that can affect the healing of skin grafts such as diabetes, smoking, and venous insufficiency.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients should be counseled regarding postoperative expectations, wound management, and restrictions so that they can make preparations prior to the operation.
  - Care of the donor site
    - Split-thickness grafts—Xeroform versus OpSite versus other coverings. May shower; more pain with Xeroform; watch for leaks and infection with OpSite
    - Full-thickness grafts—Steri-Strips. May shower; some bruising; minimal pain
  - Care of the graft site—bolster dressing. May shower if bolster is exposed, but do not let water run through the bolster continuous as this will wash out mineral oil (if used on cotton inside) and allow bolster to dry out over graft. Bolsters are usually taken down in 4 to 6 days, unless infection is suspected, then earlier.
- Choice of graft thickness
  - Split-thickness skin grafts (STSGs)
    - 12/1,000 inch is standard, with 6–16/1,000 inch being used for special situations.
    - Thinner grafts: more assured healing at the recipient site; the more dermis is left behind for subsequent harvest as necessary and the less primary contraction and greater secondary contraction.
    - Thicker grafts: more durable, as they carry more dermis with them.
    - "Sheet" (unmeshed) grafts have the advantage of better cosmesis but are encumbered by seroma or hematoma formation underneath, which can lead to local failure of the graft. These grafts should be inspected early at approximately 24 to 48 hours and any underlying fluid removed via aspiration. "Pie crusting" is unaesthetic and is not associated with higher graft survival.
    - Meshing of grafts can be performed with two advantages. One is coverage of greater recipient surface area with less donor graft. The ratios 1:2 or 1:1.5 are more commonly used, whereas 1:4 is typically reserved for extreme cases only. The larger the graft expansion, the more tenuous the coverage, and the more secondary contraction will occur. The second advantage is wound bed drainage and prevention of seroma or hematoma formation resulting in graft failure. A common method is meshing 1:1.5 but applying the graft to the recipient site in an unmeshed fashion.
  - Full-thickness skin grafts (FTSGs)
    - Primary contraction is greater (about 40%), but secondary contraction is less (about 15%), making them a good choice for joints, neck, eyelids, and so forth.

- Donor sites from FTSGs (usually straight-line layered closures) have the benefits of little postoperative pain and minimal scarring compared to STSGs.
- Choice of meshing versus sheet grafts
  - Meshing: allows for egress of wound fluids and lessens the risk of seroma and hematoma. As interstices must heal via secondary contraction and re-epithelialization, meshed grafts will contract more over time and be less durable. More wound area is able to be covered with less donor site.
  - Sheet grafts: prone to hematoma and seroma but are aesthetically more pleasing and exhibit less secondary contraction. Useful on hands and feet, across joints, and on the face and neck.

SPLIT-THICKNESS SKIN GRAFTS

Patient Positioning and Setup

- The patient is positioned either prone or supine, so that the lateral or anterolateral thigh is accessible for graft harvesting.
- The approximate donor site is marked out from several inches below the trochanter to several inches above the knee (smaller if less is needed).
- The donor site is injected with local anesthetic in the subdermal space, using a 22-gauge spinal needle. A mixture of 0.5% lidocaine with 1:200,000 concentration of epinephrine and 0.25% bupivacaine works nicely for providing both hemostasis and postoperative pain relief.
- Mineral oil is spread over the area to allow for smooth gliding of the dermatome over the skin (**FIG 2**).

Preparing the Dermatome

- The dermatome is assembled, and the appropriate width guard is attached (**FIG 3A**). A 3-in guard is appropriate for most applications and fits the contour of the thigh well in most adult patients.
- Proper seating of the blade in the machine and underneath the guard is assured; uneven seating can cause an excessively thin graft at one edge and overly thick at the other.
- The desired thickness of skin harvest is selected via the dial on the side (12/1,000 inch is shown here) (**FIG 3B**).

Harvesting the graft

- Either the surgeon (using his nondominant hand) or an assistant hold manual countertension on the skin (**FIG 4A**).
- The dermatome is pressed against the skin at a 45-degree angle and, with moderate down force, is slowly advanced the length of graft harvest (**FIG 4B,C**).

FIG 2 ● Prone patient, with the lateral thigh showing from buttock crease (left) to knee (right). Note blanching of skin from epinephrine injection and glossiness of mineral oil application.

A B

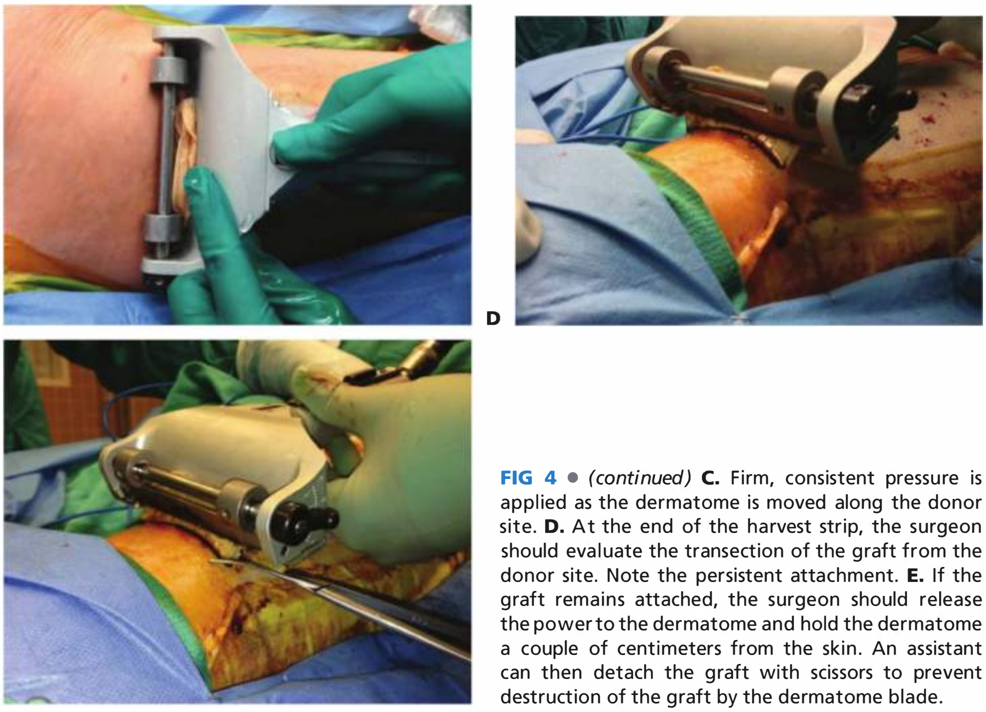
FIG 3 ● **A.** Underside of dermatome, with blade and 3-in guard attached. Blade and guard are flush against machine, as assembled. **B.** Dermatome set to 12/1,000 inch thickness.

- To complete the harvest and separate the end of the graft from the patient, the surgeon lowers the handle of the dermatome toward the patient (decreasing the angle of attack) and slowly lifts off the skin surface (**FIG 4D**).

A

B

FIG 4 ● Assistant holding countertraction on skin with the use of laparotomy sponge. **B.** Dermatome is placed on skin, running at a 45-degree angle. *(continued)*



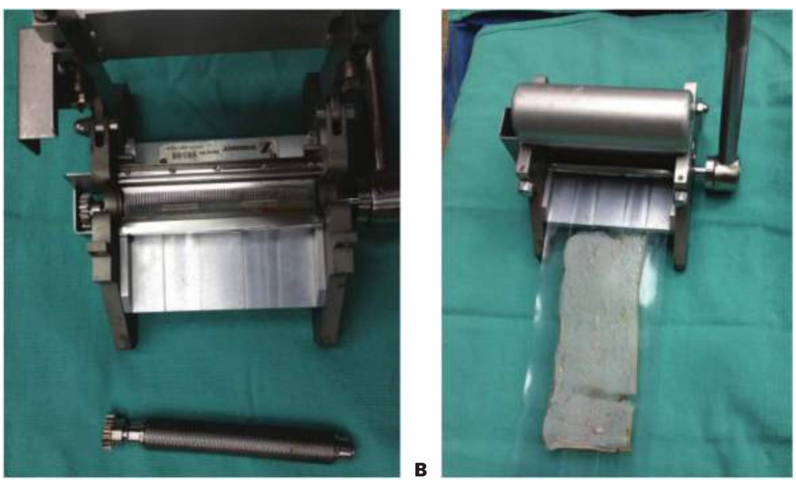
C D E

FIG 4 ● *(continued)* **C.** Firm, consistent pressure is applied as the dermatome is moved along the donor site. **D.** At the end of the harvest strip, the surgeon should evaluate the transection of the graft from the donor site. Note the persistent attachment. **E.** If the graft remains attached, the surgeon should release the power to the dermatome and hold the dermatome a couple of centimeters from the skin. An assistant can then detach the graft with scissors to prevent destruction of the graft by the dermatome blade.

- Power is released on the dermatome when it rises 1 cm above the skin, in case the graft remains attached.
- If the graft is not immediately separated from the donor site at the end of the run with the dermatome, the surgeon should release power to the dermatome and hold it a couple of centimeters over the skin until an assistant can cut it free with a Metzenbaum scissor. Otherwise, the graft is pulled back out through the blade entrance and can result in mangling of the graft (**FIG 4E**).

Meshing the Skin Graft

- For meshed grafts, the mesher is assembled, and an appropriate cutting wheel is chosen. 1:1.5 (shown here, **FIG 5A**) is a standard ratio but can be varied up to 1:4 depending on the amount of donor sites available compared to the area needing coverage as well as the specific application.
- The graft is placed superficial side down on the carrier and run through the mesher (**FIG 5B,C**).



A B

FIG 5 ● **A.** View of an opened mesher with space to place the chosen cutting wheel (in this case 1:1.5 ratio). **B.** Graft placed dermal side up on the carrier, which is positioned within the mesher entrance. *(continued)*

C

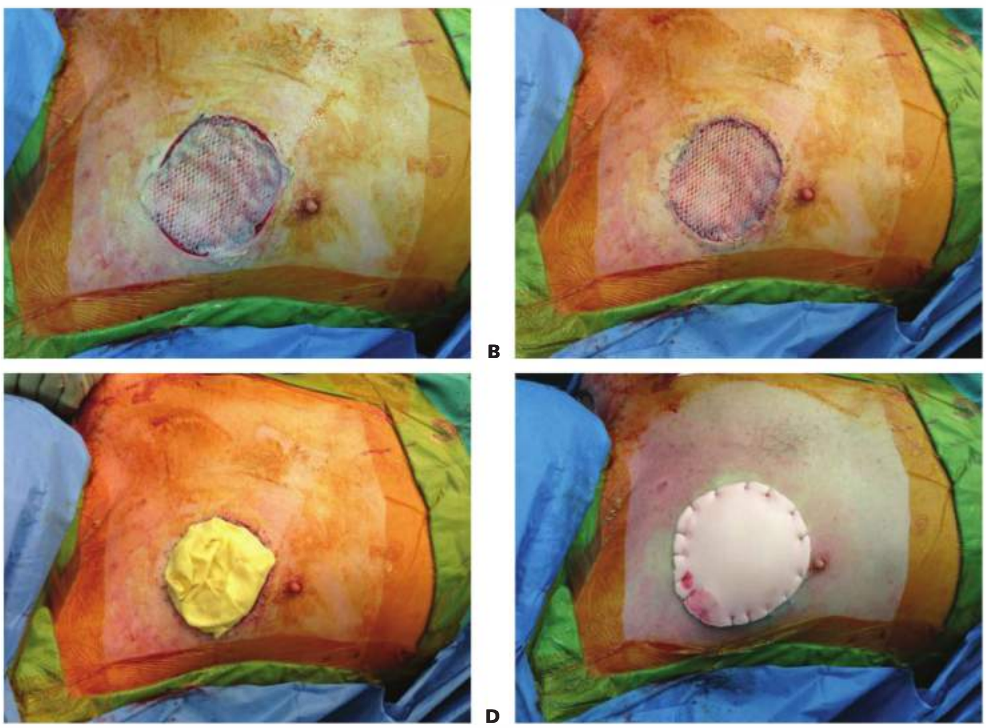
FIG 5 ● *(continued)* **C.** Graft, postmeshing.

Insertion of the Graft into the Wound Site

- The graft is placed in the wound bed, trimmed appropriately, and secured to the wound edges with surgical clips or sutures (4-0 chromic work well) (**FIG 6A,B**).
- A nonstick dressing is applied. A bolster consisting of mineral oil– and saline-soaked cotton balls or batting will provide pressure on and moisture to the graft (**FIG 6C**). Trunk wounds can be covered with Allevyn (Smith and Nephew) foam, whereas tie-over's with interrupted silk are suitable for the face and hand, or wrapping with gauze and an elastic bandage for the extremities (**FIG 6D**).

Other Considerations

- Excess ("left over") skin graft can be preserved in tissue culture media at 4°C for application to the wound should original graft loss occur. Graft survival diminishes with storage time and is generally considered to be poor after 10 to 14 days.
- Some clinical situations call for delayed graft placement (24 to 48 hours postoperatively) due to wound fluid seepage. In cases such as coverage of muscle and omental flaps, or recently debrided wounds over edematous tissues, graft application can be performed at the bedside. This saves a return trip to the operating room (OR) for the patient.



A B C D

FIG 6 ● **A.** Patient with right superior chest wound. Meshed graft placed within wound, dermal side down, and minimally expanded. **B.** The graft is trimmed appropriately and secured with stainless steel clips. **C.** Mineral oil– and saline-soaked cotton batting, wrapped in Xeroform, is shaped to the size of the wound. **D.** A foam bolster is used to secure the dressing over the graft.

PEARLS AND PITFALLS

Harvesting the graft	▪ Proper seating of the blade in the machine underneath the guard should be assured; uneven seating can cause an excessively thin graft at one edge and an overly thick one at the other. ▪ If the graft is not immediately separated from the donor site at the end of the run with the dermatome, the surgeon should release power to the dermatome and hold it over the skin for an assistant to cut it free with a Metzenbaum scissor. Otherwise, the graft can be pulled back out through the blade entrance, mangling the graft. ▪ Rinsing the graft washes away vital procoagulant factors and should be avoided, if possible.
Placing the graft in the wound bed	▪ To assure consistent application of the graft to the wound bed dermis-side down and to transfer it without bunching, it should be placed on the carrier dermis side up. ▪ If the graft is not immediately needed for wound coverage, it can be stored on the back table (appropriately marked to avoid disposal), wrapped in moistened gauze, or left on the carrier and covered with the same. ▪ Care should be taken to avoid "tenting" a graft over an uneven wound bed. Extra graft should be placed to allow for complete contour touchdown. ▪ Placement of a meshed graft does not need to involve full expansion of the graft; leaving it relatively unexpanded will allow for egress of wound fluids while speeding healing. ▪ "Pie-crusting" of sheet (unmeshed) grafts is thought to be superfluous, as it will likely not prevent a hematoma or seroma from forming between slits and is aesthetically unappealing.
Donor site	▪ Some surgeons apply epinephrine-soaked sponges to the fresh donor site to limit bleeding. This is obviated with the use of local anesthetic.

POSTOPERATIVE CARE

Patient Expectations

- Patients should be told that the donor site is likely to cause more pain than the wound site postoperatively.
- Healing stages of the graft and donor site are discussed to educate the patient.
- Over large areas of grafting and/or uneven surfaces, some graft loss is to be expected.

Wound Management

- Dressings
  - Bolsters should be left in place, barring complications such as fever and so forth, for 5 to 8 days.
  - Patients may shower and get the bolsters wet with incidental water contact. Soaking or significant water rinsing of the bolster is discouraged, as this washes out the mineral oil and allows the bolster to dry out.
  - Following bolster removal, the graft is protected with once-daily dressing changes with petrolatum gauze until it is more fully healed (usually another 7 to 10 days). After this point, the patient should moisturize the graft (and donor site) twice daily for a few months to prevent desiccation, as oil and sweat glands are not transferred with the graft.
- Donor site care
  - Typically, split-thickness donor sites are covered with petrolatum gauze, which is loosely attached to the skin with surgical clips around the perimeter. An ABD pad and a gauze wrap are applied in the OR.
    - On postoperative day 1, the wrap and ABD are removed, and the attached gauze is left open to the air. It can get wet in the shower, but afterward, and several times per day, is dried with the use of a hair dryer set on cool air only.
    - Rewrapping with gauze is performed for the patient to get dressed. The attached petrolatum gauze will form an artificial "scab" on the wound, and re-epithelialization will cause the gauze to become nonadherent at its edges over the next 10 days or so. Trimming of the gauze so that it does not catch and get pulled off is recommended.
  - Other dressings are used for donor site care, each for a specific quality. Silver-impregnated dressings help to prevent infection. Occlusive dressings are significantly less painful but are plagued by infection.

Restrictions

- Judgment is exercised to determine the degree of immobilization prescribed, depending on graft location. It is not necessary to splint the foot for grafts on the lower leg, but patients should keep the extremity elevated to prevent swelling and edema and thus graft loss.

COMPLICATIONS

- Seroma and hematoma are the most common complications. If left untreated, they will lead to graft loss due to lack of contact with the wound surface.
- Infection can destroy a graft, particularly in the early postoperative period, prior to revascularization. In the case of unexplained postoperative fevers, the dressings should be removed early and the wound inspected for infection, which can be potentially treated, with graft salvage.
- Secondary contraction of skin grafts is increased with thinner grafts and with greater expansion of meshed grafts. This can affect underlying joint mobility and aesthetics.
- Incompletely debrided or poorly vascularized wound beds can lead to nonadherence and ultimate loss of the graft.

Chapter 25 Digit Amputations

Steven C. Haase

DEFINITION

- Digital amputation refers to the removal of a finger or thumb, most commonly at the level of the phalanges or interphalangeal joints (**FIG 1**). More proximal amputations that include a significant portion of the metacarpal are referred to as ray amputations. The techniques found in this chapter have been described chiefly for the hand, although similar procedures can be used on the foot in many cases.
- Digital or ray amputation may be indicated for subungual melanoma, or for other large, invasive melanomas of the finger or thumb.

PATIENT HISTORY AND PHYSICAL FINDINGS

- It is important to assess how long the lesion has been present; how fast it has grown; and whether there has been any history of ulceration, bleeding, or pain. Lesions exhibiting rapid growth in addition to these other findings may require more aggressive treatment.
- A patient's age, handedness, occupation, and hobbies should be considered carefully in planning an operation that might significantly affect their function. In some cases, preoperative consultation with a physiatrist and/or occupational therapist may help a patient mentally prepare for what is a sometimes emotionally difficult operation.
- Physical examination should include both the epitrochlear and axillary lymph nodes. For lesions on the toes, examination should include the popliteal and inguinal basins.

Clinically node-negative patients with melanoma greater than or equal to 1 mm in thickness, or thin lesions with other worrisome histologic features, may be candidates for sentinel lymph node biopsy at the time of amputation. (see Part 5, Chapter 27). Patients with clinically involved nodes should undergo fine needle aspiration (FNA) biopsy and staging for distant metastases. These patients may require lymph node dissection at the time of amputation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Suspicious lesions require biopsy to establish diagnosis. This should include a full-thickness sampling of the skin and/or nail matrix for accurate assessment of depth of the lesion. Increased depth of invasion is consistently associated with worse prognosis.[1]
- For large or fixed lesions, radiographs of the digit should be obtained to assess for the presence of bone involvement. If radiographs demonstrate significant bone destruction, additional imaging with magnetic resonance imaging (MRI) may be required to assess the full extent of tumor spread in the hand.

SURGICAL MANAGEMENT

Positioning

- For hand operations, patients are positioned supine, with the affected extremity extended on a hand table attached to the operating room table.

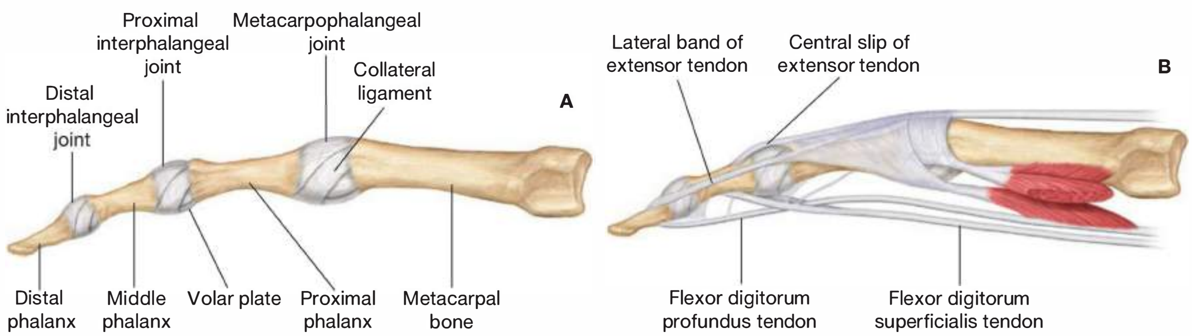


FIG 1 ● **A,B.** Anatomy of the digit.

TECHNIQUES

DIGITAL AMPUTATION

Skin Incision

- The skin incision should be designed as a "fish mouth," such that dorsal and volar flaps are created that close in a more or less transverse line of closure that gives a smooth, rounded contour to the amputation stump.
- The skin flaps should be designed with enough laxity to close over the underlying skeleton to be preserved. Typically, the level of disarticulation or osteotomy should be a few millimeters proximal to the level of the skin incision.
- Ideally, the volar flap can be designed a bit longer than the dorsal flap (**FIG 2A**) to allow resurfacing of the entire

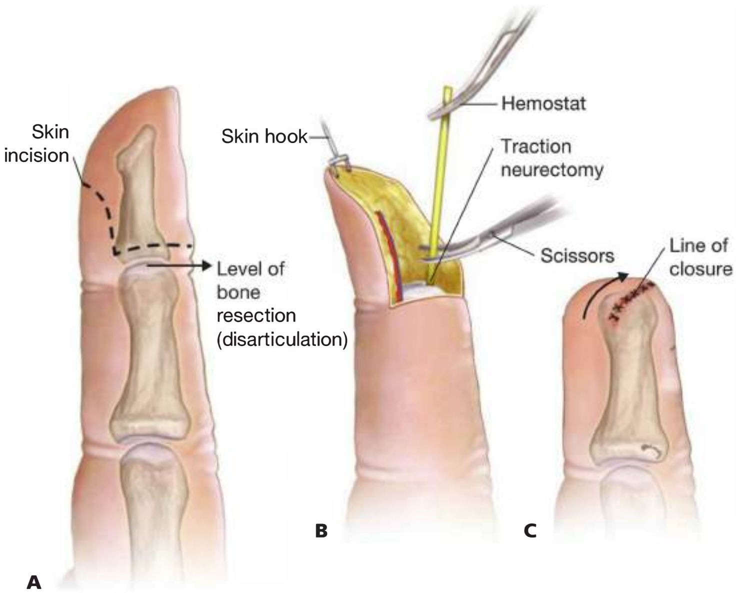

FIG 2 ● Digital amputation technique. **A.** The skin incision is designed just distal to the level of planned bone resection or disarticulation. The volar flap is designed longer than the dorsal flap to allow for coverage of the fingertip with more durable, well-innervated volar skin. **B.** After removal of the skeletal elements and nail complex, the neurovascular bundle is identified on the volar flap, and the nerve is gently dissected proximally, ultimately dividing the nerve while on traction, and allowing the stump to retract proximally. **C.** The volar skin is advanced to cover the wound, and a smooth, rounded closure is performed.

opposition surface (contact surface) of the fingertip with the thicker, more densely innervated palmar skin.

Soft Tissue Dissection

- The soft tissue should be divided in a way that minimizes devascularization of the tissues or skin flaps. Sharp scalpel dissection directly to the bone can be performed both dorsally and volarly, dividing the neurovascular bundles, tendons, and periosteum.

Bone Dissection and Osteotomy

- The periosteum should then be sharply elevated proximally using an elevator or scalpel, circumferentially around the digit. This will allow the bone cut to be positioned slightly proximal to the soft tissue dissection.
- Bone division is most efficiently accomplished with a small oscillating power saw. Instruments such as bone cutters or rongeurs tend to crush and fracture the proximal bone stock and are not recommended.
- If disarticulation is planned, the collateral ligaments should be detached from the proximal aspect of the joint, so this bulky, poorly vascularized tissue is discarded with the amputated part.

Traction Neurectomy

- The neurovascular bundle should be identified with delicate dissection. The artery may be cauterized; the nerve should be dissected away from the artery and followed proximally several millimeters. The nerve should be placed on traction, divided proximally, and allowed to retract (**FIG 2B**). This will ensure that the neuromas that inevitably form at the end of each digital nerve will be located proximally to the contact surface of the fingertip.

Closure

- Closure is usually performed with a single layer of nonabsorbable sutures (**FIG 2C**), which are removed about 2 weeks later. Do *not* suture the extensor tendon to the flexor tendon over the end of the exposed bone; this will functionally shorten the flexor tendon to that digit, resulting in weakened grip strength due to the quadrigia effect.

RAY AMPUTATION

Skin Incision

- Incisions are designed to avoid a scar in the webspace. Conceptually, the goal is to preserve one webspace and resect the other, rather than having a webspace at the operative site with a contracted scar in its midline (**FIG 3A–E**).
- Usually the dissection is performed mostly through a dorsal incision, which extends longitudinally from the base of the finger. Palmar incisions are limited to avoid the possibility of sensitive scarring in that location.

Dorsal Dissection

- Major sensory nerves in the subcutaneous tissue are preserved when possible. The extensor tendon is divided proximally and the metacarpal exposed.
- The periosteum of the metacarpal is incised longitudinally and subperiosteal dissection carried out circumferentially along the shaft of the bone. The attachments of

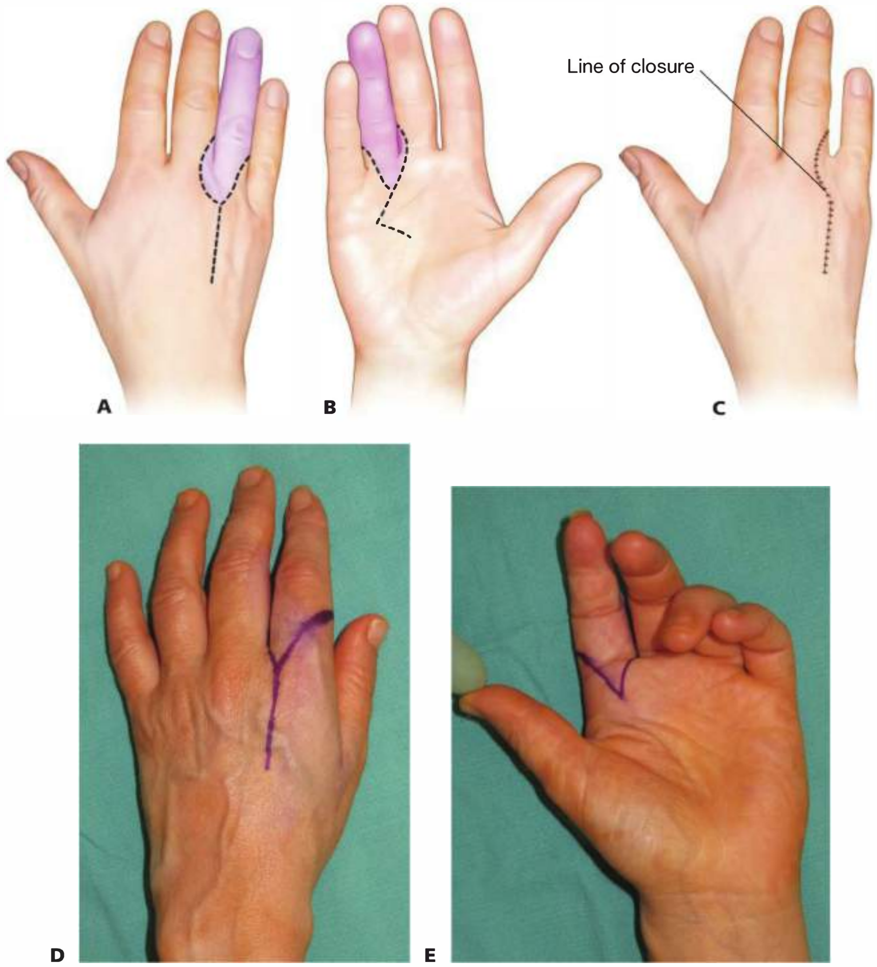

FIG 3 ● Skin incision for ray amputation. **A.** Dorsal incision can be designed proximally as a straight line, or as a zigzag, extending distally to encircle the base of the finger to be removed. Note the preservation of an intact webspace for closure, rather than dividing the web with the incision. **B.** Volar incision must be a zigzag or chevron-style incision to avoid longitudinal scars crossing the flexion creases of the palm. **C.** Closure is shown, with preservation of the delicate webspace skin. **D.** Dorsal and **(E)** volar skin markings for index finger ray amputation.

the intrinsic muscles are disrupted with this dissection; most of these do not require transfer or repair, with the exception of the origin of adductor pollicis (FIG 4). When removed from the middle metacarpal during ray amputation, this muscle origin should be reattached to the index metacarpal with bone anchors or transosseous sutures.

Bone Dissection

- For index, middle, and small finger ray amputations, the osteotomy should be performed distal to the insertion of the wrist extensors: extensor carpi radialis longus, extensor carpi radialis brevis, and extensor carpi ulnaris, respectively (refer to FIG 5).
- For the ring finger metacarpal, which has no extrinsic tendon attachments, the entire metacarpal can be disarticulated at the base and removed (if no transposition is planned).
- For middle or ring finger ray amputations, some effort should be made in eliminating the troublesome gap between digits that can result.[2,3] This can be accomplished by two principle methods:
  - Meticulous soft tissue repair, including permanent sutures in the intermetacarpal ligaments and careful postoperative splinting (FIG 6)

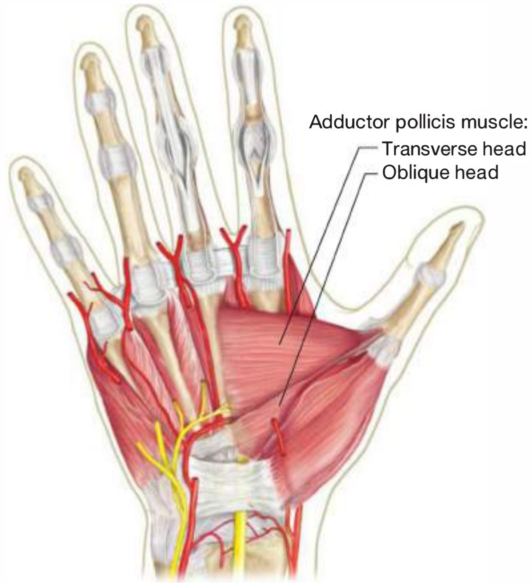

FIG 4 ● Anatomy of the adductor pollicis.

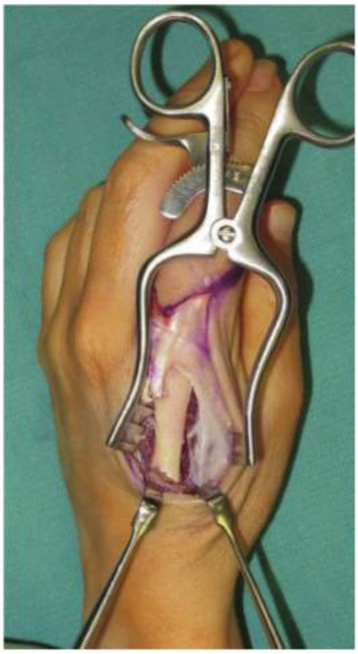

FIG 5 ● Dorsal dissection completed, with division of the metacarpal at the proximal shaft, preserving the base with its tendon attachments.

- Transposition of the adjacent border digit, requiring bony fixation of the metacarpal, and often longer postoperative immobilization (**FIG 7**)
- Once the bone has been transected, dissection proceeds around the side(s) of the metacarpal head to divide the intermetacarpal ligaments.

Volar Dissection

- The volar dissection is usually done last. The digital neurovascular bundles are identified and transected distally, keeping them rather long, in contrast to the shortening that is done for phalangeal-level amputations (**FIG 8A,B**).
- Once the ray amputation is complete, the digital nerves are folded dorsally into the periosteal sleeve left behind after metacarpal removal (**FIG 9**). The nerves are secured in this deep, padded area, surrounded by healthy interosseous muscle, where they are protected from trauma during routine hand function.

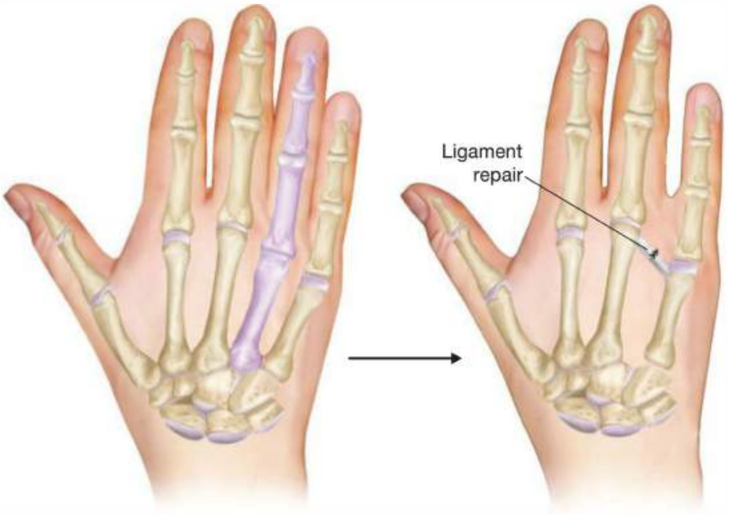

FIG 6 ● Ray resection without transposition. Using permanent sutures to reapproximate the intermetacarpal ligament, as well as meticulous skin closure, the finger "gap" can be closed with soft tissue repair alone.

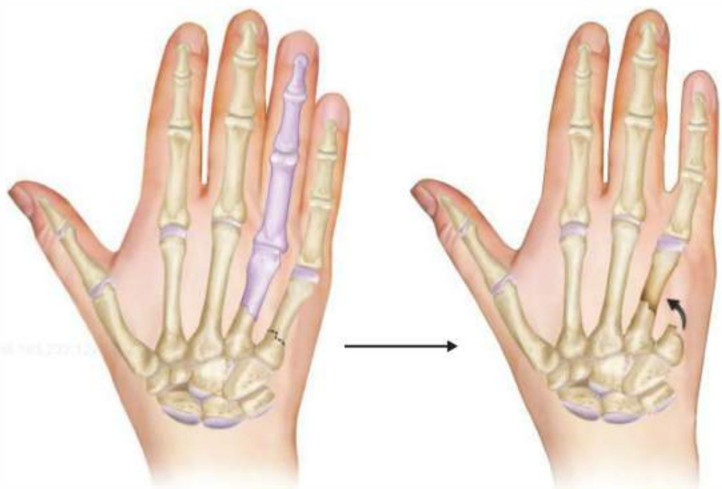

FIG 7 ● Ray resection with transposition. Transposition requires osteosynthesis of the involved metacarpals with wires, pins, or plate and screws. One advantage is the potential to minimize length discrepancy of the small finger by preserving added length at the base of the ring metacarpal, as illustrated here.

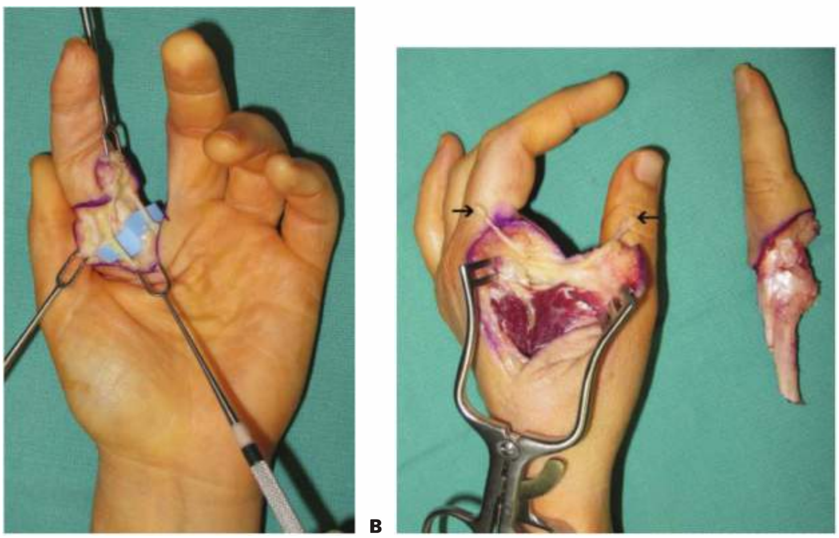


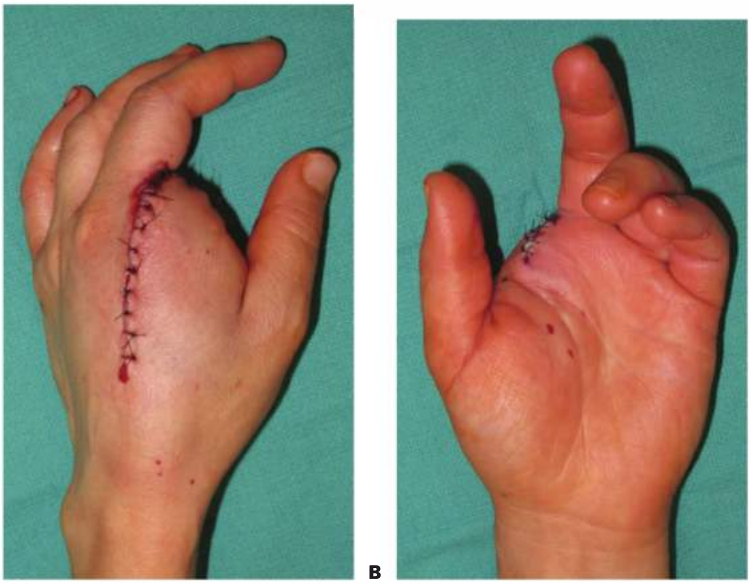
A B

FIG 8 ● **A.** Volar dissection with identification of the digital nerves, which are preserved with some length, so they can be relocated in the deeper dorsal tissues at the time of closure. **B.** Ray resection completed, with digital nerves transected *(black arrows)*.

FIG 9 ● Digital nerves *(white arrow)* transposed deep into the periosteal sleeve between the interosseous muscles.

Closure

- Skin closure should be meticulous, addressing excess laxity and/or standing cutaneous deformities ("dog ears") if encountered (**FIG 10A,B**). The relative tightness or looseness of the dorsal skin closure, in particular, can help maintain proper orientation of the adjacent digits and help avoid malalignment or "scissoring."



A B

FIG 10 ● **A,B.** Final wound closure, which avoids extensive incisions on the sensitive palmar skin.

PEARLS AND PITFALLS

Digital amputations	■ When required, retract the skin edges with skin hooks only. This avoids tissue damage that can occur from repeated grasping of the tissues with forceps.
Quadrigia effect	■ Because the flexor digitorum profundus tendons share a common muscular origin, effectively shortening any one of the tendons can lead to an overall decrease in grip strength. During force generation, the foreshortened tendon becomes tight early, preventing transmission of force to the adjacent digits.
Neuroma detection	■ It can be difficult to differentiate symptomatic neuroma from ordinary hypersensitivity after finger amputation. A diagnostic injection of local anesthetic into the specific area of the neuroma, to anesthetize the nerve in isolation, can confirm the diagnosis of neuroma.

POSTOPERATIVE CARE

- For digital amputations, the postoperative dressing should be amply padded to allow for postoperative swelling. A hand-based splint for a short time (1 or 2 weeks) can be used if desired. Prolonged immobilization should be avoided so that the remaining finger joints (including the adjacent digits) do not become stiff.
- For ray amputations, the hand should be splinted for the first 2 weeks, taking care to maintain proper alignment of the digits in the splint, to avoid divergence or convergence of the fingers on either side of the amputation site. Sometimes, temporary pinning of the fingers is warranted to maintain good alignment in this early postoperative period, as the soft tissues are healing. Splinting beyond 2 weeks may still be required for comfort and protection, but the orthosis use should not interfere with early mobilization of the interphalangeal and metacarpophalangeal joints, which may become permanently stiff if immobilized for too long.
- In all cases, consultation with a certified hand therapist may be of benefit to the patient, for help with orthosis fabrication, edema control, joint mobilization, scar massage, desensitization, and molding of the finger stump for prosthesis wear, if desired.

OUTCOMES

- Compared to the contralateral hand, patients with single-ray amputations have on average 13% less key pinch strength, 26% less oppositional strength, and 28% less grip strength at long-term follow-up.[4,5]

COMPLICATIONS

- Acute complications such as bleeding, infection, and delayed healing should be uncommon.
- Chronic complications include phantom pain and painful neuromas.
  - Persistent sensation in an amputated part is common (over 80% in one prospective study) but is not always painful.[6]
  - Neuromas will form at the stump of divided nerves but are not usually symptomatic if the nerve endings are properly padded and located away from contact surfaces.

Chapter 26

Resection of Head and Neck Melanoma

Scott A. McLean

DEFINITION

- Resection of head and neck cutaneous melanoma is performed with wide surgical margins intended to achieve histologically negative margins. Current guidelines for wide excision of the primary lesion, with an adequate margin of surrounding normal skin and deep soft tissue necessary to achieve clear surgical margins, are based on depth of invasion of the primary lesion (Table 1).[1] However, given the complex anatomic and functional nature of the head and neck, resection margins are sometimes modified to preserve normal function. Reconstruction of complex head and neck defects is often delayed until final histopathologic evaluation of margins is deemed negative. Reconstruction can be accomplished with primary closure, split- or full-thickness skin grafts, local or regional adjacent tissue transfer, or free tissue transfer.
- Patients with invasive melanoma and no clinical evidence or regional metastatic disease may warrant assessment of regional lymph nodes via sentinel lymph node (SLN) biopsy. SLN biopsy has been shown to be both accurate and prognostic in head and neck melanoma.[2,3] Current recommendations on use of SLN biopsy are based on depth of invasion of the primary lesion as well as the presence of adverse histologic features such as ulceration and mitotic rate. Patients with melanoma measuring 1 mm or greater should be offered SLN biopsy. SLN biopsy should also be considered in patients with a thickness of between 0.76 and 0.99 mm if they have any of the following adverse features: greater than or equal to 1 mitotic figure per square millimeter, lymphovascular invasion, satellitosis, or young patient age. SLN biopsy may also be considered with thin melanoma when the deep margin was broadly transected.[1–5]
- Patients who present with clinical evidence of regional metastatic disease and patients who are found to have micrometastatic disease on sentinel lymph node biopsy (SLNB) are offered completion lymph node dissection (CLND). Based on the site of the primary lesion, the nodal basins included in the CLND may include the postauricular and suboccipital lymph nodes, the parotid gland and its associated lymph nodes, and the cervical lymph nodes levels I to V (Table 2) (see Part 5, Chapter 31).[6]

Table 1: Surgical Margin Recommendations for Cutaneous Melanoma

Primary Tumor Thickness	Clinically Measured Surgical Margin
In situ	0.5–1.0 cm
≤1 mm	1 cm
1.01–2.0 mm	1–2 cm
2.01–4 mm	2 cm
>4 mm	2 cm

From National Comprehensive Cancer Network. Guidelines version 4.2014. http://www.nccn.org. Accessed August 2014.

Table 2: Nodal Basins Included in Therapeutic Lymph Node Dissection

Primary Cutaneous Lesion Location	Nodal Basins Included in Therapeutic Lymph Node Dissection
Anterolateral scalp, temple, lateral forehead, lateral cheek, and ear: all arising anterior to coronal plane through the external auditory canal	Parotid and cervical lymphatic levels I–V
Chin and neck	Cervical lymphatic levels I–V
Scalp and occiput posterior to coronal plane through the external auditory canal	Postauricular, suboccipital, and cervical lymphatic levels II–V

DIFFERENTIAL DIAGNOSIS

- Cutaneous melanoma of the head and neck usually presents as a pigmented lesion of varying size, shape, and color. Other benign and malignant cutaneous lesions can present in a similar fashion and include the following:
  - Seborrheic keratosis
  - Junctional nevi
  - Compound nevi
  - Dermal nevi
  - Hemangioma
  - Blue nevus
  - Pyogenic granuloma
  - Spitz nevus
  - Pigmented actinic keratosis
  - Pigmented or nonpigmented basal cell carcinoma
  - Squamous cell carcinoma

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history of the lesion of concern should include the duration of clinical symptoms; the presence of pruritus; bleeding; and any changes in the size, shape, or color of the lesion.
- Most cutaneous melanomas will present as either a new pigmented lesion or changes in an existing lesion that exhibit the ABCDs of melanoma: A–Asymmetry, B–Border, C–Color, D–Difference (a change in the lesion).
- A thorough past medical history should be performed and include information regarding any previous malignancies, past surgical procedures, current medications and allergies, family history of cancer, problems with anesthesia, and social history—including smoking history, occupation, sun exposure, and history of blistering sunburns.

- A focused review of systems should also be completed and include review of any constitutional, musculoskeletal, neurologic, respiratory, gastrointestinal, hepatic, skin, and lymphatic signs or symptoms.
- All newly diagnosed melanoma patients should undergo full body skin evaluation.
- A complete head and neck exam should be performed on every patient and include a thorough skin exam and palpation of the suboccipital, postauricular, parotid, and cervical nodal basins to rule out the presence of clinically palpable regional metastatic disease.
- A detailed cranial nerve exam should be performed to document preoperative cranial nerve function.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Newly diagnosed patients with localized cutaneous melanoma are not recommended to undergo distant metastatic workup. In the absence of clinical signs or symptoms of distant metastatic disease, no imaging modality has been shown to be useful in detecting occult metastatic disease and in fact more often lead to false-positive findings, requiring further unnecessary invasive procedures.[1]
- Chest x-ray and serum lactate dehydrogenase are also both insensitive for the detection of occult metastatic disease.
- Many patients will require preoperative chest x-ray, complete blood count (CBC), and electrocardiogram (EKG), depending on age, health status, and need for general anesthesia.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to proceeding to the operating room, the primary cutaneous lesion should be reexamined and confirmed with the patient. The surrounding skin should also be reexamined to make sure no new lesions have developed. In addition, the plan regarding surgical margins and primary closure versus delayed reconstruction should be confirmed with the patient. All cranial nerve functions in the operative field should also be retested prior to surgery.
- Patients who are scheduled for SLN biopsy in conjunction with excision of their primary cutaneous lesion will undergo lymphoscintigraphy prior to their definitive excision. This procedure is done in the nuclear medicine department and is enhanced by the use of single-photon emission computed tomography–computed tomography (SPECT-CT) imaging.[7] Prior to proceeding to the operating room, the SPECT-CT/lymphoscintigraphy should be reviewed to determine the likely location of the SLN(s) (**FIGS 1** and **2**). These locations should then be discussed with the patient and marked appropriately. If the location of a likely SLN is in close proximity to a cranial nerve, this should be discussed with the patient and the cranial nerve function should be well documented.
- Appropriate use of antibiotics and deep vein thrombosis (DVT) prophylaxis should also be discussed prior to proceeding to the operating room.
- In addition, it is crucial to have a thorough discussion with the anesthesia team regarding the use of long-acting paralytics. If cranial nerves are likely to be in the operative field, as is almost always the case in the resection of head and neck melanoma, the anesthesia team must be aware to avoid the use of long-acting paralytics.

Positioning

- Patients who are scheduled for wide local excision alone (melanoma in situ or T1a lesions) often can tolerate surgery under sedation with monitored anesthesia. In these cases, the head of the bed is often rotated 90 degrees away from the anesthesia cart to allow for easy access to the surgical field. Oxygen delivery methods can be designed to avoid

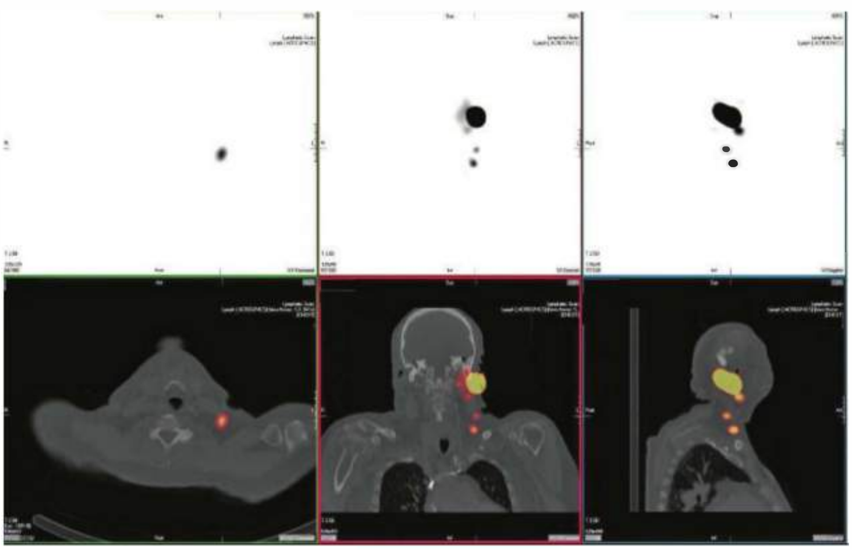

FIG 1 • Lymphoscintigraphy with SPECT-CT imaging after injection of left postauricular primary melanoma site. Imaging reveals a left level II lymph node as well as secondary drainage to left levels Va and Vb.

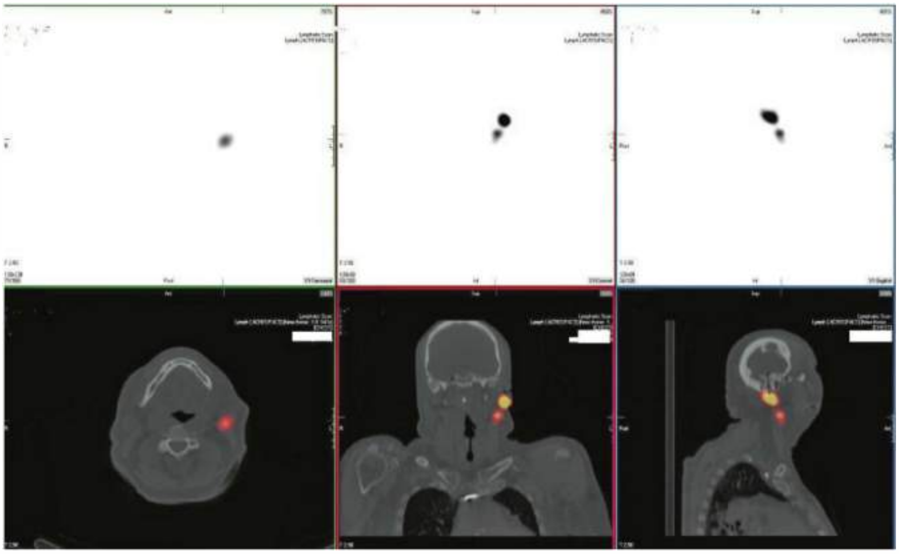

FIG 2 ● Lymphoscintigraphy with SPECT-CT imaging after injection of left postauricular primary melanoma site. Careful observation reveals the level II lymph node to be located just inferior to the tail of the parotid and just anterior to the sternocleidomastoid muscle. Likely, this represents an external jugular lymph node.

crossing the surgical field and may include either nasal cannula or mask. In these cases with free-flowing oxygen, it is very important to discuss the risk of fire with the entire operating room team. The entire face and neck can be prepped into the operative field. Wide draping can then be used with attention to avoid any tenting of drapes, which could lead to pooling of oxygen in the operative field (**FIG 3**).

- Patients who are scheduled to undergo SLN biopsy in conjunction with the primary excision are almost always placed under general anesthesia. Again, the use of long-acting paralytics must be avoided. The head of the bed can be rotated 180 degrees away from the anesthesia cart to allow for easy surgical access to the operative field. Most primary lesions can be excised with the patient in the supine position. Rarely, the patient may need to be turned prone to allow access to the posterior scalp or suboccipital nodal basin. With the patient intubated, either half of the face and neck or the entire face and neck can be prepped and draped, depending on the need for surgical access.

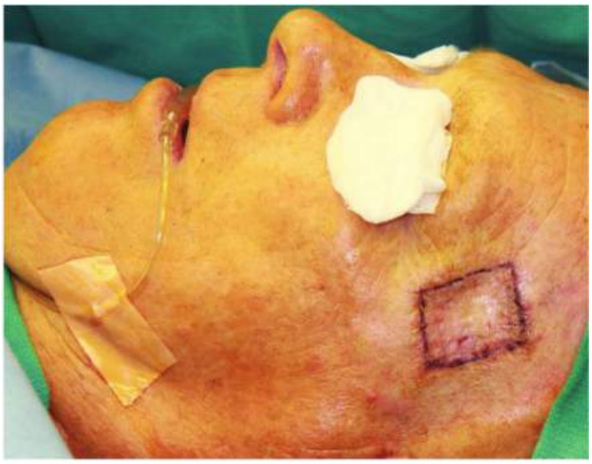

FIG 3 ● Patient is under sedation with the entire face prepped to allow for wide draping and to avoid pooling of oxygen within the surgical field.

PLACEMENT OF PLANNED INCISIONS

Primary Lesion Excision Site

- The primary lesion is carefully inspected and cleaned with a moist sponge. The lesion should be marked out with careful attention to include any evidence of dermal extension. This may include any pale, erythematous, or lightly pigmented extension from the primary lesion (**FIG 4**).
- With the primary lesion now marked, the appropriate margin is then marked circumferentially around the visible lesion. The excision margin is most often 1 to 2 cm, depending on the depth of invasion of the primary lesion.
- In certain functional situations, the excision margin may be left a little short of standard margins. For example, if a lower eyelid lesion requires 2-cm margins, but at 1 cm the excision would cross the lid margin, it may be acceptable to use 1 cm (**FIG 5**). In this case, the surgeon must be willing to reexcise this margin should it return positive on final histopathologic review.

Injection of Methylene Blue Dye

- To assist with SLN identification, the dermis surrounding the primary lesion is injected with methylene blue dye. Usually only 1 or 2 mL of dye is injected (**FIG 6**).

FIG 4 ● The main lesion is pink and raised. Notice the pigmented extension into the surrounding skin. The entire pigmented area must be marked out prior to marking out circumferential margins.

- The injection is made with a 30-gauge needle with the bevel of the needle facing up. There should be slight pressure as the dye is injected and visually the dermis should begin to turn blue. If the dermis is not turning blue or the injection is passing with no resistance, the needle is likely too deep. This will cause the subcutaneous tissue to turn blue and can make recognition of tissue planes more difficult.
- Several injections should be made into the dermis surrounding the primary lesion until the lesion is surrounded by blue dye (**FIG 7**).

FIG 5 ● In this planned resection, the lower eyelid margin is left a little narrow in the hopes of avoiding postoperative ectropion. The margins must be carefully examined by pathology and reexcised should they return positive.

FIG 6 ● Methylene blue dye injected circumferentially into the dermis surrounding the lesion. A 30-gauge needle is used and effort is made to inject directly into the dermis only.

Placement of Incisions for Sentinel Lymph Node Biopsy

- The preoperative lymphoscintigraphy/SPECT-CT is again reviewed to help determine the approximate location of the SLNs in relation to visible or palpable anatomic structures. The intraoperative gamma probe can then be used to confirm the site of the sentinel nodes. Once the location is confirmed, incisions are marked to allow access to remove the sentinel nodes (**FIG 8**).
- Marking the planned incisions should take into account placement along relaxed skin tension lines. In addition, consideration should be given to any future potential procedures such as rotation flap reconstruction sites or the need for parotidectomy and cervical lymphadenectomy (**FIG 9**).
- At this point, all planned incisions are usually injected with local anesthesia. Typically 1% lidocaine with 1:100,000 epinephrine solution is used. A small volume should be used to help avoid inadvertent paralysis of cranial nerves close to the operative sites.

FIG 7 ● Methylene blue dye injected into the dermis circumferentially around the lesion.

FIG 8 ● The intraoperative gamma probe is used to confirm the sites of the potential SLNs.

FIG 9 ● Small incisions are planned along relaxed skin tension lines.

EXCISION OF THE PRIMARY LESION

Skin Incision

- The skin surrounding the primary lesion is now sharply incised, being careful to follow the exact marking. The incision is carried thru the subcutaneous tissue, now being careful to avoid beveling the cut toward the primary lesion.

Determining the Depth of the Excision

- Once the peripheral incisions are made around the primary lesion, the depth of the excision must be determined. In general, the depth of the excision is carried to the fascial plane deep to the subcutaneous tissue. The depth of the excision is highly dependent on the location of the primary lesion, the size and depth of the lesion, and the amount of subcutaneous tissue deep to the lesion.
- For facial lesions, the excision is most often carried to a plane just above the facial musculature (**FIG 10**).
- Preauricular lesions are excised to a depth of the parotid fascia (**FIG 11**).
- Nasal lesions are excised above the level of the nasal cartilages.
- Auricular lesions are removed either with or without the underlying cartilage, depending on the size of the primary lesion. In many cases, the underlying cartilage should be removed to ensure adequate negative margins.
- Scalp lesions are usually excised in a subgaleal plane with the underlying pericranium left intact. In large bulky lesions, the underlying pericranium can also be removed to allow for wider clear margins (**FIG 12**).

FIG 10 ● The facial lesion has been excised to a depth just above the facial musculature.

FIG 11 ● Preauricular lesions are excised to a depth just above the parotid fascia.

- Neck skin can be excised either with or without the underlying platysma muscle, depending on the size of the lesion. If there is any concern about deep invasion, it is easy to remove platysma.
- With all excisions, attention must be paid to avoiding injury to any underlying cranial nerves.

Orientation

- Once the primary lesion is completely excised, it must be carefully oriented and marked for permanent pathology. Marking stitches should be easily understood and allow for easy communication between surgeon and pathologist. Any areas of special concern should also be noted on the pathology request, such as when margins are less than ideal due to functional considerations.

FIG 12 ● Scalp lesions are usually excised in a subgaleal plane with the underlying pericranium left intact.

SENTINEL LYMPH NODE BIOPSY

Intraoperative Gamma Probe

- The intraoperative gamma probe is now used to confirm the site of the SLN. In some cases, the primary excision site should be surveyed to look for potential SLNs, which may be deep to the primary excision site. These nodes may not appear on the SPECT-CT due to the shadowing caused by the high intensity of the primary lesion injection site. Sometimes, a blue lymphatic channel can be seen at the edge of the excision site and can be followed to an SLN (**FIG 13**).

Incision and Node Dissection

- Before proceeding with lymph node dissection, it is important to confirm that the patient has not been given any paralytic agents.
- After confirming the previously marked SLN sites with the gamma probe, the incision is made and carried to the deep soft tissue. Usually a 2- to 3-cm incision is long enough to allow for easy dissection and visualization.
- With the incision made, skin hooks are used to retract the skin edges. Blunt dissection is then used to enter the deeper soft tissue. In the neck, dissection will go deep to the platysma muscle. In the preauricular region, the dissection will often proceed deep to the parotid fascia into the parotid parenchyma.
- The intraoperative gamma probe is used frequently to help determine the direction of further dissection. As the tip of the probe gets closer to the sentinel node, the gamma counts will increase.
- Oftentimes, a blue lymphatic channel can be identified and can then be followed to the SLN (**FIGS 14** and **15**).
- Once the node is identified, it is carefully removed with blunt dissection and judicious use of bipolar electrocautery.
- The node is then examined away from the patient to document the gamma count and the presence of blue dye. The node is labeled with the anatomic

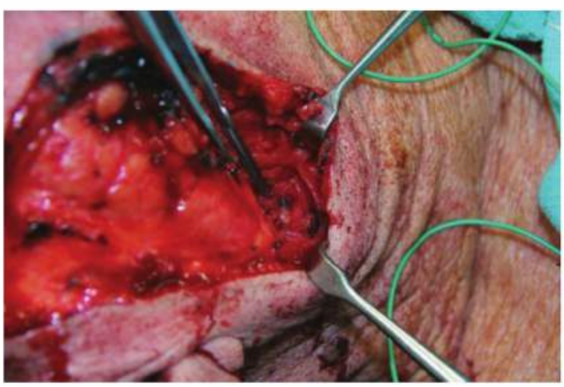

FIG 13 ● The SLN is identified deep to the primary excision site.

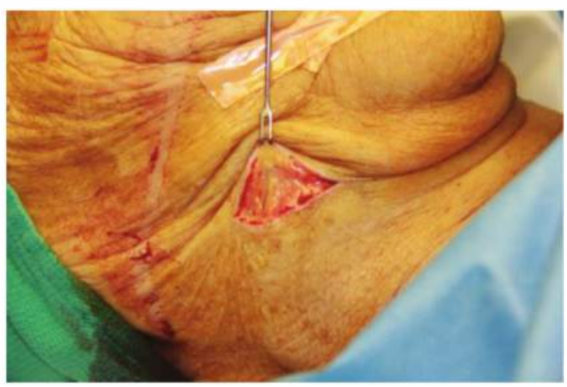

FIG 14 ● Oftentimes, a blue lymphatic channel can be identified.

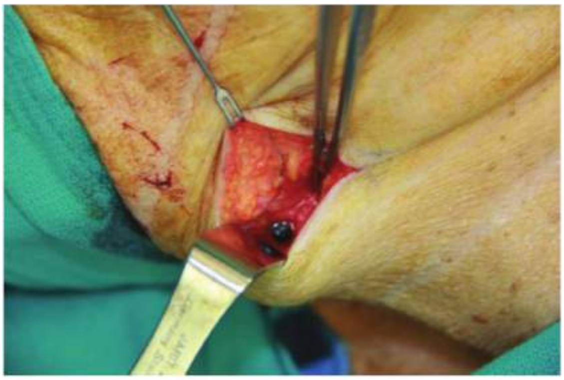

FIG 15 ● Lymphatic channels can then be followed to the SLN.

location, gamma count, and presence of blue dye and sent for histopathology.

Confirmation and Closure

- After removing the SLN, the gamma probe is then used to reexamine the surgical bed. The area where the node was removed should now have a very low count compared to the count prior to node removal. As a general rule, the count should drop to less than 10% of the count prior to node removal. If the count remains elevated, further dissection is warranted to remove any other SLNs identified.
- Once all potential SLNs are removed, the surgical bed is irrigated with saline. A Valsalva maneuver should be performed to confirm there is no ongoing bleeding. The incision can be closed in standard fashion and a small pressure dressing applied.

PRIMARY CLOSURE VERSUS DELAYED RECONSTRUCTION OF THE PRIMARY SITE

Primary Closure

- After the primary lesion has been resected and the SLN biopsy completed, it is time to determine the best method of closing the primary site. If the primary site can be closed without distorting the surgical margins and without the use of rotation flaps or grafts, this can be done immediately. Should a margin return positive on permanent pathology, it would still be easy to return for wider excision.
- This is usually the case for small lesions or for lesions on the neck where excess skin can easily be advanced.
- In these cases, bilateral Burrow's triangle excisions can be performed along the direction of relaxed skin tension lines. The skin is then undermined, advanced, and closed with deep absorbable suture and superficial suture at the skin edge.
- The wound is then dressed with a small pressure dressing, which can be removed after 24 hours.

FIG 16 ● Circumferential purse-string suture is used to decrease the size of the wound.

Delayed Reconstruction

- In many cases, reconstruction of the primary resection site will require significant tissue rearrangement, skin grafting, or even free tissue transfer. In these situations, it is preferable to wait for final histopathologic confirmation of negative surgical margins prior to proceeding with definitive reconstruction.
- In these cases, the size of the wound can often be decreased with use of a circumferential purse-string suture (**FIG 16**).
- The wound can then be dressed with a moist bolster dressing using Vaseline or Xeroform gauze, bacitracin, cotton balls (**FIG 17**), or a foam-type dressing (**FIG 18**). The bolster dressing can be secured with either silk suture or surgical staples.
- Wound infections are very rare in the head and neck and therefore postoperative antibiotics are not routinely used even in the setting of an open wound with a bolster

FIG 17 ● A Xeroform gauze dressing is placed over the resection site.

FIG 18 ● A Reston foam bolster is secured to the scalp to apply pressure after either resection or skin graft reconstruction.

applied. In some cases, such as immune suppression or previous infection, antibiotics may be indicated.

Skin Graft and Rotation Flap Reconstruction

- Once the final surgical margins have returned clear, definitive reconstruction can be completed. The method of reconstruction is dependent on the site of the defect and the goals of the patient. Complex facial defects should be addressed by colleagues with experience in facial plastic and reconstructive surgery.
- Facial skin and preauricular skin defects are most often closed with the use of cervicofacial rotation flaps and transposition flaps. Incisions are planned along relaxed skin tension lines when possible and are carried to postauricular and posterior cervical skin. These flaps create standing cutaneous deformities along the arc of rotation, which will need to be excised. Very large defects can be closed and achieve excellent cosmetic outcomes (**FIGS 19–21**).
- Eyelid defects can be very difficult to repair without causing significant ectropion. Lid-tightening procedures can be done in conjunction with skin grafts, transposition flaps, and rotation flaps. Oculoplastic surgeons should be involved if there is concern about postoperative eyelid function (**FIGS 22–24**).
- Nasal defects can be closed with skin grafts, composite grafts, transposition flaps, advancement flaps, and the interpolated paramedian forehead flap. Each technique can yield excellent results when used in the proper clinical setting (**FIGS 25–27**).
- Auricular defects are most easily closed with wedge excision and advancement flap closure. Transposition flaps can be used to reconstruct large defects and achieve acceptable cosmetic results (**FIGS 28** and **29**).

FIG 19 ● Large facial defect with posterior cervical incision made to allow for cervicofacial rotation flap reconstruction.

FIG 20 ● Cervicofacial rotation flap brought into position.

FIG 21 ● Excellent cosmetic result several weeks after cervicofacial reconstruction of large facial defect.

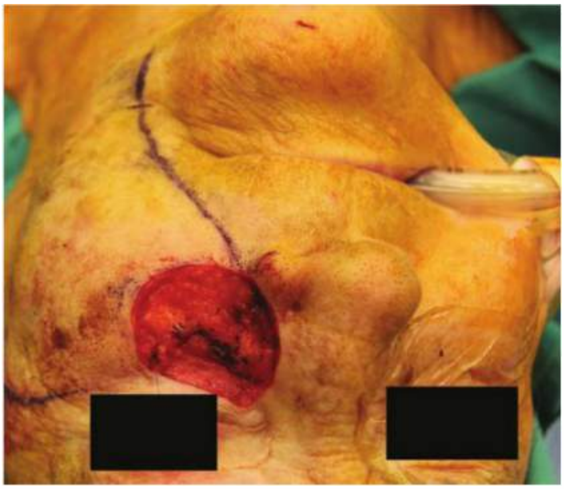

FIG 22 ● Large rotation flap designed for reconstruction of lower eyelid defect.

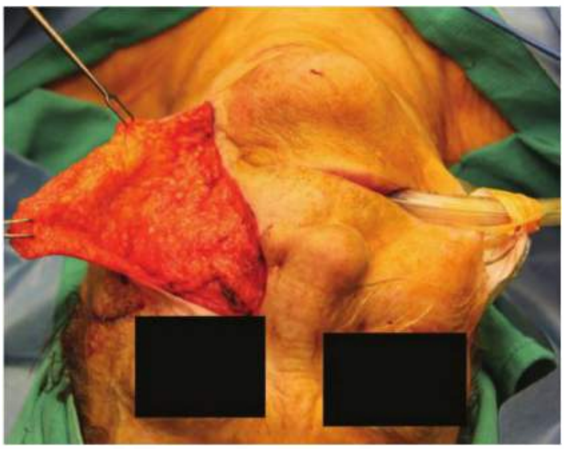

FIG 23 ● The flap is raised far enough to allow for tension-free closure.

FIG 24 ● The rotation flap is sewn into place with no tension inferiorly, thus avoiding postoperative ectropion.

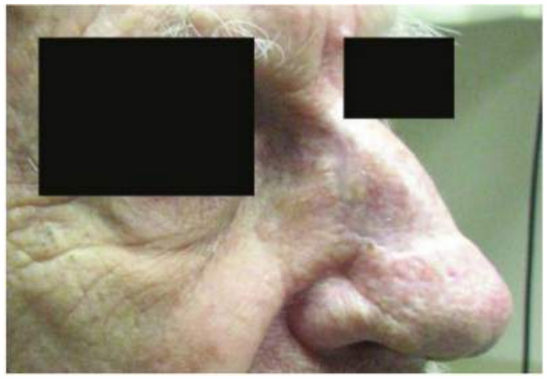

FIG 25 ● Postoperative result after full-thickness skin graft reconstruction of the nasal dorsum.

- Scalp defects are most easily closed with the use of full-thickness or split-thickness skin grafts. In older patients, large amounts of supraclavicular skin can be harvested and used to graft large scalp defects. The skin is thinned to the dermal layer, making sure to remove all subcutaneous tissue. The skin graft can be placed over intact periosteum or can be grafted directly to exposed bone. In this case, a burr can be used to burr down the bone until punctate vessels are seen. The graft is then secured with a bolster dressing and left intact for 7 to 10 days.
- Neck skin defects can almost always be closed with adjacent tissue transfer reconstruction as described earlier.

FIG 26 ● Postoperative result after paramedian forehead flap reconstruction of right lateral nasal wall and alar rim with use of ear cartilage grafting to alar rim (lateral view).

FIG 27 ● Postoperative result after paramedian forehead flap reconstruction of right lateral nasal wall and alar rim with use of ear cartilage grafting to alar rim (frontal view).

FIG 28 ● Resection of left lower ear and helical rim.

FIG 29 ● Reconstruction of left ear with postauricular transposition flaps.

PEARLS AND PITFALLS

Indications and preoperative workup	■ A complete history and physical exam should be performed including full body skin check. ■ If SLN biopsy is indicated, lymphoscintigraphy with SPECT-CT imaging should be reviewed prior to surgery. ■ A detailed cranial nerve exam should be completed prior to proceeding with surgery.
Excision of primary lesion	■ The primary lesion should be marked to include any pale, erythematous, or pigmented adjacent skin. One to 2-cm circumferential margins are marked depending of depth of invasion of the primary lesion. ■ The depth of excision needs to include enough normal tissue to ensure complete surgical excision. ■ Mark the specimen with clear orientation sutures to allow for definitive margin analysis.

SLNB	■ Review preoperative lymphoscintigraphy/SPECT-CT to identify likely sites of SLNs. ■ Carefully, inject methylene blue dye circumferentially into the dermis surrounding the primary lesion. ■ Ensure anesthesia has not paralyzed the patient prior to lymph node surgery. ■ Make incisions along relaxed skin tension lines and keep in mind the possible need for rotation advancement flap reconstruction or future parotid/neck dissection incisions. ■ Use the intraoperative gamma probe to localize SLNs and make sure that all potential SLNs are removed.
Closure vs. delayed reconstruction	■ If wound can be closed by simple advancement flap without reorienting margins, then wound can be closed primarily. ■ If rotation/transposition flap or skin graft is needed, it may be wise to delay reconstruction until final surgical margins are clear. ■ Facial plastic and oculoplastic colleagues should be consulted for closure of complex wounds.

POSTOPERATIVE CARE

- Small pressure dressings are usually applied to small advancement flap reconstruction sites as well as SLN biopsy sites and are left intact for 24 hours. Larger cervicofacial advancement flap reconstruction sites are dressed with Jobst pressure dressings and are left intact for 2 to 3 days. When the dressings are removed, the incisions should be kept clean with half-strength peroxide and moist with Vaseline. Topical antibiotic ointment may be used for 2 to 3 days but can cause skin irritation with longer use. When skin grafts are used, the bolster dressing is left intact for 7 to 10 days. After the bolster is removed, the graft is kept moist with Vaseline for 1 to 2 weeks or until the wound has completely healed.

OUTCOMES

- In the hands of experienced head and neck surgeons, an SLN can be identified in nearly all patients. In patients with cutaneous melanoma of the head and neck with Breslow depth of 1 mm or greater or with Breslow depth between 0.75 mm and 0.99 mm with other adverse features, approximately 20% are found to have a positive SLN. Upon completion lymphadenectomy, 25% of patients with a positive SLN will have at least one more positive non-SLN. Approximately 4% of patients with negative SLNs will fail regionally within the sentinel node basin.[2]
- Positive SLN status is the factor most strongly associated with decreased recurrence-free survival (hazard ratio [HR] 4.23) and decreased overall survival (HR 3.33).[2] The estimated 4-year overall survival approaches 84% in patients with negative SLN biopsy and decreases to an estimated 58% in patients with a positive SLN.[2]

COMPLICATIONS

- Seroma or hematoma at the SLN biopsy site
- Infection at either the SLNB or primary resection site
- Wound dehiscence or epidermolysis of rotation flap reconstruction site
- Decrease in sensation at either surgical site
- Theoretical risk of cranial nerve injury
- Poor cosmetic outcome

Chapter 27 Sentinel Lymph Node Biopsy for Melanoma

Merrick I. Ross Michael Kim

DEFINITIONS

- The sentinel lymph node(s) are defined as the first nodes to receive direct lymphatic drainage from the cutaneous site of a primary melanoma and therefore the most likely lymph node(s) to harbor microscopic metastases. The technique of lymphatic mapping and sentinel lymph node (SLN) biopsy is used to determine the histologic status of the regional lymph node basin(s) in patients with early-stage (American Joint Committee on Cancer [AJCC] clinical stages I and II) melanoma without performing a formal lymph node dissection. The SLN concept as well as the minimally invasive technique, which initially used intradermal injections of vital blue dye[1] (**FIG 1**) and was later modified with the addition of radiolabeled colloid injections[2,3] at the site of the primary melanoma, was first studied and reported in detail by Morton and colleagues, demonstrating proof of concept in a large group of patients with primary melanoma and clinically negative regional lymph nodes.[1] This and several subsequent studies have confirmed that the lymphatic drainage patterns from specific regions of the skin can be accurately determined, the SLN is the most likely first site of regional lymph node metastasis, and if the SLN is histologically negative, the remaining lymph nodes in the mapped basin are unlikely to contain disease.

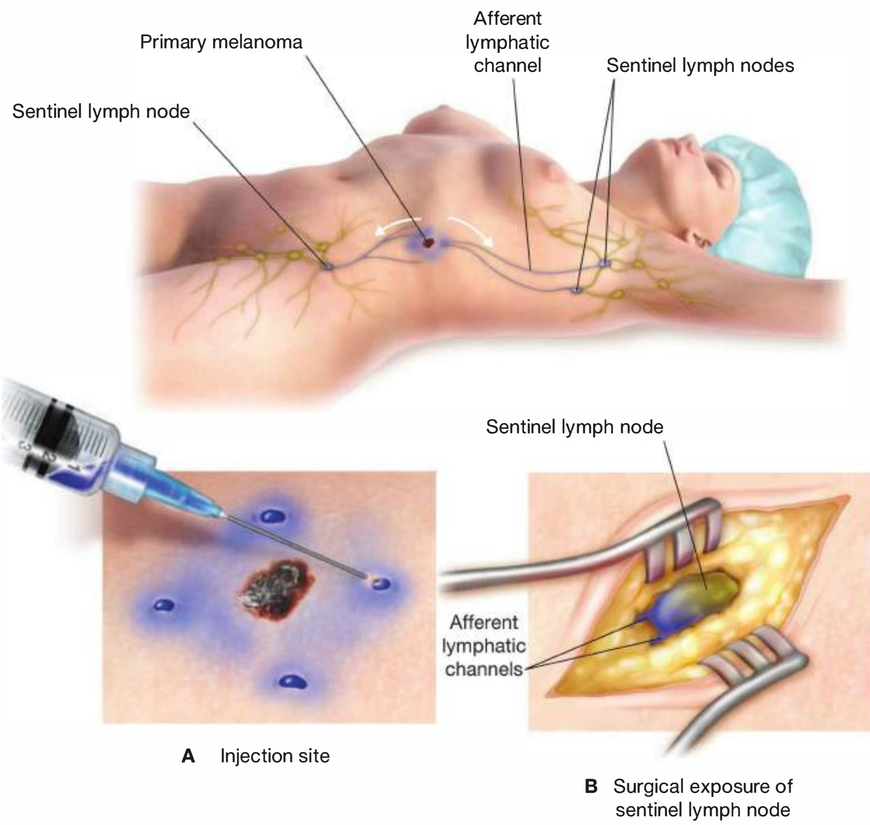

FIG 1 ● Sentinel node localization using blue dye injections. An artistic rendition of the sentinel node concept and afferent lymphatic drainage patterns is depicted. After the intradermal injection of blue dye around a primary cutaneous melanoma (left abdominal wall, **Panel A**), afferent lymphatic drainage to a left inguinal sentinel lymph node and two left axillary sentinel lymph nodes is shown. **Panel B** shows surgical exposure, using a self-retaining retractor, of the first of two sentinel nodes in the left axilla. Note the two afferent lymphatic vessels entering the sentinel node. Both nodes in the axilla would be defined as "sentinel" because they each receive first (primary) echelon drainage from a specific afferent lymphatic vessel. Both nodes need to be removed from the axilla as well as the SLN in the groin to complete the surgical procedure of SLN biopsy.

The reported accuracy (sensitivity) of SLN biopsy is 95%.[1,3–5] The term "biopsy" is perhaps a misnomer (particularly to patients) because the biopsy procedure is excisional in nature in that the entire SLN is removed and subjected to rigorous histologic analysis. Alternatively, the term "sentinel lymphadenectomy" can be used to define the surgical procedure.

CLINICAL IMPORTANCE

- Improving outcomes: The sobering reality is that once patients with melanoma develop clinically apparent (palpable) nodal disease (advanced AJCC stage III), the risk of subsequent distant stage IV disease and recurrent lymph node basin disease, despite a complete therapeutic lymphadenectomy, is at least 50%[6] and 15% to 50%,[7] respectively. Therefore, the original motivation to study SLN biopsy was to establish an effective method of identifying and then treating lymph node disease early when microscopic, an approach termed "selective lymphadenectomy," not to be confused with the aforementioned "sentinel lymphadenectomy," which refers specifically to the SLN biopsy procedure. Such an approach would prevent the development of clinically palpable nodal disease and in turn improve the outcomes for the node-positive patients in terms of both regional disease control and survival. The collective experience with SLN biopsy demonstrates that these two goals have been accomplished.[8,9]
- Staging and reducing morbidity: The stages I and II melanoma patient population represent at least 85% of the newly diagnosed patients. The prognosis of this group is very heterogeneous and dependent on a variety of primary tumor factors, specifically tumor thickness, ulceration, and mitotic rate, and probably most importantly, the presence of occult lymph node involvement.[10] The role of SLN biopsy as a staging tool has been well established, as several published multivariable analyses demonstrate that the histologic status of the SLN is the strongest independent predictor of survival for stages I and II melanoma and therefore offers another motivation for SLN biopsy.[10,11] The procedure is also intended to identify patients with pathologically node-negative disease for whom additional surgery is not indicated and adjuvant systemic therapy may not be of benefit, sparing these patients the morbidity of unnecessary surgery and treatment-related toxicities.
- SLN biopsy is now accepted as a standard of care[12,13] in the surgical management of appropriately selected melanoma patients. Central to the success of this minimally invasive approach, and in turn achieving the earlier described staging and treatment goals, is the consistent and accurate identification and complete removal of the SLN(s).
- Although in simplest terms SLN biopsy is a straightforward surgical procedure, in reality, the overall approach integrates several necessary components: identification of the appropriate candidates, careful physical examination of the potential nodal basins at risk, preoperative assessment of the lymphatic drainage patterns, intraoperative localization and removal of all the SLN(s), and careful histologic assessment of the SLN(s).

IDENTIFYING THE APPROPRIATE CANDIDATES

- Primary invasive cutaneous melanoma: The selection criteria for identifying the appropriate candidates for SLN biopsy is based on the predicted risk for the presence of microscopic lymph node involvement for those patients with newly diagnosed primary melanoma and clinically negative nodes. This is best determined by the various primary tumor factors inclusive of tumor thickness, ulceration,[14] and mitotic rate, which define the five AJCC stages I and II substages of primary melanoma.[10] The consensus recommendations are to offer SLN biopsy to any patient with a thickness of 1 mm or greater as long as they are safe operative candidates. SLN biopsy should also be strongly considered in any patient with a thickness of 0.7 to 0.99 mm, particularly if they have at least one of the following adverse prognostic features: Clark level IV or V, one mitotic figure or more per square millimeter, and lymphovascular invasion or microsatellites.[12,15–17] For patients with a thickness of less than 0.76 mm, SLN can be considered if, based on other adverse risk factors, a risk of 8% to 10% of SLN involvement is anticipated. This, however, would be a minority of patients in this subset.[14] Although these patients represent the vast majority who will be offered an SLN biopsy, a variety of other clinical scenarios are encountered with some frequency where SLN may also be considered. These scenarios are described in the 6 bulleted points that follow directly.
- Primary melanoma in an ambiguous (unpredictable) lymphatic drainage site (i.e., head and neck or trunk location) and proven synchronous nodal involvement in at least one, but not all, of the potential regional lymph node basins at risk: These patients may be candidates for SLN biopsy to stage the other regional nodal basins proven to receive direct lymphatic drainage from the primary site but without clinical nodal involvement. Generally speaking, these patients will undergo treatment of the primary melanoma and the involved nodal basin with a wide excision and formal therapeutic lymphadenectomy in the same operative setting. In the event that preoperative lymphoscintigraphy (**FIG 2**) demonstrates lymphatic drainage to an additional but clinically negative regional nodal basin, SLN biopsy

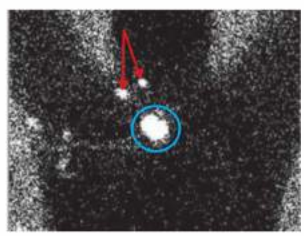

FIG 2 ● Lymphoscintigraphy showing lymphatic drainage to more than one nodal basin. An anterior–posterior view of a lymphoscintigraphy is shown, demonstrating lymphatic drainage from a primary melanoma site *(blue circle)* in an ambiguous (unpredictable) drainage location. Afferent drainage is seen to the right axilla and right neck *(red arrows)*. This patient presented with a newly diagnosed melanoma in the right mid back. Palpable nodes were appreciated on physical exam in the right axilla; an ultrasound-guided fine needle aspiration confirmed metastatic disease. The neck was clinically uninvolved by palpation and ultrasound. The patient underwent surgery with curative intent, which included a right axillary dissection, wide excision of the primary site, and an SLN biopsy in the right neck. Final pathology showed micrometastatic disease in both SLNs removed.

can also be performed at the same time in an attempt to be inclusive in the treatment of all nodal disease, both macro- and microscopic.

- Mucosal melanoma: Patients with primary mucosal melanomas that are in locations with easy access for direct injection with the SLN localizing agents, conjunctival and anorectal in particular, can be candidates for SLN biopsy as part of their initial surgical management strategy. Although specific primary tumor criteria for these lesions are not well established for predicting the presence of occult regional node involvement, these tumors are most often diagnosed late and likely to have a high enough inherent risk to consider SLN biopsy.
- True locally recurrent melanoma: Some patients develop recurrent melanoma at the edge of a previous wide excision site and may have one of the following three histologic features: in situ disease alone, in situ disease plus an invasive component, or invasive (dermal) component only. All three of these events are likely the result of an inadequate wide excision and an undetected positive margin and therefore represent a "true" local recurrence and have a good chance for long-term survival with surgical treatment. Most of these patients have clinically negative nodes, and in the context of a recurrent invasive component with the appropriate tumor characteristics (see earlier discussion), it is rational to offer these patients an SLN biopsy as a part of the definitive surgical therapy.
- Limited satellite/in-transit metastases: In contrast to the patients with "true" locally recurrent disease, these patients represent manifestations of the biologic disease continuum of regional cutaneous metastases (stage III). Not infrequently, these patients will present with clinically negative regional lymph nodes, stage IIIb. If the extent of the regionally metastatic disease is limited (one or two lesions), a surgical approach to the recurrence is rational. The presence of synchronous microscopic nodal disease not only impacts disease stage, advancing to IIIc and therefore the prognosis, but also the treatment strategies. Therefore, SLN biopsy could also be used in this clinical scenario in conjunction with the resection of the recurrence(s).
- After a wide excision: It is typical and preferable that the SLN biopsy be performed together in a single operative setting in conjunction with the definitive wide excision of the primary melanoma following a diagnostic incisional or excisional biopsy. Occasionally, a patient will have undergone a formal wide excision of the primary melanoma site and then be referred for consideration of an SLN biopsy. A theoretical concern is that the lymphatic drainage pattern of the skin brought together to close the surgical defect or surrounding a skin graft reconstruction has either been altered by the surgery or is far enough away from the original primary lesion that it may not accurately reflect that of the removed skin that was directly adjacent to the primary melanoma, resulting in the identification and removal of the wrong SLN(s). A few publications have put most of these concerns to rest. The data shows that although more afferent lymphatic vessels are likely to be accessed because of the broadened area injected, leading to more SLNs being removed and even the possibility of additional nodal basins explored in sites of ambiguous drainage (trunk and head and neck), the correct SLNs will likely be among the specimens removed, providing accurate nodal staging information.[18] As long as complex rotational flaps were not used for the reconstruction, SLN can be recommended to patients when this clinical setting is encountered.
- Prior surgery in a nodal basin: Occasionally, a primary melanoma will be diagnosed in a location with predicted or possible lymphatic drainage to a regional nodal basin in which surgical intervention has previously been performed, such as an SLN biopsy or lymph node dissection, as treatment for a previous melanoma or other malignancies. An SLN biopsy may still be possible, but a preoperative lymphoscintigraphy is mandated to determine how the lymphatic drainage has been affected or altered by the previous nodal surgery. Lymphatic drainage patterns may be demonstrated in one or more of the remaining nodes (if any exist) in the previously treated basin or diverted to another basin. This information is critical for appropriate surgical planning and operative positioning.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Pertinent information such as a prior personal history of melanoma or other malignancies and current or recent symptoms referable to the presence of metastatic disease should be elicited from the patient during the history.
- Questions about allergic reactions to antibiotics, sulfa in particular, and intravenous (IV) contrast agents should be documented as this information may suggest an increased risk of an allergic reaction to the isosulfan blue dye and therefore may influence the decision to use a different blue dye such as methylene blue or not use any blue dye at all for the SLN procedure (see more details in the following text).
- A thorough head-to-toe skin examination should be performed with the intent of identifying additional suspicious lesions that could represent another primary melanoma or other skin cancers. Diagnostic full-thickness punch or excisional biopsies should be performed on selected lesions.
- Special attention should be paid to the region of the index melanoma. Visual inspection as well as palpation of the biopsy site and surrounding skin and soft tissues should be performed to determine the presence of any residual primary disease and/or satellite and in-transit metastases.
- Skin and soft tissues between the primary lesion and draining lymph node basins should be palpated and closely examined for in-transit disease. All suspicious cutaneous and subcutaneous lesions may undergo fine needle aspiration for pathologic diagnosis.
- All potential regional lymph node basins should be palpated for the presence of clinically apparent disease. This examination should include the epitrochlear and popliteal minor nodal basins when the primary melanoma is located distal to the elbow and knee, respectively.
- Palpable lymph nodes suspicious for metastatic disease should be assessed by either direct fine needle aspiration or further examined with ultrasound and biopsied with ultrasound guidance if confirmed to be radiographically suspicious. Such data may obviate the need for SLN biopsy in that basin and instead invoke a formal radiographic staging evaluation prior to carrying out a therapeutic lymph node dissection of the affected lymph node basin(s).

HISTOLOGIC EVALUATION OF THE PRIMARY MELANOMA

- An experienced dermatopathologist should review all pathology slides related to the melanocytic lesion in question to both confirm the diagnosis of melanoma as well as to provide the microstaging (tumor thickness, ulceration status, and mitotic rate) information and other relevant adverse histologic features (see earlier discussion).
- The decision to proceed with an SLN biopsy should be based on the earlier described established criteria. In some situations, however, the primary lesion is essentially intact and the diagnostic biopsy represents only a small sampling of the entire lesion or very superficial in depth. This type of biopsy may accurately render a definitive diagnosis of melanoma but may lack the histologic features needed to recommend an SLN biopsy. In this situation, the entire lesion should be narrowly removed as an excisional biopsy for complete histologic evaluation.

PREOPERATIVE RADIOGRAPHIC STUDIES

- Although *symptom-directed* preoperative radiographic imaging is a good practice in patients with newly diagnosed melanomas, generally speaking, most newly diagnosed early stage patients are asymptomatic; therefore, no special radiographic imaging is required or recommended prior to performing an SLN biopsy for most primary melanoma patients.[19] In the asymptomatic patient, extensive radiographic staging is more likely to result in false-positive rather than true positive findings. One possible exception would be the patients with both very thick (>4 mm) and ulcerated primary lesions. Many surgeons would obtain complete radiographic staging inclusive of computed tomography (CT) of chest/abdomen/pelvis or positron emission tomography (PET) scan and magnetic resonance imaging (MRI) of the brain routinely for this high-risk group.[19]
- In contrast, in patients with a locally metastatic lesion or a limited number of in-transit metastases for whom an SLN biopsy is being considered as part of the definitive surgical management, a thorough preoperative radiographic staging evaluation should be performed.[19]
- As mentioned earlier, ultrasound examination should be performed in patients with suspicious palpable nodes. Furthermore, ultrasound evaluation of the regional nodal basins should also be used as an adjunct to physical examination particularly of the axilla, in obese patients, with thick and ulcerated melanomas to evaluate for the presence of macroscopically involved nodes. In these situations, the sensitivity of physical examination is low and the risk of harboring synchronous macroscopically involved nodes is relatively high. Ultrasound examination suspicious for nodal involvement can be confirmed with an ultrasound-guided fine needle aspiration (**FIG 3**).
- The success of any SLN program is dependent on the preoperative determination of the lymphatic drainage patterns from the primary melanoma site. Although the nodal basins at risk in extremity melanomas are relatively predictable, such is not the case for head and neck and trunk melanomas where lymphatic drainage patterns are considered ambiguous or unpredictable. Preoperative identification of lymphatic drainage patterns is accomplished with *lymphoscintigraphy*.[20,21]

FIG 3 ● Ultrasound-guided fine needle aspiration of a suspicious nonpalpable lymph node. A static ultrasound image of biopsy needle *(black arrow)* within the node *(red arrow)* is shown.

PREOPERATIVE LYMPHOSCINTIGRAPHY

- Once the decision is made to perform an SLN biopsy, the most important preoperative decision is whether or not to perform a lymphoscintigraphy.
- The technique of cutaneous lymphoscintigraphy provides an objective description of the lymphatic drainage pattern from a primary cutaneous lesion to the nodal basin(s) that receive direct afferent lymphatic drainage. Through the use of external gamma camera images, the migration of the radioactive tracer that is injected intradermally (where the invasive melanoma cells are located) at the site of the primary tumor can be visualized to determine the following: (1) the major lymph node basin(s) receiving direct lymphatic drainage, (2) number and relative location of sentinel nodes within the basin, and (3) the existence and location of SLN(s) located outside of a formal lymph node basin, referred to as either "interval" or "in-transit" SLNs that are located in the subcutaneous tissues between the primary tumor and the formal nodal basin or *ectopic* in completely unpredicted anatomic locations.[22] The lymphatic drainage patterns mimic how melanoma cells metastasize within the lymphatic compartment. Approximately 5% to 10% of the time, an interval or in-transit SLN pattern will be identified during lymphoscintigraphy on the trunk; these nodes are just as likely to be involved with metastatic disease as the SLNs in the formal nodal basins.[22] **FIG 4** provides a simplified schematic of potential lymphatic drainage patterns.
- Two radiopharmaceutical agents are now available in the United States to be used for lymphoscintigraphy and for intraoperative SLN localization, both using a dose of 0.5 to 1.0 mCi of the radiotracer technetium-99m. Radiolabelled sulfur colloid has been the historical standard and is still used commonly, to date, but not specifically approved for

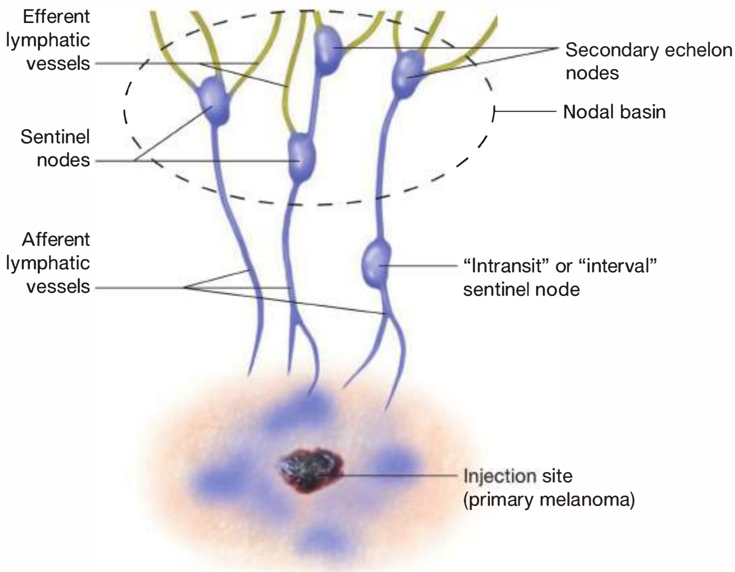

FIG 4 • Lymphatic drainage patterns. A schematic of potential lymphatic drainage patterns from the primary site to the regional nodal basin is shown. The first (primary echelon) node of drainage from a specific afferent lymphatic vessel is defined as an SLN. Up- or downstream drainage from the SLN to another node via efferent lymphatic vessels are considered secondary echelon nodes. Occasionally, primary lymphatic drainage is to a lymph node proximal to the formal basin in the subcutaneous tissue and termed as either an "interval" or "in-transit" SLN.

this use. Recently, the U.S. Food and Drug Administration (FDA) has approved the use of Tilmanocept,[23] which is a formulation of a dextran framework with several attached mannose residues and a technetium-99m binding site.

- In theory, the sulfur colloid particles migrate from the injection site through the afferent lymphatic vessels and are actively taken up by the macrophages in the first draining nodes (the sentinel nodes). Similarly, Tilmanocept migrates to the sentinel nodes from the injection site but is then covalently bound to the macrophages in the sentinel node as a result of the mannose residues, limiting significant pass through to secondary echelon nodes.
- Two types of images can be created. The routine examination is termed "planar" and provides images in two perpendicular planes: posterior–anterior (P-A) and/or anterior–posterior (A-P), or both, and lateral views[20] (**FIG 5**). These images visualize the injection site, the afferent lymphatic channels, and the accumulation of the radiotracer in the SLNs. The A-P and P-A views give the clinician medial and lateral as well as superior–inferior orientations, whereas the lateral views provide anterior and posterior localizations and also superior–inferior localizations. A transmission scan adds the contour of the body to the image and provides additional anatomic localizing information. When radioactive tracer injection sites (primary melanoma site) overlies or is in close proximity to a draining lymph node basin in at least one visual plane, the radioactivity in the sentinel node will not be visualized in that plane. Perpendicular images are necessary in order to visualize the sentinel activity separate from the injection site activity.

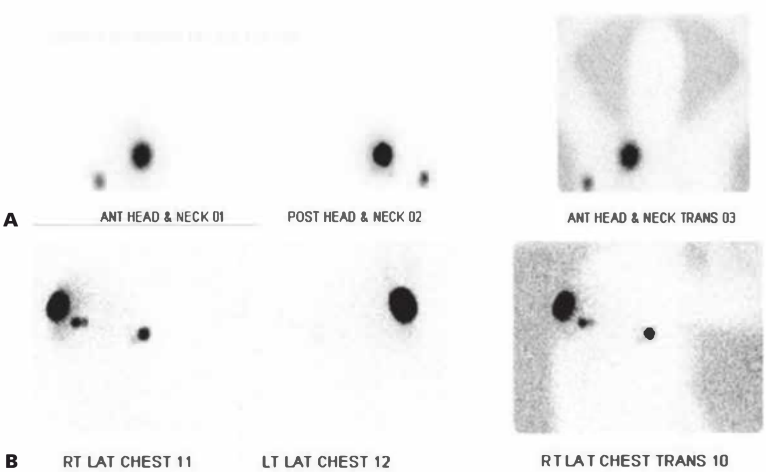

FIG 5 • Planar lymphoscintigraphy. Typical example of a cutaneous lymphatic drainage scan, obtained by injecting the technetium-99m–labelled tracer in the intradermal location at the primary melanoma site, is shown. The injection site, the afferent lymphatic vessels, and the SLNs in the regional basin nodal are visualized. A-P and P-A **(A)** as well as right and left lateral images **(B)** are taken to visualize the drainage pattern in perpendicular visual planes. The last image in both rows is the transmission scan that outlines the contour of the body to facilitate anatomic localization.

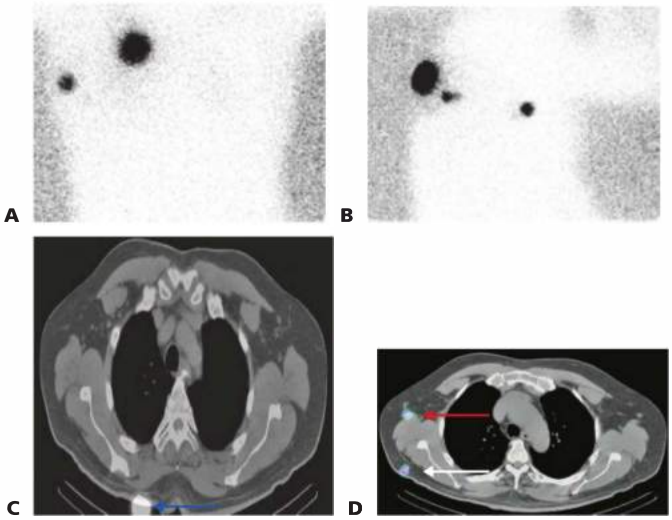

FIG 6 ● SPECT-CT lymphoscintigraphy. Planar lymphoscintigraphy of primary melanoma is shown in the top row, with anterior view in **(A)** and lateral view in **(B)**. Selected SPECT-CT images of the same patient are seen in the bottom row. Only the axillary SLN is seen in **(A)** and an additional SLN is seen in **(B)**, which was obscured by the overlying activity transmitted to the axilla from the injection site. The additional SLN in **(B)** is likely an in-transit node, the exact anatomic location of which is better visualized in the transaxial view of the SPECT-CT image in **(D)**. In **(C)**, the *blue arrow* indicates the injection site and in **(D)**, a few cross-sectional images inferior the *white arrow* identifies the in-transit SLN and the *red arrow* the axillary SLN, both of which are located in the same A-P visual plane.

- More recently, single-photon emission computed tomography–computed tomography (SPECT-CT) lymphoscintigraphy[21] has been developed, providing more exact anatomic localizations. With this method, serial cross-sectional, axial, coronal, and sagittal images are obtained and fused with the nuclear images. Relatively precise locations of the SLN and injection sites can be accomplished and is therefore particularly helpful in primary tumor locations such in the head and neck regions where multiple SLNs may be present or in locations where the potential nodal basins, and therefore the SLNs, may be in close proximity to the injection's site and lie within one of the same visual planes as the injection's site. In this latter situation, the SLN radioactivity will be obscured by activity within the injection site in one or more planes and therefore possibly go undetected on a "planar" study. Although obtaining a perpendicular image may visualize the SLN activity in a different line of sight, as described earlier, the SPECT-CT provides consistent three-dimensional imaging. The SPECT-CT images are also better at determining the presence of and delineating the location of interval or in-transit SLNs (**FIGS 6** and **7**).
- In the management of primary tumors located in cutaneous regions predicted to have ambiguous lymphatic drainage, such as in the head and neck and trunk, a preoperative lymphoscintigraphy is mandated. The extent of ambiguous cutaneous lymphatic drainage includes a very large area of the trunk and head and neck regions and is underestimated by the original classic descriptions of lymphatic drainage patterns. **FIG 8** illustrates the actual regions of ambiguous drainage. **FIG 9** demonstrates an example of ambiguous drainage.
- For extremity lesions, a formal lymphoscintigraphy is not essential as the basins at risk are predictable and intraoperative scanning can be performed with the handheld gamma probe. Some clinicians, however, will obtain a preoperative study for extremity lesions as well, particularly if the primary tumor is located distal to the knee or elbow to have a preoperative assessment for the presence of popliteal (**FIG 10**) or epitrochlear drainage patterns. Even in the proximal extremity locations, a preoperative lymphoscintigraphy can provide useful information in determining whether any upstream drainage from the thigh to the pelvis or the upper arm to the neck is primary (sentinel) or secondary echelon.
- Whereas some clinicians will schedule the lymphoscintigraphy on a day prior to the surgical procedure, others will obtain the study on the day of the surgery. In the latter scenario, the injection of the technetium-99m–labeled radiotracer that is used for the scan can be used for the gamma probe–directed intraoperative localization of the SLN. Because the half-life of technetium-99m is only 6 hours, when the lymphoscintigraphy is performed on a day remote from the surgery, another injection is required on the day of surgery unless a larger (three times) dose of the radiotracer is given the evening before the surgery.
- The lymphoscintigraphic images should be viewed by the surgeon and displayed in the operating room (OR) at the time of the SLN biopsy surgery to facilitate operative positioning, the intraoperative identification of the SLNs, and subsequent removal of all of the SLNs.

SURGICAL MANAGEMENT

Preoperative Planning

- Except in situations when the patient has already undergone a wide excision of the primary melanoma and then is referred for SLN biopsy, the SLN biopsy is carried out in the same operative setting as the definitive wide excision of the primary site.
- The surgery is performed as a day surgery, most conveniently in an ambulatory OR setting, under general anesthesia or with local anesthesia supported with intravenous sedation. Therefore, the patient should be nil per os (NPO) after midnight.
- Because frequently the entire index clinical lesion has been removed with either the shave or excisional diagnostic biopsy, identifying the correct site at the time of

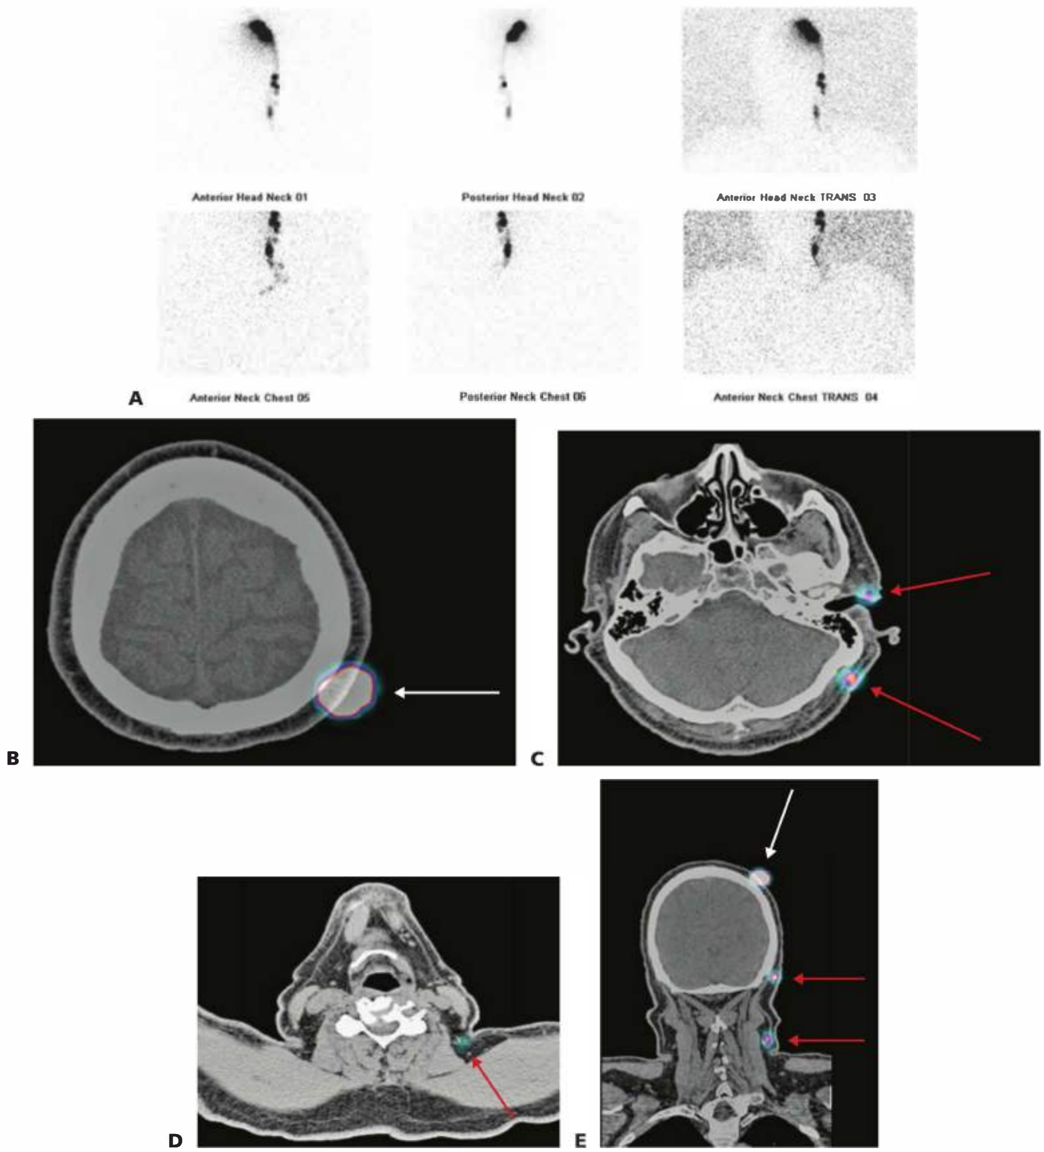

FIG 7 • SPECT-CT lymphoscintigraphy. Planar lymphoscintigraphy of a primary melanoma on the left scalp is shown in **(A)**, demonstrating multiple SLNs, the anatomic locations of which are difficult to define. In **(B–D)**, the SPECT-CT images are shown, with the *white arrows* indicating the injection site and the *red arrows* the SLNs, providing more exact localization with the use of cross-sectional (**B** and **C**) and coronal views in **(E)**.

lymphoscintigraphy or surgical procedure may be difficult. This is further complicated by the fact that these patients frequently have undergone other biopsies of skin lesions either prior to or at the time of the melanoma diagnosis. Because the accuracy of the SLN biopsy is dependent on injecting the correct site, careful documentation of the primary melanoma biopsy location to be injected should be carried out during the first clinic visit when the decision to perform the SLN biopsy is made. Digital images of this site can be obtained and downloaded in the patient's electronic medical record.

- Once the index lesion has been identified and clearly marked in the preoperative holding area and confirmed by the patient and/or family member, the patient can go to nuclear medicine for the radiotracer injection followed by the lymphoscintigraphy if not already completed on a day remote from the actual surgical procedure. The radiotracer is injected intradermally in the normal skin, just adjacent and as close as possible to the intact residual lesion (if present) or the biopsy site by the radiologist or technician. A four-point injection technique surrounding the lesion is employed with a 30-gauge needle attached to a 1-cc syringe (**FIG 11**).

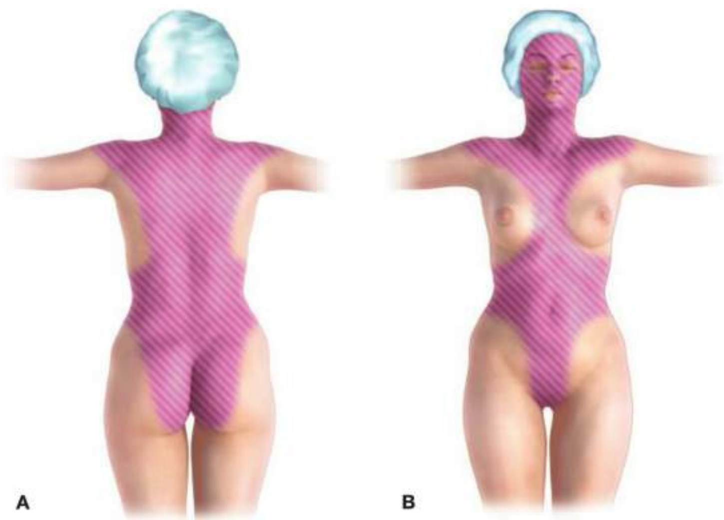

FIG 8 ● Areas of ambiguous lymphatic drainage. The regions of ambiguous (unpredictable) cutaneous lymphatic drainage include broad areas of the posterior **(A)** and anterior **(B)** trunk and the entire surface area of the head and neck.

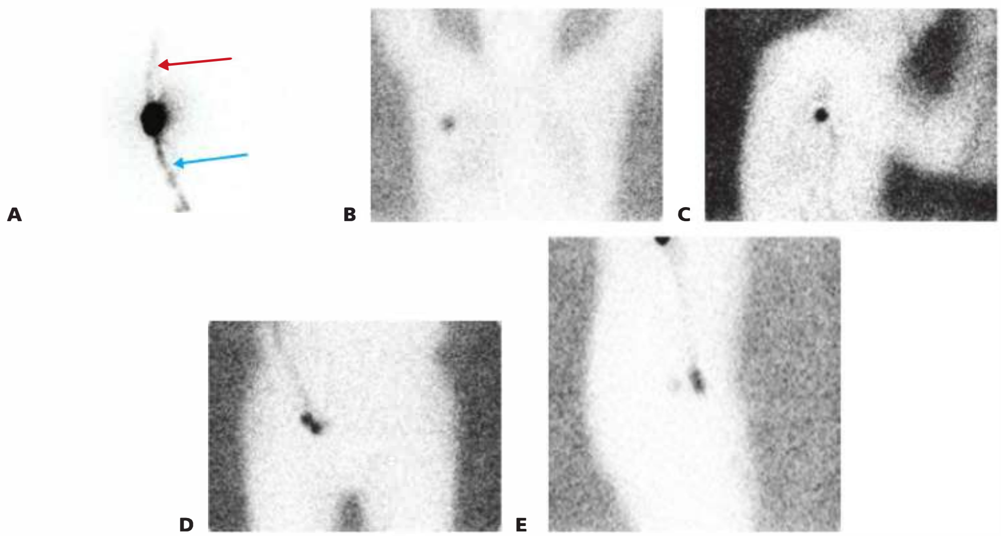

FIG 9 ● Ambiguous lymphatic drainage. Lymphoscintigraphy of melanoma on the right flank is displayed. The primary injection site is shown in **(A)**, demonstrating afferent lymphatic vessels draining in a bidirectional fashion to the ipsilateral axilla *(red arrow)* and groin *(blue arrow)*. In **(B)** and **(C)**, the axillary SLN is visualized in two perpendicular planes. In **(D)** and **(E)**, the inguinal SLN is visualized in two perpendicular planes.

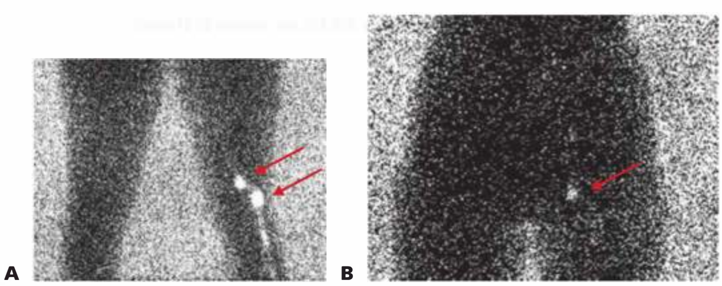

FIG 10 ● Visualization of popliteal SLN. Lymphoscintigraphy of melanoma on the plantar surface of the calcaneus demonstrating both popliteal **(A)** and inguinal **(B)** SLNs *(arrows)* is shown.

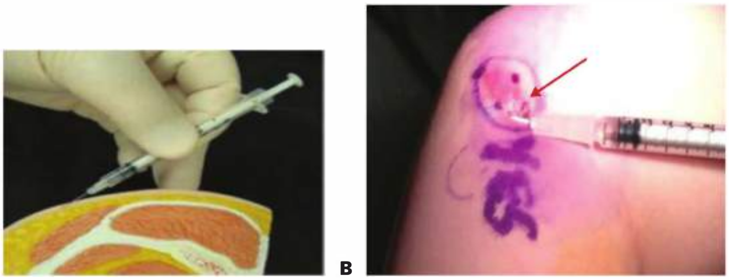

A B

FIG 11 ● Radiotracer injection technique. The correct technique and needle location for an intradermal injection is shown using a soft tissue model in **(A)**. An actual intradermal injection of the radiotracer at the primary melanoma site using a 1-cc syringe and a 30-gauge needle is shown in **(B)**. Note the wheal formation *(arrow)* confirming the intradermal location.

The usual dose of the radiotracer is 0.5 to 1 mCi of technetium-99m. For extremity lesions, the surgeon may choose not to obtain a lymphoscintigraphy (see earlier discussion) and have the patient return to the preoperative holding area directly after the injection. Also for extremity primaries, if permissible by the nuclear medicine department and if a lymphoscintigraphy is not going to be obtained, the surgeon can perform the injection of the radiotracer in the OR just prior to injecting the blue dye.

- Generally speaking, scheduling the injection that will be performed by the nuclear medicine staff approximately 1 hour prior to the surgery start time is adequate, but 2 or 3 hours may be required if a SPECT-CT lymphoscintigraphy is planned.
- Open communication with anesthesia personnel should take place prior to arrival in the OR to make sure the IV is placed thoughtfully at a site removed from the planned sites of the surgical procedures.
- The patient should be administered appropriate broad-spectrum antibiotic prophylaxis to reduce the risk of surgical site infection.
- The handheld gamma probe should already be in the OR.
- If the plan is to use the vital blue dye as another SLN localizing agent, this should be drawn up in 1-cc aliquots in the OR prior to the arrival of the patient.

Operative Positioning

- Thoughtful operative positioning is more of an art than a science but is an important step that will reduce operative times, limit the number of position changes, facilitate intraoperative scanning with the handheld gamma probe, and more importantly, optimize the complete identification and removal of all SLNs.
- The lymphoscintigraphic images should be displayed in the OR.
- Once in the OR, the gamma probe is used to transcutaneously scan all the planned nodal basins and SLN locations to be explored to make sure that the radiotracer has migrated. Alternatively, the patient can be scanned with the handheld gamma probe in the holding area prior to entering the OR to make sure the radiotracer has migrated in the event that a lymphoscintigraphy was not performed on the day of the surgery or not needed (i.e., for extremity primary).
- The gamma probe should also be used to scan potential additional sites that may not have been specifically identified on the lymphoscintigraphy, such as in the epitrochlear and popliteal regions for primary lesions distal to the elbow and knee respectively, all of the major regional nodal basins in the neck for head and neck and upper trunk primaries close to the midline, contralateral axilla for mid and upper back and chest lesions close to the midline, contralateral inguinal basin for lower abdomen and lower back primaries close to the midline, and ipsilateral axilla and inguinal regions for lateralized flank primaries. Additional SLN sites may be identified and these findings may influence operative positioning and the regions to be prepped and draped. The arm(s) and leg(s) when performing SLN biopsies in the axillae and groins, respectively, should be circumferentially prepped and draped so position changes can be performed sterilely to facilitate adequate exposure of the lymph node basins intended for biopsy. Moreover, primary lesion(s) intended to undergo wide local excision should also be clearly visible and accessible.
- Whenever possible, patients should be positioned in a way to expose both the SLN and wide excision sites in one supine or lateral position. This will allow one session of prepping and draping and avoid the time it takes to change positions. This can usually be accomplished when the primary lesion is on one of the extremities, anywhere on the trunk or head and neck locations when all of the SLN sites are on the ipsilateral side of the primary, and anywhere on the anterior trunk and anterior head and neck regions even when the draining nodal are bilateral. In contrast, the most problematic locations are posterior neck and trunk lesions close to the midline when bilateral nodal basin (i.e., both axillae, both cervical, or both inguinal) drainage is identified or two or more different basins on opposite sides of the body (i.e., left axilla and right neck) contain SLNs. In these latter scenarios, at least one position change will be required.
- When foot/lower leg cutaneous lesions localize SLN(s) to the popliteal fossae, prone positioning is best suited for such patients for adequate visualization and access to the SLN(s). The patient may then be subsequently repositioned in the supine or lateral decubitus position for excision of corresponding primary lesions if that site is not accessible in the prone position. Another option for this scenario would be to place the patient in the lateral decubitus position, avoiding a position change.
- The patient should also be positioned to facilitate the surgeon in scanning the nodal basin and the intervening tissues with the handheld gamma probe positioned perpendicular to or in a direction pointed away from the injection site to limit the "shine-through" radioactivity emanating from the injection site that may obscure the radioactivity in the SLN and in turn hamper ones ability to discriminate SLN radioactivity from the injection site activity.
- After the patient is positioned, multiple steps are carried out to accomplish a complete and accurate sentinel lymphadenectomy.[24]

INJECTION OF BLUE DYE

- Once the patient is positioned, the vital blue dye is injected at the primary site using a similar four-point intradermal injection technique that was used for injecting the radiotracer. Approximately 2 to 3 cc of blue dye is injected using 1-cc tuberculin syringes and a 25-gauge needle (**FIG 12**).
- Although it is not mandatory that the blue dye be used, most surgeons feel that the two localizing agents complement each other in successfully identifying and removing the SLNs.
- The blue dyes most commonly used are isosulfan blue and methylene blue in the United States and patent Blue V in Europe and Australia. The isosulfan seems to concentrate in the SLNs in a more uniform manner compared to methylene blue, making it easier to visualize. Some surgeons prefer to use methylene blue because of the potential, albeit very low risk, of an allergic reaction to isosulfan blue.[25] However, at least one report documents increased postoperative complications with the use of methylene blue.[26]
- After the blue dye is injected, the patient is then appropriately prepped and draped. The time that transpires during the prepping and draping is long enough for the blue dye to travel through the lymphatic vessels to the SLNs.

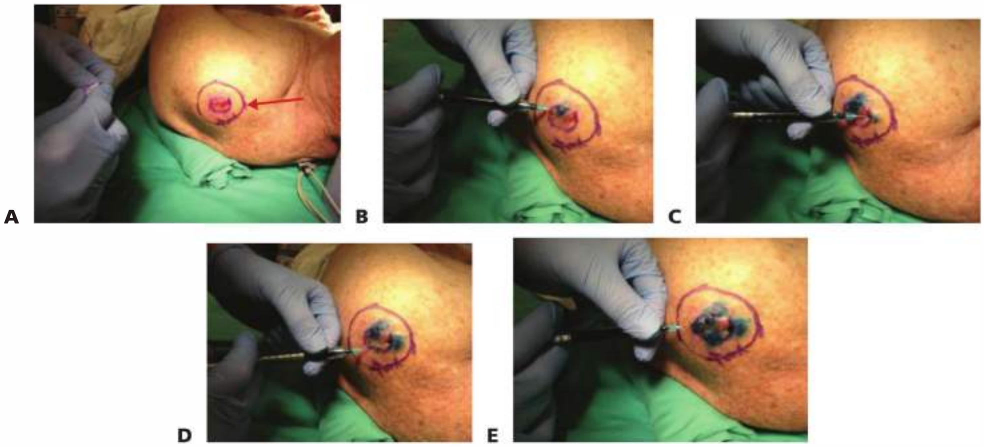

FIG 12 ● Blue dye injection technique. The primary melanoma is shown **(A)** with planned margins measured and drawn *(arrow)*. The four-point intradermal injection of the blue dye is shown in images **(B–E)**.

INTRAOPERATIVE LOCALIZATION AND SURGICAL EXCISION OF THE SENTINEL NODES

- Most commonly, both the SLN biopsy and the wide excision of the primary site will be performed in the same operative setting. Generally, if the blue dye is used, the nodal basin exploration and removal of the SLN is approached first in order to take advantage of the visualization of the SLN afforded by the blue dye. If the wide excision is performed first, the blue dye will be removed as well, limiting the continued flow of dye to the SLN and in turn the visualization of the SLN.
- The use of the handheld gamma probe is central to this procedure. The probe is placed within a sterile ultrasound cover after the patient is prepped and draped.
- If the planned wide excision site (injection site) is in close proximity to the nodal basin, the shine-through activity may be greater than the sentinel activity. The following maneuvers are used to discriminate SLN activity from the shine-through activity: As the gamma probe is transcutaneously passed from the injection site to the nodal basin, the counts will diminish in proportion to the distance from the injection site. A sentinel node area is identified when the radioactive counts increase as the probe is moved further away from the injection site compared to a location that is closer to the injection site (**FIG 13**). The radioactive counts should again decrease as the gamma probe is passed further beyond the sentinel node. The use of a removable collimator can be helpful in reducing shine-through activity. Make sure that when passing the probe from the injection site to the nodal basin, the probe is positioned perpendicular to or directed away from the injection site. If none of these maneuvers are successful, the wide excision can then be performed first, which very effectively removes the background shine-through counts. This maneuver will also remove the blue dye and stop the continued flow of dye to the nodal basin and in turn significantly reduce the ability to use the blue dye as an aid in identifying the SLN.
- If the patient is positioned correctly, the surgeon will be able to transcutaneously localize the epicenter of the SLN activity with the handheld gamma (which represents a small percentage of the radioactivity at the injection site)

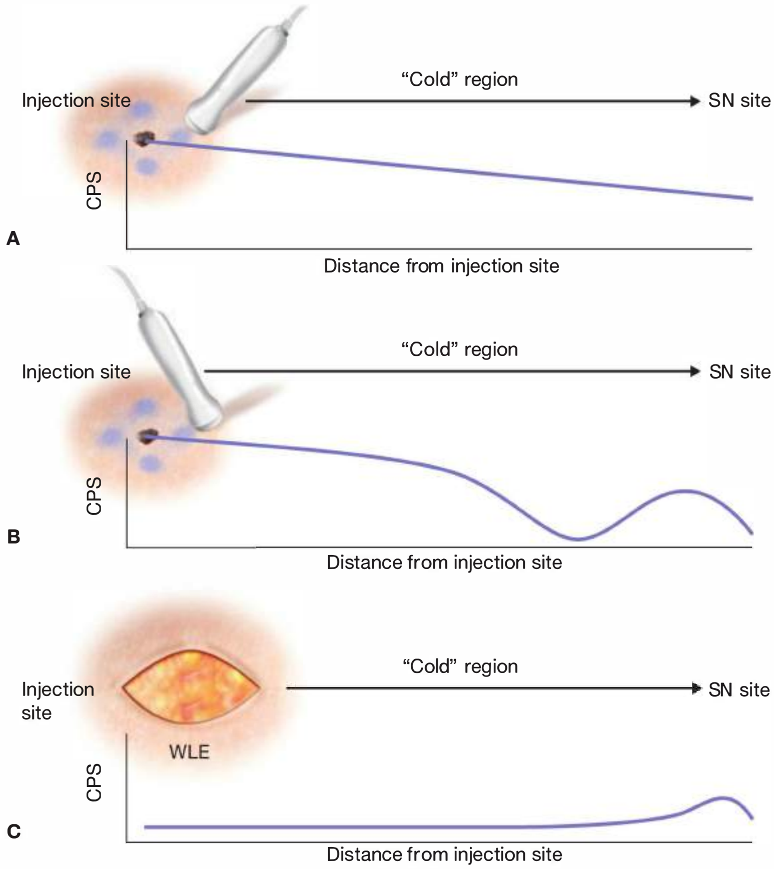

FIG 13 ● Conceptualization of intraoperative SLN scanning. Three conceptual graphs are shown, with the x-axis representing radioactive count per second (CPS) and the y-axis distance of the SLN from the injection site. The amount of radioactivity that travels to the SLN is a small percentage of the radioactivity injected. Shine-through radioactivity from the injection site may obscure the ability to detect to the radioactivity in the SLN, particularly if the injection is close to the nodal basin and/or SLNs. Although placing a collimator on the end of the probe may block out much of the shine-through activity and allow the detection of the SLN, it also narrows the exposed area of radioactivity detection crystal on the probe and in turn reduces the counts detected from the node. In **(A)**, scanning for the SLN is performed with the probe pointed at the injection site. Even though the probe is moving away from the site, shine-through counts detected may be greater than the counts in the SLN, limiting the ability to discriminate SLN activity versus shine-through injection activity. In **(B)**, the same maneuver is performed, now with the probe pointed away from the injection site, allowing the detection of a step-up in activity as one reaches the SLN. In **(C)**, the wide excision has been performed, essentially removing any shine-through activity and in turn facilitating the detection of the SLN activity. This latter maneuver is often used when trying to find the remaining SLNs with less radioactivity after the first, most radioactive SLN has been identified and removed.

within the nodal basin without too much difficulty especially if the injection site is at some distance from the nodal basin (**FIG 14**).

- The epicenter of SLN activity is marked with a sterile marking pen and used for surgical incision planning.
- The nodal basin is approached with a small biopsy incision directed by the handheld gamma probe over the epicenter of radioactivity. We make sure that this biopsy incision can be easily incorporated and excised en bloc as part of a formal lymphadenectomy incision if that is required at a later date should the sentinel node reveal metastases (**FIG 15**).
- The dermis and subcutaneous tissue is divided with cautery, advancing deeper for approximately 1 to 2 cm at a time between pauses during which time the trajectory of the line of dissection toward the radioactive signal may be confirmed with the gamma probe. Using this technique, the surgeon is able to localize and directly advance to the targeted SLN(s) with minimal tissue disruption (**FIG 16**).
- In most situations, the SLNs are deep to the subcutaneous investing fascial layer (i.e., Scarpa's in the groin and platysma in the neck), which needs to be incised in order to enter the nodal basin proper (**FIG 16C**).

FIG 14 ● Thoughtful positioning in the OR. The left lateral position is correctly chosen in this patient with a primary melanoma on the right midback with a lymphoscintigraphy showing drainage to the right axilla and a probable in-transit node over the scapula. This position facilitates not only performing the SLN biopsies and the wide excision without a position change but also scanning for the SLN nodes perpendicular to and directed away from the injection site. Under each frame, the numbers represent the counts per second of radioactivity where the gamma probe is placed. Note that the highest count is over the injection site, then counts decrease moving away from the injection until they increase to identify the in-transit node, then decrease again as the in-transit node is passed, then increase again in the axilla. The last frame in the second column shows the SLN sites marked and in the last column on the right the two frames show the in-transit SLN and the axillary SLN.

A B

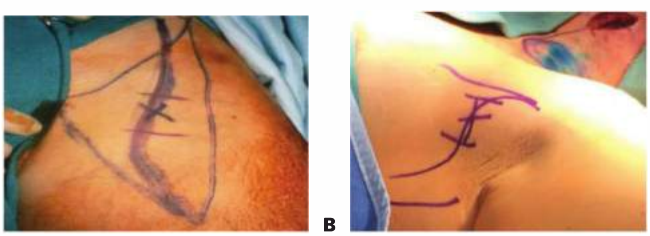

FIG 15 ● Skin marking and planned SLN biopsy incision. Examples of transcutaneous SLN localization with the gamma probe in two nodal basins: **(A)** inguinal and **(B)** axillary. In each frame, the SLN biopsy incision is drawn to incorporate the location of the SLN, marked with an "X" as well as a future formal lymphadenectomy should that be required.

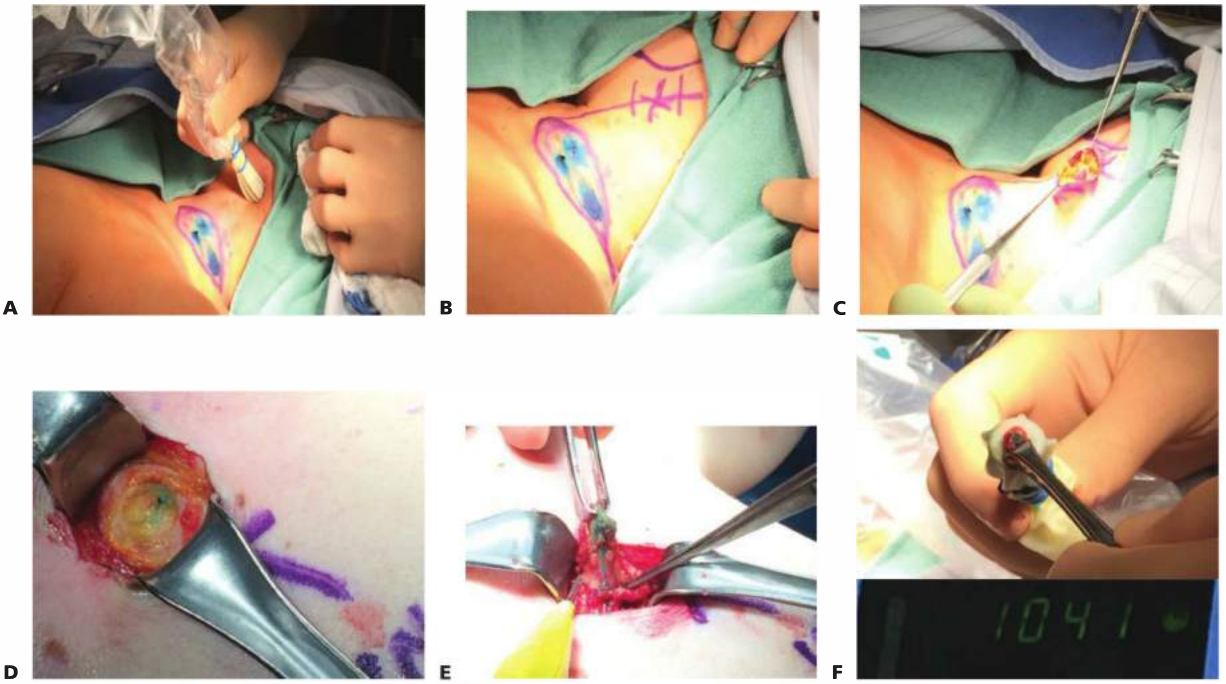

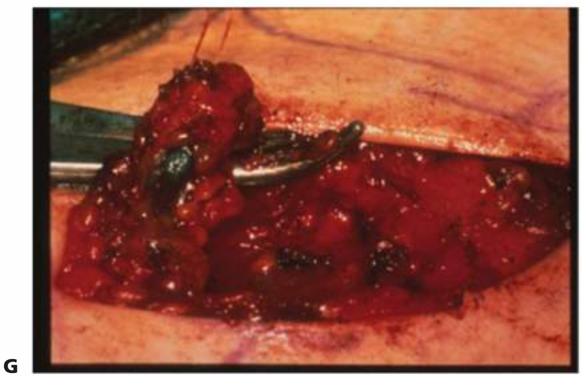

FIG 16 ● Steps in excising the SLNs. The surgical steps used in the actual removal of the SLNs. (**A**) Transcutaneous localization, **(B)** marking the epicenter of radioactivity and planning the incision, **(C)** making the incision, incising the dermis and the subcutaneous tissue to expose the fascia, **(D)** incising the fascia to enter the nodal basin proper, **(E)** dissecting the SLN from the surrounding tissue, delivering the node into the wound, then removing the node after clipping or clamping then cutting the afferent vessels and vascular pedicle to remove the node, **(F)** ex vivo counting of the SLN, **(G)** rechecking the nodal basin for significant residual radioactivity, and removing additional SLNs.

- Skin hooks, handheld Richardson-type retractors, or blunt self-retaining retractors can be used for exposure (**FIG 16D**).
- Once the nodal basin is entered, the localization of the SLN may be further facilitated by either following a blue-stained lymphatic channel toward the blue node or by direct visualization of the blue-stained lymph node (**FIG 16E**).
- The visualization of the blue dye is helpful in rapidly identifying which lymph node has accumulated the radiotracer, discriminating the SLN from the other nonstained surrounding nodes that are usually in close proximity.
- The SLN is then dissected free from the surrounding tissues. This is facilitated by gently grasping the node with a pickup and then delivering the node to a more superficial location in the basin. We prefer to use a pickup with broad and blunt jaws such as Hayes-Martin, rather than a DeBakey or Adson, to avoid tearing the node. Some surgeons place a figure-of-eight stitch in the node for this maneuver, but this can also carry the risk of tearing the node. Once mobilized and delivered, the intervening lymphatic channels can be identified because of the blue dye and are clipped or tied to limit the development of a postoperative seroma. The vascular pedicle is then clamped, cut, and then tied.
- Ex vivo counts of the node are then documented with the handheld gamma probe and recorded (**FIG 16F**). After removing the initial SLN, the nodal basin is then scanned for residual radioactive counts with the gamma probe pointed away from the injection site. If the background activity in the nodal basin is still high because of close proximity to the injection site, the wide local excision of the primary site may be performed. This removes any significant background activity (shine through) and

allows for a more complete evaluation of residual SLN counts within the nodal basin.

- Additional nodes identified by the presence of high residual radioactivity and/or blue dye staining are then removed and labeled as sentinel nodes, with numbers assigned sequentially in the order of identification. Nodes are defined as sentinel if they are blue and/or contain radioactivity significantly above background. Nodes are removed and labeled as "sentinel" until no focal basin radioactivity is greater than 10% of the "hottest" sentinel node removed.
- The skin and soft tissue between the injection site and nodal basin(s) should also be scanned to identify and subsequently remove any "in-transit" or "interval" SLNs. Similarly, if the background counts are too high because of proximity to the injection site, the wide excision can be performed to decrease the shine through and facilitate the exploration for the in-transit SLNs.

CLOSURE

- Hemostasis should be ensured and divided fascial layers closed with interrupted 3-0 absorbable sutures. Drains are usually not needed.
- Skin may then be approximated using interrupted, buried absorbable sutures in the dermis followed by a running subcuticular stitch with a 4-0 absorbable monofilament suture. Steri-Strips or a skin adhesive may then be applied.

PATHOLOGIC EVALUATION OF THE SENTINEL NODES

- A dedicated dermatopathologist should process the node and read the pathology slides.
- The SLN are serially sectioned using either along the long axis of the node or a bread-loafing technique across the short axis of the node (**FIG 17**). The width of the serially sliced sections is partly dependent on the size of the node but usually are made in 2-mm intervals.
- Frozen section evaluation of the SLNs are not recommended out of concern of leaving behind nodal tissue with small-volume diseases in the cryostat and therefore will go undetected. Such events could reduce the accuracy of the pathologic evaluation of the SLN.[27]
- The tissue slices are embedded in paraffin blocks for permanent section evaluation. All the blocks are stained with hematoxylin and eosin. If these are negative, additional sections are taken for immunostaining.

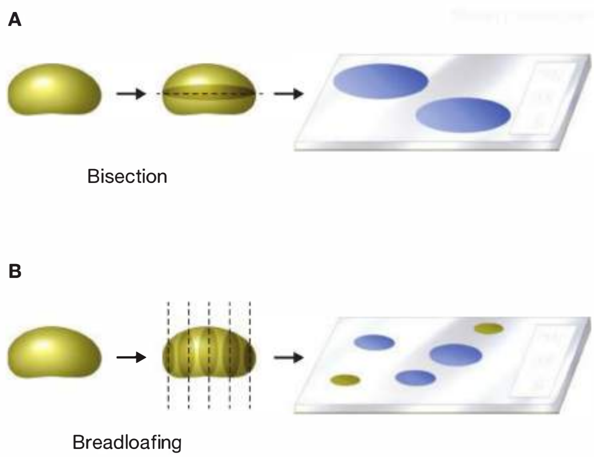

FIG 17 ● Histologic examination of the SLN. Schematic representation of sectioning of lymph nodes, with routine bisection in **(A)** creating two samples to be stained and serial sectioning in **(B)**, resulting in multiple sections for staining.

COMPLICATIONS

- No identifiable drainage to SLN(s)
- Removing the "wrong" node and leaving behind the true SLN
- Hematoma
- Seroma
- Infection (cellulitis or infected seroma)
- Paresthesias
- Lymphedema

TECHNIQUES

POSTOPERATIVE CARE

- Always examine the patient before discharge to make sure a hematoma has not developed.
- Instruct the patient what to look for in terms of seroma and surgical site infection.
- Remind them about the blue dye in the urine.
- Keep the SLN site dry for 48 hours.

OUTCOMES

- Using the dual localizing technique of radiotracer and blue dye injections, the SLN identification rate approaches 100%.[3]
- The frequency of a false-negative event defined as the development of clinical nodal disease in the same nodal basin subsequent to the removal of a negative SLN is 3% to 5%.[28] A false-negative event is most commonly a result of very small volume disease undetected by the original pathologic evaluation of the SLN removed, and therefore, a formal lymphadenectomy was not performed. For such an event to occur, another lymph node with subclinical disease was likely present in the same nodal basin at the time of the SLN procedure as the source of the subsequent clinical nodal recurrence. Another reason for a false-negative event leading to a nodal recurrence is the inaccurate identification of the SLN and removing a node that was not sentinel and leaving behind the true SLN that harbored microscopic disease.[28]
- Lymphedema, although rare, can occur and is most common following an SLN biopsy in the groin in conjunction with a wide excision on the thigh or lower leg.

PEARLS AND PITFALLS

Head and neck primaries	■ The lymphatic drainage from these primary lesions is the most ambiguous and least predictable. Therefore, a SPECT-CT lymphoscintigraphy is strongly encouraged. ■ Due to the close proximity to important structures when treating melanomas of the face, the excision margins for the primary lesion may have to be selectively narrowed to avoid injury to these structures and any associated functional or cosmetic impairments (see Part 5, Chapter 26). It is important to note that injected blue dye at the primary site left behind in the remaining skin after the wide excision can tattoo the skin for long periods of time. Therefore, excision margins are clearly delineated with a marking pen prior to the injection of the blue dye. In this way, the volume of dye injected can be adjusted to ensure that the blue staining is limited to the skin to be excised. ■ The SLNs in the neck are surprisingly small; the use of blue dye is particularly helpful. ■ The lymphatic drainage in the head and neck region is very rapid and the flow of blue dye can be diluted out if too much time transpires between the injection and the exploration of the nodal basin for the SLN. Therefore, in contrast to other primary sites, the blue dye is injected under sterile conditions after the patient is prepped and draped. ■ The SLNs in the neck region are often adjacent to important nerves, such as the spinal accessory, great auricular, and branches of the facial nerve.
Injection of blue dye	■ An injection performed in the intradermal location creates some resistance and can result in the needle becoming separated from the syringe, splattering blue dye on oneself, the patient and OR staff. Therefore, the use of 1-cc Luer lock–type syringes is recommended. ■ Remember to tell patient that his or her urine will be blue/green colored for 24 hours. ■ Any blue dye staining of the skin not removed by the wide excision may take several months to completely fade away. ■ If the patient has already had a wide excision, a preoperative discussion should take place about whether or not to use the blue dye for the planned SLN biopsy. Another excision should not be performed just to remove the blue dye to avoid a tattooing effect. The only time that another excision should take place is when it is necessary to remove the injection site radioactivity that is obscuring your ability to adequately scan the nodal basin for the SLN.

Complications	■ **No drainage observed from the injection site** to an SLN is almost always a result of an error in injection technique. The appropriate technique involves an intradermal injection that raises a wheel and causes some discomfort to the patient. The most common error is injecting the radiotracer too deep into the subcutaneous tissues where the concentration of lymphatic vessels is low or directly into the excisional biopsy site. Hallmarks of a subcutaneous injection include lack of pain during the injection, radiotracer activity seen in the liver on the lymphoscintigraphic images, and no drainage to a nodal basin. ■ **Recurrent seromas** at the SLN biopsy site are conveniently handled by using a "seroma cath" system, composed of a percutaneously placed angiocatheter, a clear tubing, and a small suction bulb. This technique can also be used to treat infected seromas along with antibiotics rather than opening up the wound. ■ **Incorrect identification of the SLN** can lead to leaving behind microscopic nodal disease, which will be the source of subsequent clinical lymph node recurrence. One important maneuver to minimize the frequency of such events is to always view the lymphoscintigraphic images prior to the surgery and display the images in the OR rather than depending on the reading by the radiologist.

Chapter 28

Axillary Lymph Node Dissection for Melanoma

Michael S. Sabel

DEFINITION

- Axillary lymph node dissection (ALND) involves the surgical excision of the lymph node–bearing tissue from the axilla. For melanoma patients, a complete ALND is considered the standard of care for patients with both micrometastatic disease, as demonstrated on sentinel lymph node (SLN) biopsy and clinically evident disease.
- The axilla is divided into anatomic levels based on the relationship of the nodes to the pectoralis minor muscle (**FIG 1**). Level I nodes are located lateral to the pectoralis minor, level II nodes are seated deep to the pectoralis minor, and the level III nodes are medial to the pectoralis minor. For patients with clinical evident axillary disease, a level I-III dissection is recommended. For patients with a positive axillary SLN biopsy, a level I-III dissection is often performed, but a level I-II dissection may be adequate.[1,2] This chapter will describe an ALND encompassing levels I, II, and III.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history should focus on the patient's melanoma history, including the histology of the primary tumor, disease-free interval between the primary diagnosis and the diagnosis of regional metastases, and the extent of both locoregional and distant disease. The history should also focus on comorbidities, past medical history, and medications that might impact the patient's surgical candidacy.
- The history should also include a thorough review of systems, specifically looking for symptoms suggestive of distant disease. Patients with symptoms worrisome for stage IV disease should have body imaging before proceeding with surgery.
- A complete physical examination should pay particular attention to signs of local, regional, and distant disease. The site of the primary tumor and the skin between it and the regional basin should be examined for signs of in-transit recurrences. A complete lymph node exam should be performed. This should not just be limited to the axilla of concern but bilateral cervical, supraclavicular, epitrochlear, axillary, and inguinal basins. Suspicious nodes outside of the draining basins may represent stage IV disease.
- For the involved axilla, the exam should focus on the extent of disease, including the size of the involved nodes and fixation. The ipsilateral arm should be examined for lymphedema, weakness, or sensory deficit, as these may be indicative of involvement of the axillary vein or brachial plexus. You should also document any conditions affecting the shoulder or upper extremity, which limits range of motion.
- For patients who had an SLN biopsy or excisional biopsy, it is important to document any sensory or motor deficits that may have occurred at the first surgery as well as any seroma, hematoma, or infection. It may also be helpful to note the orientation of the incision, as this may impact the orientation of the ALND incision.
- It is important to review with patients the expected postoperative course including drain management and arm exercises, as well as short-term and long-term morbidity, including the risk, prevention, and management of lymphedema.

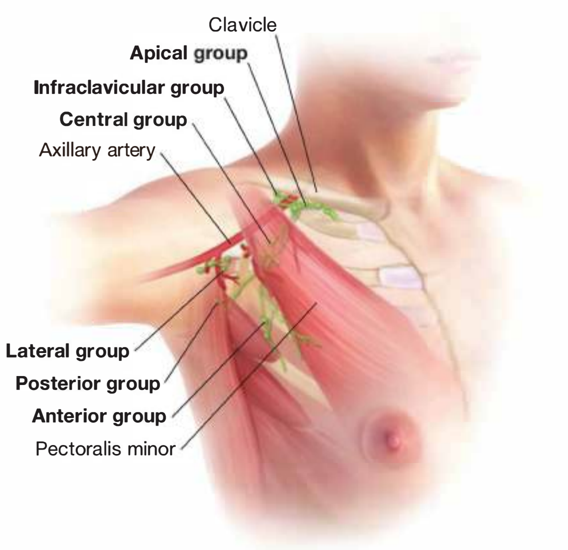

FIG 1 ● Levels of axillary lymph nodes. The level I nodes are located lateral to the pectoralis minor muscle, the level II nodes are located deep to the pectoralis minor, whereas the level III nodes are located medial to the pectoralis minor.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- For asymptomatic patients with micrometastatic disease identified on SLN biopsy, there are no imaging studies necessary before proceeding with ALND.[3] For patients with thick, ulcerated tumors (American Joint Commission Center [AJCC] stage T4b) and a positive SLN, the risk of distant disease may justify preoperative body imaging, with either a computed tomography (CT) scan or positron emission tomography (PET)/CT.[4] However, for patients with micrometastatic disease, preoperative staging studies have a high false-positive rate, may lead to unnecessary follow-up studies or biopsies, and rarely alter surgical decision making.
- Patients with symptoms concerning for metastatic disease should undergo staging with either a CT of the chest, abdomen, and pelvis or a PET/CT and a magnetic resonance imaging (MRI) of the brain. Patients with clinically evident regional disease should also undergo distant staging, as there

is a higher chance of detecting metastatic disease that might alter surgical decision making.[3]

- For patients with fixed, matted lymph nodes; skin involvement; or neurovascular symptoms of the involved arm (paresthesias, motor and sensory deficits, lymphedema, limited range of motion), MRI of the chest wall can be helpful in determining resectability. Unresectable or borderline resectable patients could be considered for neoadjuvant therapy with newer biologic and targeted therapies.

SURGICAL MANAGEMENT

Preoperative Planning

- In the preoperative area, the side of the ALND should be clearly marked and confirmed with the patient before proceeding to the operating room (OR).
- Intravenous (IV) antibiotics are indicated for ALND.[5] Sequential compression devices (SCDs) should be used for deep venous thrombosis (DVT) prophylaxis. Patients with a history of DVT or genetic predisposition toward clotting should receive subcutaneous heparin.
- Many surgeons prefer the use of short-acting neuromuscular blocking agents during induction, so that the patients are not paralyzed during the procedure. This allows identification of the thoracodorsal, long thoracic, and medial and lateral pectoral nerves by mechanical stimulation. However, this is not essential and some surgeons prefer paralysis with a long-acting neuromuscular blocking agent to prevent muscular contraction and allow for retraction of the pectoralis major and minor muscles. Either way, this should be discussed with the anesthesiologist prior to the case.

Positioning

- The patient should be positioned supine on the OR table, toward the edge of the side of the ALND so that the posterior axillary line is in-line with the edge of the table. The ipsilateral arm is abducted at 90 degrees on a padded arm board. It is important not to extend the arm past 90 degrees to avoid brachial plexus injury.
- The endotracheal tube should be located away from the involved arm and adequate space should be preserved above the arm for the surgical assistant.
- The chest wall, lower neck, and entire arm should be prepped and draped into the surgical field using a sterile stockinette and Kerlix wrap. This allows the arm to be rotated over the chest, relaxing the pectoralis major and minor (**FIG 2**).

FIG 2 ● Preoperative positioning and draping for an ALND. The arm should be prepped into the field with a stockinette and Kerlix wrap so it can be rotated over the chest during the procedure.

INCISION

- Typically, a "lazy S" incision is used along the pectoralis major muscle, extending posteriorly at the level of the axillary hair line, and then inferiorly along the latissimus dorsi muscle (**FIG 3**). For patients with a prior excisional or SLN biopsy incision, this should be encompassed into the ALND incision, and thus might impact the choice of incision. For patients with bulky adenopathy, particularly those with nodes close to the skin, the skin overlying the nodes should be included with the specimen. Be sure there is adequate skin to allow for a tension-free closure.
- After incising the skin with a scalpel, electrocautery is used to divide the subcutaneous tissue and elevate skin

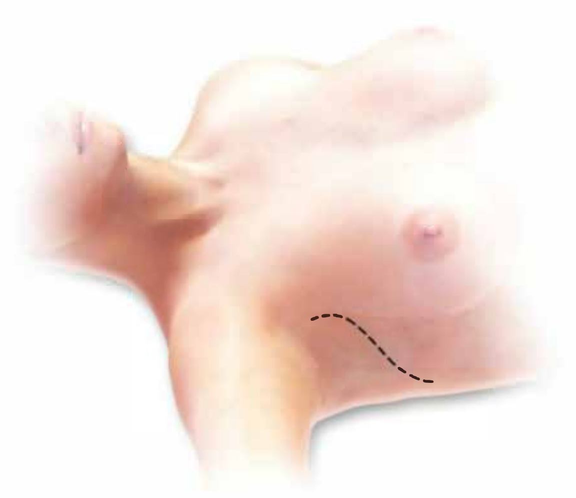

FIG 3 ● The "lazy S" incision for an ALND. One can begin with the transverse incision and extend the pectoralis and latissimus arms as needed.

TECHNIQUES

flaps. Unless mandated by the presence of bulky disease, the skin flaps should not be too thin and get progressively thicker as they are raised. Thin skin flaps will increase the risk of wound complications and give the axilla a sunken-in appearance.

- The skin is elevated using skin hooks or sharp rakes. It is important that the surgical assistant holds the flaps straight up and not retract them back (which residents will sometimes do in order to get a better view). The surgeon retracts the tissue with the opposite hand in order to apply strong countertraction and identify the appropriate tissue plane.
- Surgeons are often hesitant to go too far or too deep while elevating the inferior skin flap at this initial point of the operation for fear of injuring the long thoracic nerve. However, raising an adequate inferior flap allows for greater mobility of the specimen and easier dissection. The inferior flap should be raised to approximately the level of the 5th rib.
- Once the flaps are elevated, the next step will be to identify some of the borders of the axilla: the pectoralis major and minor muscles, the latissimus dorsi muscle, and the axillary vein. Although individual surgeons have their preferences, there is no correct order, and the presence of large lymph nodes might mandate changing your approach. In this chapter, we will describe a medial-to-lateral approach.

IDENTIFICATION AND RETRACTION OF THE PECTORALIS MAJOR AND MINOR

- The pectoralis major muscle is usually the easiest margin to begin with, as it is often easily palpable upon raising the flaps (and may become apparent while elevating the superior flap). Once the pectoralis major is identified, the length of the lateral border should be exposed (**FIG 4**).
- Once the pectoralis major muscle is freed, it is retracted anteriorly and medially to expose the interpectoral nodes and the pectoralis minor muscle. This, and the remainder of the operation, is facilitated by the use of a Thompson retractor (**FIG 5**).
- The tissue between the pectoralis major and minor muscle that contains the interpectoral (Rotter's) nodes is included with the specimen, dissecting it off the pectoralis minor muscle. As the dissection proceeds onto the pectoralis minor, the medial pectoral bundle can be observed coming either through or lateral to the pectoralis minor (**FIG 6**). This should be preserved. There is often an accompanying vein with a branch going into the specimen. This will need to be clipped, taking care not to clip the medial pectoral nerve.

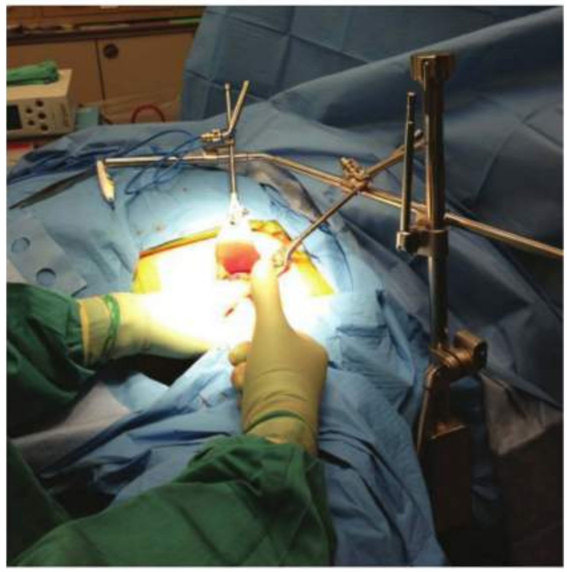

FIG 5 ● The Thompson retractor provides excellent exposure for an ALND.

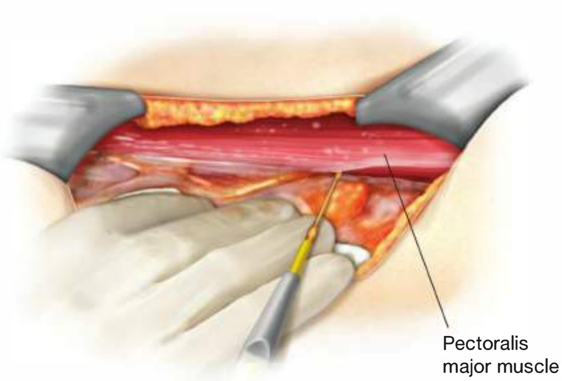

FIG 4 ● The pectoralis major muscle is identified and cleaned off along the lateral edge.

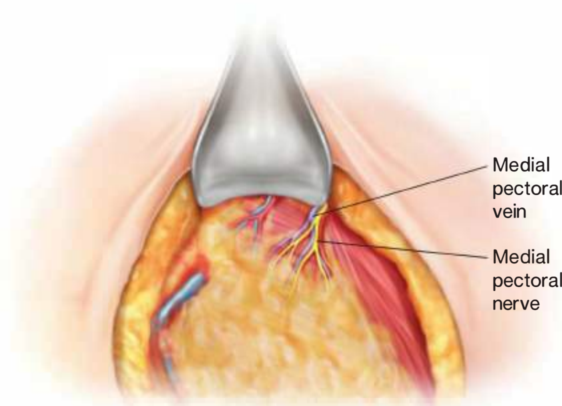

FIG 6 ● The medial pectoral nerve.

- For patients undergoing an ALND for a positive SLN, the pectoralis minor can be preserved. The lateral edge of the pectoralis minor muscle is freed by dividing the axillary fascia (FIG 7). The axillary fascia is an extension of the clavipectoral fascia that divides the subcutaneous fat from the axillary fat. Upon dividing the fascia, you will notice the protrusion of a more yellow, globular fat. This is the lymph node–bearing tissue that needs to be excised.
- The axillary contents are now swept laterally and the pectoralis minor muscle exposed along its length. Once this is done, the Thompson retractor can be repositioned so that both the pectoralis major and minor can be retracted anteriorly.
- If there is bulky adenopathy and exposure of the upper axillary lymph nodes is difficult, it may be necessary to divide the pectoralis minor muscle, and this is described subsequently.

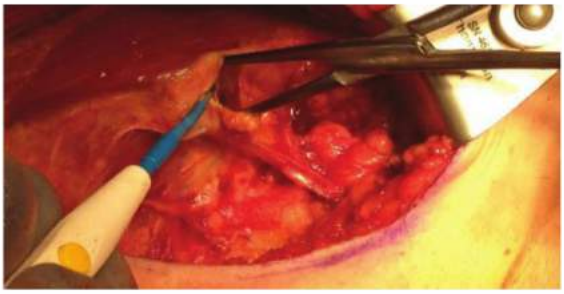

FIG 7 ● The axillary (clavipectoral) fascia is divided with cautery, revealing the axillary fat underneath.

IDENTIFICATION OF THE AXILLARY VEIN

- The vein often becomes visible medially during the elevation of the pectoralis musculature. If not, its general location can be anticipated by identifying the underarm dimple at the inferior aspect of the upper arm and tracing it toward the chest wall (FIG 8). Dissection down to the vein should not be performed directly with cautery to avoid an inadvertent injury, but rather, a careful dissection is recommended (FIG 9). Small venous branches and lymphatics should be clipped or suture ligated. It is also important not to find yourself superior to the vein, as the axillary artery and brachial plexus can be injured. Once the vein has been identified, the inferior margin should be cleared. It is not necessary to skeletonize the vein.

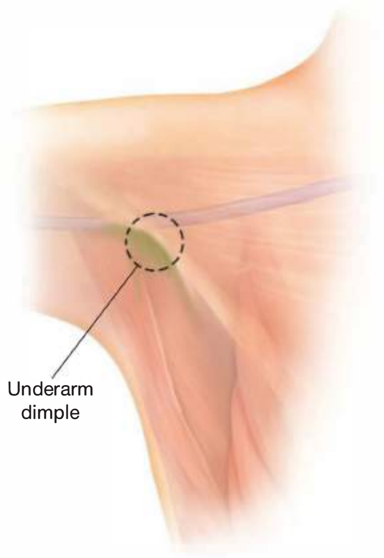

FIG 8 ● The position of the axillary vein in the axilla can be estimated by locating the underarm dimple and tracing this back toward the chest wall.

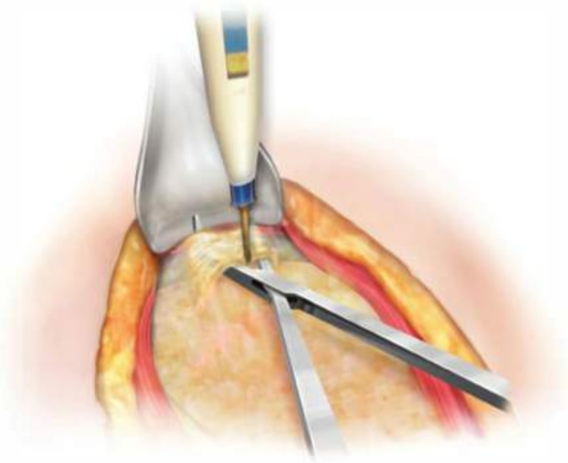

FIG 9 ● Exposure of the axillary vein is accomplished by careful dissection with a right angle and cautery.

THE LATISSIMUS DORSI MUSCLE

- The final boundary to identify is the latissimus dorsi muscle. Again, this is often seen during the elevation of the inferior flap. If not, the lateral skin should be retracted laterally using skin hooks or sharp rakes, and the axillary contents retracted medially. Dissection down through the subcutaneous fat will identify the muscle (FIG 10). In obese patients, be careful not to overestimate how lateral the muscle is, as you may dissect past it and raise an unnecessary posterolateral flap. Likewise, being too medial puts the thoracodorsal bundle at risk. Once identified, it should be cleared by staying on the anterior surface of the muscle.

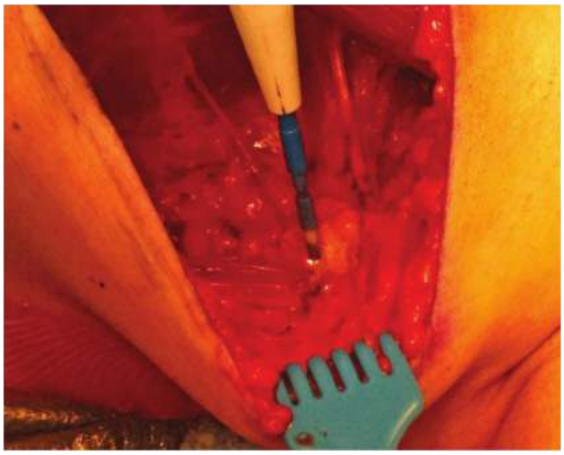

FIG 10 ● With lateral traction on the skin, the latissimus dorsi muscle is exposed and cleared on its anterior surface.

- In a small percentage of cases (approximately 5% to 7%), you may identify a more superficial muscle extending from the latissimus dorsi muscle to the pectoralis muscle, over the axillary vein. This is a muscular–tendinous structure known as a Langer's arch (**FIG 11**). This can often be disorienting, so it is important you be aware of this possibility and continue to dissect laterally to identify the latissimus dorsi. The Langer's arch, if present, will need to be divided and excised with the specimen.
- The latissimus muscle should be cleared up to the point where the tendinous insertion is reached beneath the axillary vein.

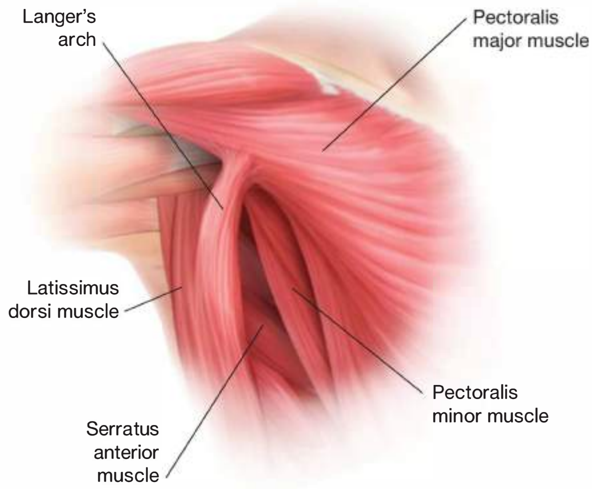

FIG 11 ● Anatomy of a Langer's arch.

THE THORACODORSAL NEUROVASCULAR BUNDLE

- Once the intersection between the vein and the latissimus is identified, the axillary contents are freed from lateral to medial. Lymphatics should be clipped rather than cauterized. The intercostobrachial nerve will be in this tissue, extending toward the arm and is commonly sacrificed during this operation. It is important to note that the intercostobrachial nerve does not need to be sacrificed. It can be dissected free by bivalving the specimen and freeing the nerve. However, this is not commonly done when an ALND is being performed for known cancer.
- It is important not to divide the axillary tissue to identify the thoracodorsal vein, but rather, make sure all the tissue between the latissimus dorsi and thoracodorsal bundle is dissected and included with the specimen. Failure to do this, for example, making the thoracodorsal bundle the lateral margin, will leave behind several lymph nodes. As these nodes primarily drain the arm, this is particularly important in melanoma.
- As the axillary vein is cleared medially, the thoracodorsal vein can be identified. The thoracodorsal vein comes off the posterior aspect of the vein. The other large tributary off the axillary vein is the lateral thoracic vein, but this comes off inferiorly, which serves as an important clue that it is not the thoracodorsal vein (**FIG 12**). Although the lateral thoracic vein will need to be ligated, this should not be done until the thoracodorsal vein is clearly identified. The thoracodorsal nerve may be directly behind the lateral thoracic vein, so take care when ligating it.
- Once the thoracodorsal vein is visualized, the artery can usually be seen pulsating in close proximity. The nerve, however, at this level, does not run next to the

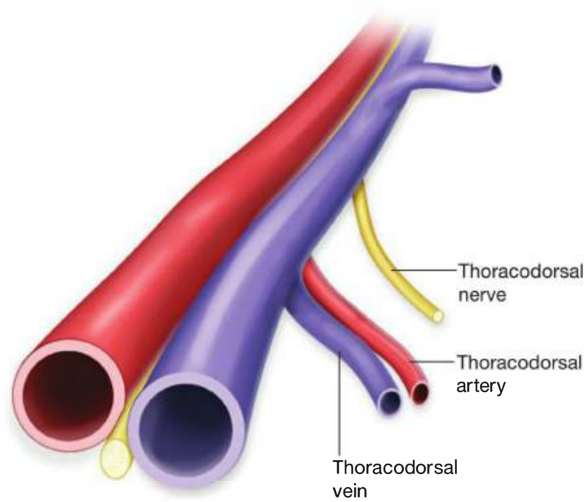

FIG 12 ● Whereas the lateral thoracic nerve enters the axillary vein on the inferior surface, the thoracodorsal vein tends to enter more posteriorly. This can be an important clue as to which vein you are looking at.

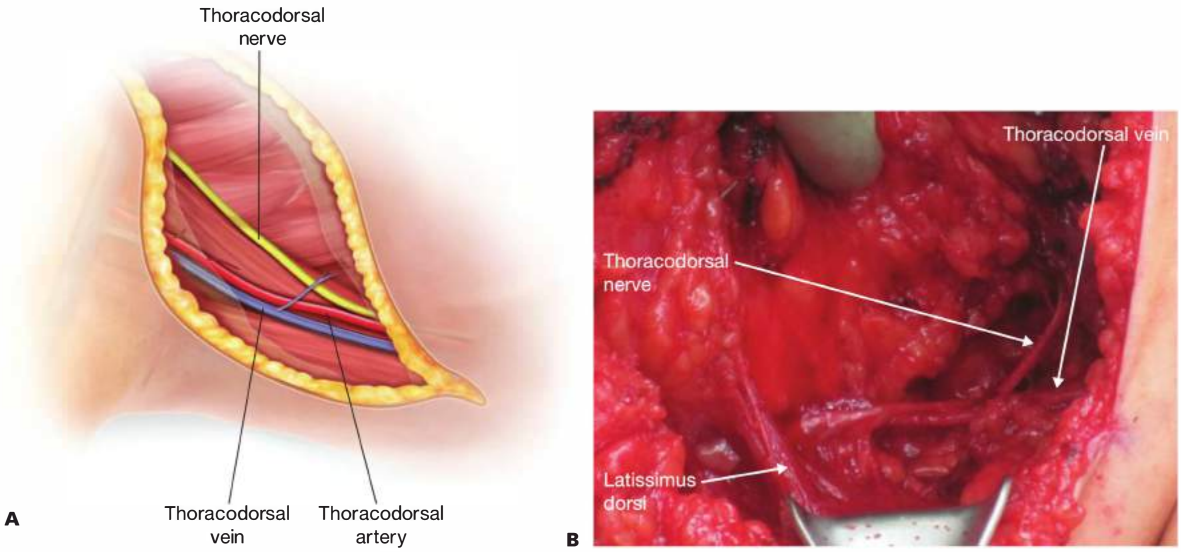

FIG 13 ● **A.** Relationship of the thoracodorsal nerve to the artery and vein. **B.** Intraoperative photo showing the nerve medial to the vein and artery and then joining the bundle inferiorly.

vein but is usually seated more medial, joining the vein and artery 1 to 2 cm inferiorly (**FIG 13A,B**). The nerve can easily be damaged by assuming it is next to the vein and dividing the more medial tissue. Careful dissection, avoiding the electrocautery, should be used to identify the nerve and trace it inferiorly until it joins the bundle.

- Although these anatomic relationships are generally true, the anatomy can be distorted by both bulky adenopathy and prior surgery. These can distort the relative positions of these structures, and this should be considered when having difficulty identifying them.
- Once the thoracodorsal nerve, artery, and vein are identified, they can be traced and dissected free down to their insertion into the latissimus dorsi. This can be facilitated by retracting the axillary contents anteromedially (which can sometimes be done with the long blade of the Thompson retractor). Although this step can be completed later, we prefer to free the entire bundle now, when visibility is optimized (**FIG 14**). There will be branches off of the thoracodorsal toward the specimen that will need to be clipped or ligated.

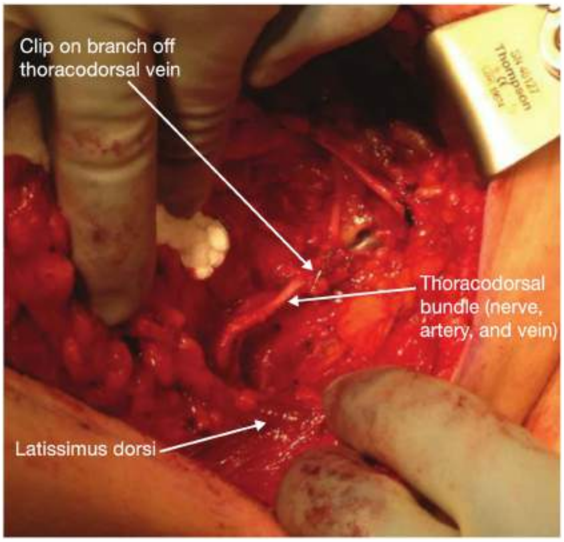

FIG 14 ● With the axillary contents swept medially from the latissimus dorsi, the entire bundle is visualized.

DISSECTION OF THE LEVEL II AND LEVEL III NODES

- Once the thoracodorsal is free, the axillary contents are released and the pectoralis major and minor once again retracted medially and anteriorly. The serratus anterior is identified and you will notice the yellow axillary fat extending up along the serratus, under the pectoralis minor, and along the axillary vein, like the top of a pyramid. This tissue bears the level II and III nodes. The axillary contents are dissected off of the serratus anterior. There is often a large vein that will need to be ligated.
- The intercostobrachial nerve can be seen exiting from the serratus anterior. Although this was likely ligated laterally, it needs to be divided again. The nerve should be cut with scissors flush with the muscle. This minimizes the chance of a neuroma and postoperative neuropathic pain, which is more likely if the nerve is divided with cautery or clips.
- The axillary fat is dissected off of the axillary vein. If you haven't already, you will note the axillary fat extending

superior to the vein, overlying the brachial plexus. This fat should be included with the specimen. There is a plane of tissue between the fat and the brachial plexus that allows this fat to be retracted inferiorly and can be easily dissected free, dividing only some loose areolar tissue (**FIG 15A,B**). Excessive cautery near the brachial plexus is strongly discouraged, and care is taken to clip or suture ligate any small vessels.

- Dissection of the upper axillary lymph nodes is facilitated by adducting the arm over the chest and held by an assistant. This allows the surgeon to reposition the Thompson retractor and gain more medial-anterior retraction, opening the axilla. The level II, and in some patients, the level III nodes, can be accessed this way and dissected from the thoracic inlet off the chest wall. It is important to carefully ligate the specimen and any small vessels, as this is a difficult area to return to in the case of bleeding.
- In many patients, based on body habitus or in the presence of bulky adenopathy, it is not possible to completely dissect the upper axillary lymph nodes just by adducting the arm over the chest. In this case, there are two options. The pectoralis minor muscle can be divided or an infraclavicular approach can be taken.

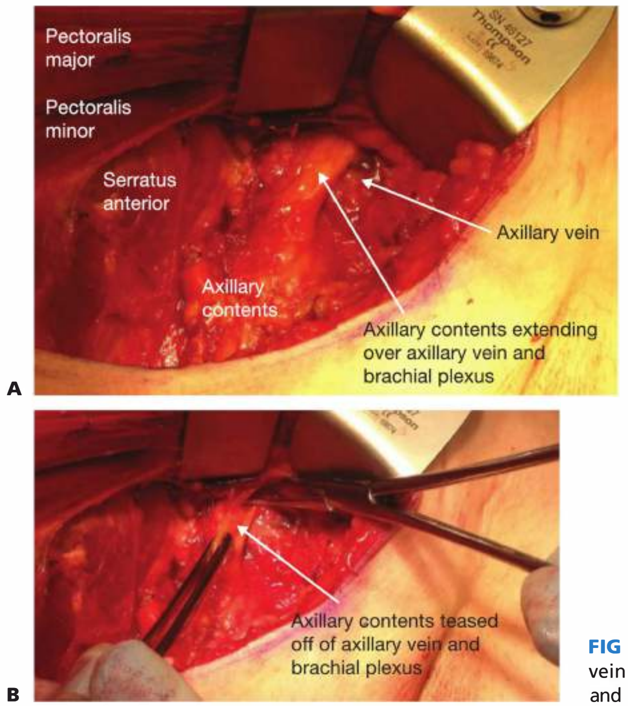

FIG 15 ● **A.** Axillary contents extending superiorly over the vein and brachial plexus. **B.** This is teased down with a forceps and included with the specimen.

DIVISION OF THE PECTORALIS MINOR MUSCLE (PATEY PROCEDURE)

- In some cases, there may be direct involvement of the pectoralis minor muscle by tumor. In this case, the pectoralis minor should be resected en bloc with the axillary contents, dividing the muscle at the insertion point on the coracoid process and dividing it off the chest wall inferiorly (**FIG 16**). This greatly facilitates the removal of the level III lymph nodes.

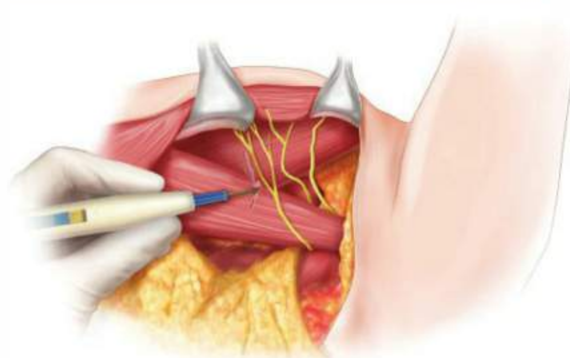

FIG 16 ● The pectoralis minor muscle is divided to obtain easier access to the level III lymph nodes, taking care not to injure the pectoral nerves.

INFRACLAVICULAR APPROACH

- An alternate approach is to make a second transverse incision, approximately 2 cm below the clavicle, and then separating the clavicular from the sternal heads of the pectoralis major (**FIG 17**). The level III nodes can then be excised, taking care not to injure the neurovascular structures. Division of the pectoralis minor is adequate in the great majority of patients, but the infraclavicular approach can be extremely beneficial in patients with bulky adenopathy at the confluence of the cephalic and axillary veins and in patients who recur in level III after a prior level I and II ALND.

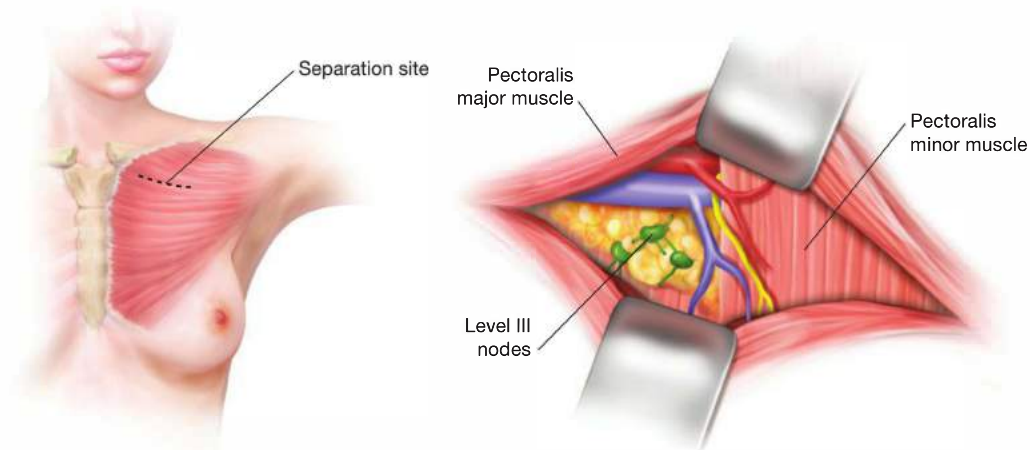

FIG 17 ● An alternate approach to the level III axillary nodes is to make an incision 2 cm below the clavicle and separate the clavicular and sternal heads of the pectoralis major.

EXPOSURE OF THE LONG THORACIC NERVE

- Once the level II and III nodes are free, they are brought laterally. The final structure to identify will be the long thoracic nerve. The nerve is commonly described as running along the serratus anterior, but this is incorrect. It is actually outside the fascia of the serratus, and this is exaggerated by the lateral retraction. Therefore, dissection directly on the serratus anterior will not identify the nerve and may lead to inadvertent injury. Dissection should be performed slightly laterally to the chest wall (**FIG 18**), and cautery should be used sparingly.
- Two anatomic landmarks can often help identify the nerve or estimate its position. First, the long thoracic and thoracodorsal nerve are roughly in the same anteroposterior (AP) plane. Therefore, by noting the location of the thoracodorsal nerve, you can estimate where you should be looking for the nerve. As before, this relationship can be altered by bulky disease or prior surgery. Second, the thoracodorsal vein often gives off a crossing branch toward the chest wall. This usually enters the chest wall at the level of the nerve.
- Once identified, the specimen is separated from the long thoracic nerve by carefully dissecting laterally to the nerve, allowing the nerve to move medially along the chest wall. This can often be done bluntly, but care should be taken not to stretch the nerve too much, as this can lead to injury and a temporary winged scapula.

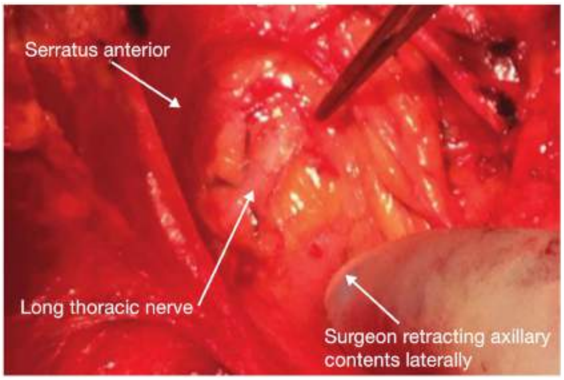

FIG 18 ● The long thoracic nerve is identified just lateral to the serratus anterior, which is emphasized by lateral retraction of the specimen.

REMOVAL OF THE SPECIMEN

- With both nerves free, the next step is to remove the tissue from between the nerves off of the underlying subscapularis muscle. At the level of the axillary vein, the fibrofatty tissue between the nerves should be clamped, taking care to be sure both nerves are free (FIG 19). The tissue is divided and tied off. This can be done in multiple steps. Once the subscapularis muscle is seen, the tissue can be easily divided off the muscle, constantly visualizing the nerves. Excessive lateral retraction can sometimes pull the serratus and the nerve, leading to accidental injury. This dissection should be carried inferiorly, past the point where both nerves enter their respective muscles. This can be facilitated by repositioning of the Thompson retractor.
- At this point, the specimen may still be attached inferiorly. Other than some veins going to the specimen, which can be suture ligated, this tissue can be divided with cautery, releasing the specimen, which is sent to pathology.

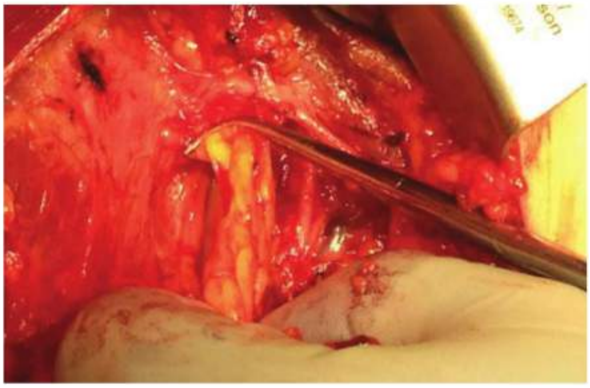

FIG 19 ● The axillary tissue below the vein and between the long thoracic and thoracodorsal nerve is clamped, being sure that both nerves are completely free. The tissue is divided and then taken off the subscapularis muscle.

DRAIN PLACEMENT AND INCISION CLOSURE

- The wound should be irrigated with saline or sterile water and thoroughly examined for hemostasis. This should include retraction of the pectoralis major and minor to explore this area. While assuring hemostasis, be careful not to use cautery near the long thoracic or thoracodorsal nerves.
- A single 10-mm flat channel drain is placed through a separate incision inferiorly and sutured to the skin. The drain should be cut so it just lies inferior to the axillary vein. The incision is closed using deep dermal 3-0 absorbable sutures and, for the typical closure, skin adhesive or absorbable monofilament suture. If a large amount of skin is needed to be excised, Nylon sutures may be appropriate.

PEARLS AND PITFALLS

Preoperative planning	■ A thorough neurovascular exam of the involved extremity is critical. Any suggestion of neurovascular involvement should prompt an MRI to assure resectability. ■ For patients who had prior axillary surgery, document any sensory or motor defects, as a nerve injury may have already occurred. ■ Be sure the patient is aware of what to expect postoperatively, including short-term and long-term lymphedema risk reduction and management.
Positioning	■ Having the arm prepped into the field so that it can be retracted over the chest is critical to performing a complete ALND.
Skin flaps	■ Avoid excessively thin flaps as this will lead to wound complications and a "sunken-in" appearance to the axilla. ■ Raise an adequate inferior flap early, as this allows better mobilization of the specimen and better exposure.
Elevating the pectoralis major and minor	■ Every attempt to preserve the medial pectoral nerve should be made. This requires care when mobilizing the pectoralis muscles.

Identifying the latissimus dorsi	■ Careful dissection should land you on the anterior surface of the latissimus dorsi. If you do not see it, slow down and use a right angle rather than continue to cauterize. If you are too medial, you could injure the thoracodorsal bundle. Be careful you are not too lateral (particularly in an obese patient).
Identifying the vein	■ Use the underarm dimple to estimate the location of the axillary vein. Being too far superior risks injury to the brachial plexus.
Thoracodorsal bundle	■ The thoracodorsal vein comes off the axillary vein posteriorly. If you find a vein coming off the inferior aspect of the axillary vein, it is probably the lateral thoracic, but do not ligate it until you have seen the thoracodorsal. ■ The nerve is usually medial to the vein at this level but not always. ■ If you can not locate the bundle, you can identify it at the level of the latissimus and trace it back toward the axillary vein.
Long thoracic nerve	■ Do not dissect directly on the serratus anterior—you will be medial to the nerve and mobilize it into your specimen. ■ Expect the long thoracic nerve in roughly the same AP plane as the thoracodorsal vein. ■ If you trace the thoracodorsal nerve along its length, a branch will head medially to the chest wall precisely where the long thoracic nerve lies.
Altered anatomy	■ Remember, bulky adenopathy or prior surgery (such as an SLN biopsy) can alter these relationships.

POSTOPERATIVE CARE

- The drain will remain in place until the output falls below 30 mL per 24 hours for 2 days in a row. The patient and their family should be shown how to care for the drain and record the drain output. A visiting nurse can be of assistance.
- Patients should be instructed to avoid repetitive activities with the arm or heavy lifting. Some surgeons also advise avoiding reaching over 90 degrees, particularly if the incision was excessively tight. However, patients should be encouraged to use the arm for normal activities and should be given exercises to maintain normal range of motion. Slings should not be given to patients.
- Once the drains are removed, physical therapy can be extremely helpful with returning to full range of motion.
- Patient education about the signs and symptoms of lymphedema and lymphedema prevention. Early recognition of lymphedema can improve the likelihood of management.
- Patients with stage III melanoma should be referred to medical oncology for a discussion of adjuvant therapies (high-dose interferon α-2b, biochemotherapy) or clinical trial. Patients with disease at high risk for relapse should also be considered for adjuvant radiation.

OUTCOMES

- For prospective trials, the adequacy of an ALND is often based on the number of lymph nodes identified within the axillary specimen. Morton et al.[6] in the MSLT-I trial recommended 15 or more nodes for an ALND, and this is a reasonable benchmark. However, this number will vary not only with surgical technique but also body habitus and the pathologist.
- For patients with AJCC stage IIIa disease, defined as having a nonulcerated primary with 1 to 3 nodes containing micrometastatic disease (diagnosed on SLN biopsy), the 5-year survival is approximately 78%, whereas the 10-year survival is 68%. For patients with AJCC stage IIIb disease, defined as either having an ulcerated primary with micrometastatic disease in 1 to 3 nodes or a nonulcerated primary with macrometastatic disease in 1 to 3 nodes, the 5-year survival is 59%, whereas the 10-year survival is 43%. For patients with AJCC stage IIIc disease, defined as an ulcerated primary with macrometastatic disease in 1 to 3 nodes, or any patient with 4 or more nodes, matted nodes, or in-transit disease and positive nodes, the 5-year survival is 40% and the 10-year survival is 24%. However, there can be considerable variability, as survival is impacted not only by the nodal status but also by age, gender, the Breslow thickness of the primary melanoma, the presence of ulceration, and the tumor mitotic rate.[7]
- Although data related specifically to ALNDs is limited, the reported regional recurrence rates after an ALND performed for a positive SLN biopsy are around 4% to 5%.[1,8,9]
- Regional recurrence after ALND is higher in patients with two or more positive axillary nodes, extracapsular extension, or any node greater than 3 cm in size. For patients with such high-risk features, axillary recurrence can be as high as 23% to 50%.[10–12] Although it does not appear to impact overall survival, the use of adjuvant radiation can reduce the risk of axillary recurrence by 50%.[13–15]

COMPLICATIONS

- Infection
- Hematoma
- Seroma
- Limited range of motion at the shoulder
- Axillary web syndrome
- Paresthesias of the axilla and upper inner arm
- Axillary vein thrombosis
- Lymphedema
- Winged scapula (injury to the long thoracic nerve)
- Latissimus dorsi paralysis (injury to the thoracodorsal nerve)
- Brachial plexus injury

Chapter 29

Inguinal Lymph Node Dissection (Inguinofemoral and Ilioinguinal) for Metastatic Melanoma

Amod A. Sarnaik   Vernon K. Sondak

DEFINITION

- Inguinofemoral lymphadenectomy (or superficial inguinal lymph node dissection) is defined as the en bloc removal of all lymphatic tissue contained within the femoral triangle, as well as the node-bearing tissue superior to the inguinal ligament but superficial to the external abdominal oblique aponeurosis, up to the level of the anterior superior iliac spine (ASIS).
- The procedure can be combined with a pelvic (also known as deep inguinal) node dissection, in which case it is designated as an ilioinguinal lymphadenectomy, that includes the separate removal of the obturator and external iliac lymph nodes at least up to the level of the iliac bifurcation.
- The procedure has been used for the management of inguinal metastasis from penile and vulvar carcinoma as well as cutaneous malignancies such as squamous cell, basal cell, adnexal, and Merkel cell carcinoma, but it is most commonly used for metastatic melanoma, the focus of this chapter.

DIFFERENTIAL DIAGNOSIS

- Patients who present with a palpable inguinal mass with a history of melanoma should be considered to have metastatic melanoma until proven otherwise.
- Patients who present with a palpable inguinal mass without a known history of melanoma should be investigated for a primary malignancy with complete skin/mucosal surface physical examination including the vulva, penis and perianal skin/anal canal, and a digital rectal examination to evaluate for melanoma, nonmelanoma skin cancer (squamous cell, basal cell, Merkel cell, or adnexal carcinoma), vulvar, penile, and anal cancer.
- For patients presenting with a palpable groin mass but without history or physical evidence of skin/mucosal surface cancers, the differential diagnoses include inguinal/femoral hernias, femoral aneurysm, reactive/infectious lymphadenopathy (cat-scratch fever or posttraumatic), lymphoma, or metastatic cancer of unknown primary origin (including melanoma).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Prompt diagnosis of inguinal metastasis by the least invasive means when possible is a good start to minimize the morbidity of subsequent inguinal node dissection.
  - Patients with clinically occult inguinal disease can be diagnosed with sentinel lymph node biopsy. Inguinofemoral lymphadenectomy for microscopic nodal disease identified with sentinel lymph node biopsy appears to be associated with less morbidity compared to lymphadenectomy for macroscopic nodal disease.[1]
  - Patients with palpable groin masses not determined to be an aneurysm or hernia should be considered for a percutaneous fine needle or core needle biopsy to establish the diagnosis. If the mass is difficult to palpate or characterize, a diagnostic ultrasound with subsequent ultrasound-guided biopsy could be considered. Open biopsy should be reserved for when percutaneous biopsy is nondiagnostic, as the resulting scar and biopsy cavity from an open biopsy of a palpable mass render subsequent lymphadenectomy technically more difficult and can often result in wider skin flaps than what otherwise would be necessary.[2]
- Although currently considered to be the standard of care, the role of completion inguinofemoral lymphadenectomy in patients with micrometastatic melanoma found on sentinel lymph node biopsy is under investigation. Nodal observation as a potential alternative to immediate completion lymphadenectomy in melanoma patients with a positive sentinel node is being evaluated in the ongoing Multicenter Selective Lymphadenectomy Trial II. The trial randomizes patients with a positive sentinel lymph node to either immediate lymphadenectomy or observation with serial clinical examinations and ultrasonography. The patients randomized to observation may undergo a delayed completion lymphadenectomy if there is regional recurrence or may avoid the procedure and its associated morbidity if there is no evidence of regional disease during follow-up.
- Ilioinguinal lymphadenectomy is typically warranted for patients with radiographic evidence of metastatic disease in the pelvis. Other indications for an ilioinguinal lymph node dissection have not been definitively established and therefore are controversial. The clinical benefit of ilioinguinal lymphadenectomy for clinically occult metastatic disease when the pelvic nodes appear to be radiographically normal has not been demonstrated in a randomized, prospective trial to date. However, there are indications that are generally considered but not yet established.
  - Relative indications for ilioinguinal lymphadenectomy include any palpable inguinofemoral disease or four or more micrometastatic lymph nodes found at the setting of prior sentinel lymph node biopsy.
  - A possible but not yet established indication is any positive inguinofemoral sentinel lymph node biopsy result where the lymphoscintigraphy indicated evidence of "hot" nodes in the pelvis that were not removed in the sentinel lymph node procedure.
  - Some surgeons advocate for the positive status of the so-called "Cloquet's node" as an indication for ilioinguinal lymphadenectomy. However, there is a lack of uniform definition of Cloquet's node, as well as known examples

of lymphoscintigraphy performed for sentinel node biopsy where there is direct drainage from low or mid-inguinal nodes to pelvic nodes, bypassing all high inguinal nodes that would include Cloquet's node. Due to these factors, we do not rely on the status of Cloquet's node in any way.[2]

- Inguinofemoral or ilioinguinal lymph node dissections are performed under general anesthesia; therefore, the patient should be assessed for perioperative cardiac risk factors and referred for preoperative testing including cardiac stress test when clinically warranted.
- Patients should be clinically assessed for any preoperative lymphedema and typically are referred for fitted gradient compression stocking measurements to be used in the postoperative period. Although proof of the value of compression therapy is lacking, it is thought that early institution of compression therapy might minimize the risk of lymphedema in the early postoperative period.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Prior to lymphadenectomy, patients who are diagnosed with palpable inguinal metastatic melanoma typically are recommended to undergo whole body imaging (positron emission tomography–computed tomography [PET/CT] plus brain magnetic resonance imaging [MRI] or equivalent). Surgery is typically pursued in the absence of biopsy-proven distant disease, whereas systemic therapy is typically pursued if biopsy-proven distant disease is found.
- Patients who are diagnosed with micrometastatic inguinal melanoma by sentinel lymph node biopsy are not routinely recommended to undergo imaging due to the relatively low frequency of findings that are truly positive.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative planning for a complete lymphadenectomy starts with careful consideration of the diagnostic procedures required to establish the diagnosis of metastatic disease. Percutaneous needle biopsy where feasible should be considered for palpable disease as discussed above. Orientation of the sentinel node incision should be planned to facilitate a potential inguinal lymph node dissection that will include resection of the sentinel node biopsy scar and cavity.
  - When the sentinel node is mapped below the inguinal ligament, the sentinel node incision should ideally be vertically oriented and at least 0.5 cm distal to the groin crease (**FIG 1A**).
  - When the sentinel node is mapped to above the inguinal ligament (typically with a flank primary melanoma), the sentinel node incision should ideally be obliquely or transversely oriented and at least 0.5 cm proximal to the groin crease (**FIG 1B**).
- For planning the completion lymphadenectomy, the operative side and site should be identified with the agreement of the patient and/or the representative of the patient in the preoperative holding area.
- Patients with a prior history of deep vein thrombosis (DVT) or known genetic predisposition to thrombosis are given a prophylactic dose of low-molecular-weight heparin preoperatively.
- A first-generation cephalosporin such as cefazolin (or equivalent if allergic to cephalosporins or penicillin) are routinely given intravenously within 30–60 minutes of the creation of the skin incision.

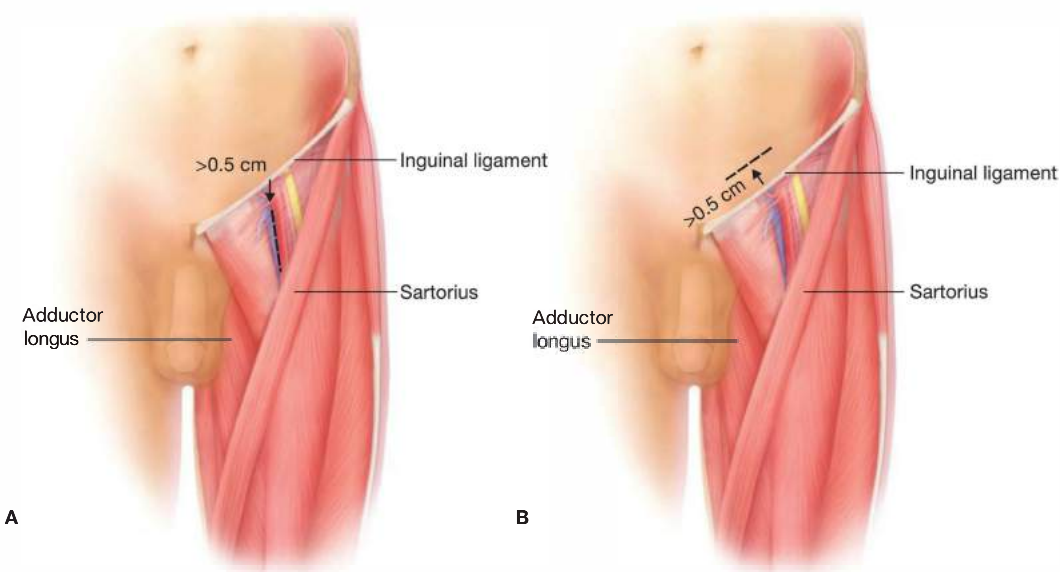

FIG 1 ● **A.** The recommended orientation for sentinel node biopsy incision when the draining nodes map to the region inferior to the groin crease. **B.** The recommended orientation for sentinel node biopsy incision when the draining nodes map to the region superior to the groin crease.

Positioning

- The patient is placed in the supine position on a standard operating table. A sequential compression device (SCD) (knee length ipsilateral and thigh length contralateral) should be placed for DVT prophylaxis prior to induction of anesthesia. General anesthesia is required using either a laryngeal mask or endotracheal tube for inguinofemoral lymphadenectomy, but endotracheal tube is preferred for ilioinguinal dissections. Long-acting paralytic agents at induction are often avoided to allow for motor nerve stimulation to be evident during the course of the procedure. A urinary catheter is inserted for ilioinguinal dissections but may potentially be omitted for inguinofemoral dissections at the discretion of the surgeon. The patient is placed in a slight frog-leg position with all pressure points padded. The operative field should be prepared from the abdominal wall at the level of the umbilicus to the level of the knee. A groin towel secured with a sterile adhesive drape can be used to cover and exclude the genitalia from the field.

INGUINOFEMORAL (OR SUPERFICIAL) LYMPHADENECTOMY

Skin Incision and Raising of Flaps

- As stated previously, a well-placed node biopsy incision, or avoiding the creation of a preexisting incision by percutaneous instead of open biopsy of palpable metastasis, is important to minimize the area of required skin flaps.
- For a positive sentinel node where the sentinel node scar is below the inguinal crease, a curvilinear incision is made in a vertical orientation with an ellipse of skin to facilitate excision of the previous cavity of dissection (**FIG 2A**). For a positive sentinel node where the sentinel node scar is above the inguinal crease, a transversely or obliquely oriented incision is made to excise the previous cavity of dissection. A second counterincision can be made below the inguinal crease to reach the remaining femoral nodes (**FIG 2B**). In thin individuals, retraction can frequently allow for the extirpation of the femoral nodes distal to the inguinal crease without the need for the second incision.
- For palpable disease without a pre-existing biopsy scar, a skin incision is configured in a lazy "S" fashion (**FIG 2C**). If the tumor is close to the skin, an ellipse of skin overlying the palpable tumor should be included. The incision should also include any scar from prior node biopsy procedure if applicable. This incision can be extended in a cranial direction if needed for an ilioinguinal lymphadenectomy.
- Skin flaps are raised in order to clear the anticipated boundaries of the dissection (below) without being so thin to cause postoperative skin necrosis. Limiting the extent of the flaps to the borders of the femoral triangle avoids an unnecessarily wide field of dissection and therefore may be associated with a reduction in morbidity.
- The dissection is continued to the level of the muscular fascia with the following boundaries (**FIG 2D**):
  - Anterior superior iliac spine (ASIS) superolaterally
  - Pubic tubercle superomedially
  - The superior extent of dissection should encompass the tissue from the ASIS to the pubic tubercle resulting in approximately 3–5-cm clearance above inguinal ligament while leaving external oblique fascia intact.
  - Sartorius muscle laterally, incising the fascia
  - Adductor longus medially, incising the fascia
  - Crossing of the sartorius and adductor longus distally (the so-called apex of the femoral triangle)
- It should be noted that while there have been isolated reports suggesting that incising the fascia of the sartorius and adductor longus may increase lymphedema, this has not been established in large series and most surgeons incise the muscle fasciae as described earlier.
- During the course of the dissection, tissue that potentially contains lymphatic vessels should be clipped, tied, or sealed with harmonic shears.[3]
- A key point of the upper extent of the dissection on the abdominal wall is that the lymphadenectomy clears the subcutaneous and node-bearing tissue down to the external oblique fascia from the boundary of the ASIS to the pubic tubercle proximally and down to the inguinal ligament distally (**FIG 3**). The dissection can typically preserve the spermatic cord in males, but the round ligament can be divided, if necessary due to the presence of disease, in females.

Dissection of the Saphenous Vein Distally

- The distal portion of the saphenous vein is encountered along the medial boundary of the dissection approximately 3–5 cm proximal to the apex of the femoral triangle. In most cases, the saphenous vein is tied off distally with 2-0 silk and divided. The saphenous vein can potentially be preserved in select cases where the procedure is performed for micrometastatic disease, when and if any existing seroma cavity and scar tissue is separate from the vein.[1,4] Although saphenous vein preservation might theoretically reduce the likelihood of postoperative DVT and lymphedema, this maneuver has never been definitively shown to reduce postoperative complications in any prospective, randomized study. Therefore, saphenous preservation should only be considered in select cases performed for micrometastatic disease, where the vein is not involved with scar or seroma cavity, and the maneuver should never compromise the extent of dissection.

Dissection of the Femoral Vessels

- The superficial femoral artery is identified at the distal aspect of the dissection at the apex of the femoral triangle. At this level, the femoral artery lies anterior to the femoral vein. As the dissection proceeds distal to proximal, the femoral artery courses laterally while the femoral vein courses medially. The anterior surfaces of the femoral vessels are skeletonized, and the dissection is extended laterally at the same depth as the vessels to avoid injury to the femoral nerve, which is generally not directly visualized. The relationship of the femoral vessels to the boundaries of the femoral triangle is shown in **FIG 4**.

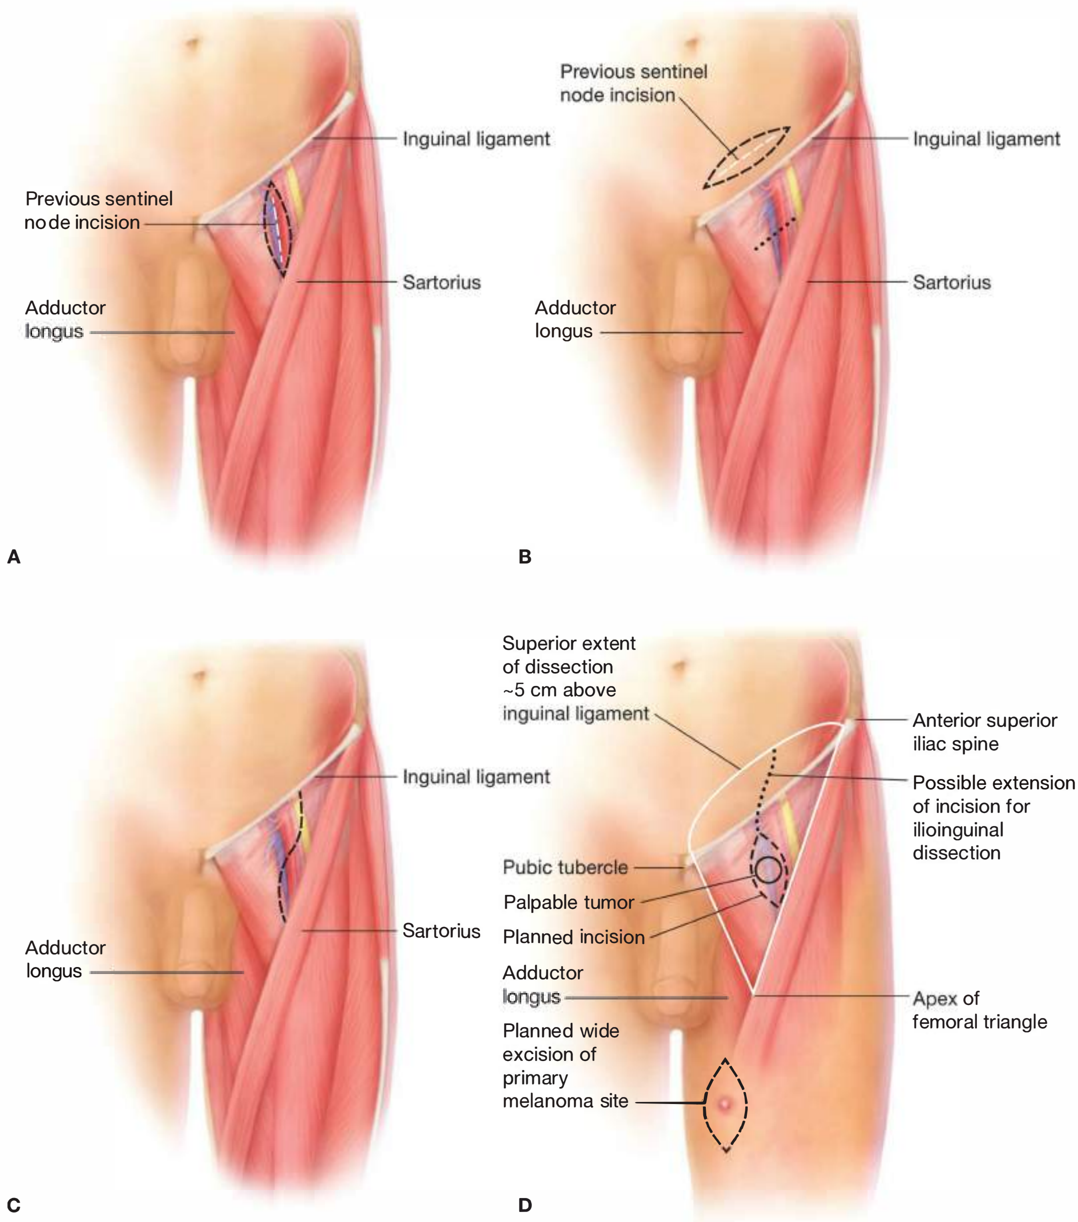

FIG 2 ● **A.** The recommended orientation of a curvilinear incision for the indication of a positive sentinel node that mapped to the region inferior to the groin crease. **B.** The recommended orientation of an elliptical incision above the groin crease combined if necessary with a linear incision inferior to the groin crease. **C.** The recommended orientation of a lazy S incision that can include an ellipse of skin overlying palpable disease. Of note, to facilitate exposure for an ilioinguinal lymphadenectomy, it may be required for the incision to cross the groin crease. **D.** The operative field with denoted boundaries of the extent of inguinofemoral lymphadenectomy (white line) in a patient with an intact primary melanoma and clinically evident nodal disease. Note that the planned incision includes the palpable metastasis and that the incision can be optionally extended onto the abdominal wall for an ilioinguinal lymphadenectomy.

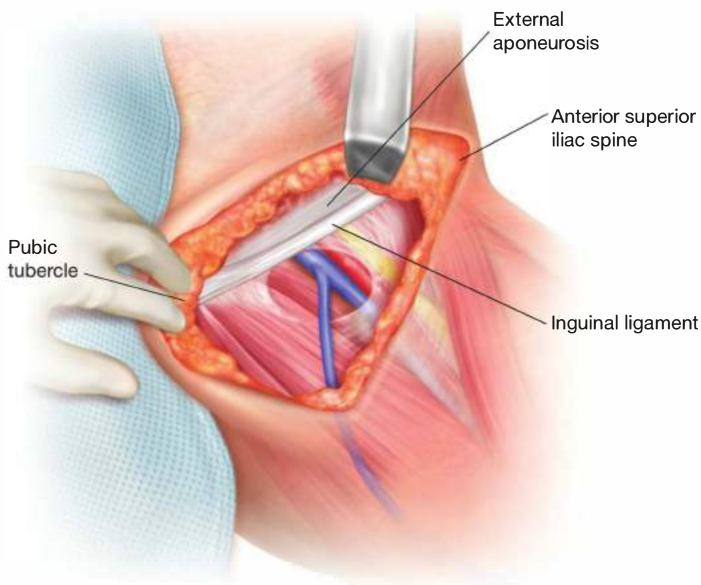

FIG 3 ● The superior extent of dissection clears all subcutaneous tissue 3–5 cm proximal to the inguinal ligament to a depth bounded by the underlying external oblique aponeurosis.

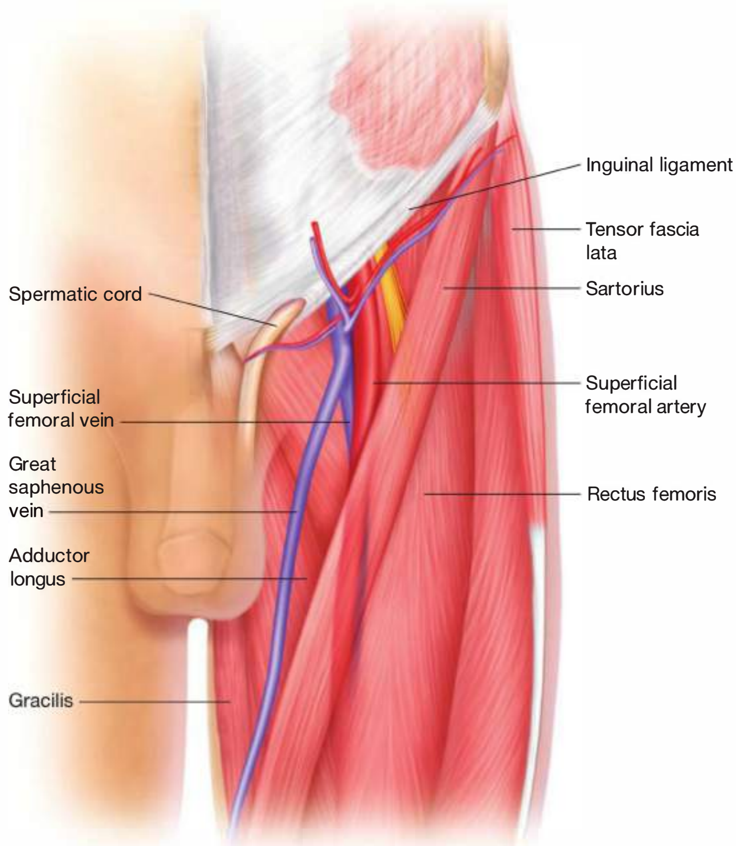

FIG 4 ● The relationship of the femoral artery and vein to the boundaries of the femoral triangle. Note at the distal apex of the femoral triangle, the femoral artery lies superficial to the femoral vein.

Completion of the Dissection and Ligation of the Saphenofemoral Junction

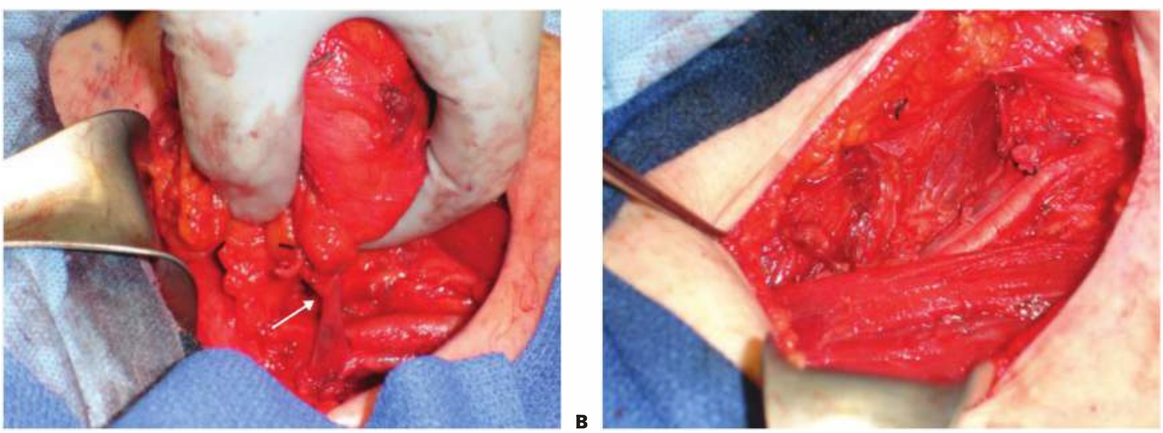
- The dissection continues in a distal to proximal direction up to the level of the saphenofemoral junction. If the saphenous vein is to be preserved, it is fully freed from the specimen; generally, several small- to medium-sized tributaries draining the specimen need to be divided and ligated individually. Otherwise, the entirety of the saphenous vein is included in the specimen and the remaining soft tissue is circumferentially dissected so that the specimen remains adherent only by the saphenofemoral junction (**FIG 5A**).
- The saphenous vein is doubly ligated at the level of the saphenofemoral junction, usually with a 3-0 silk suture ligature and a 2-0 silk tie, taking care not to narrow the femoral vein (**FIG 5B**). A formal closure of the stump with vascular suture is not routinely required but may be necessary if the saphenofemoral junction is very broad or if palpable tumor extends in close proximity to the femoral vein itself.

Sartorius Muscle Transposition Flap

- Sartorius muscle transposition is used to cover the exposed femoral vessels in the groin whenever there is concern about the integrity of the overlying skin flap closure. Some surgeons routinely perform this in all cases, whereas others do it selectively or not at all.[1,5] We use it in most cases but routinely omit it when the incision is placed high in the groin (i.e., not directly overlying the exposed vessels) and in selected younger patients, including children, especially athletes or other very active individuals.
- The tendinous portion of the sartorius muscle is taken off its point of origin at the ASIS with electrocautery. It is important to divide the muscle as high as possible to maximize the length of muscle available for the flap. It is critical to obtain meticulous hemostasis at the cut muscle edge, as there is little or no tissue at that level to tamponade bleeding and a small ooze can continue for hours postoperatively. To mobilize the muscle for the transposition flap without tension, a few lateral feeding vessels generally need to be tied off, and the lateral fascia is incised well down the length of the muscle. The muscle is transposed over the femoral vessels and secured in place to the external abdominal oblique aponeurosis/inguinal ligament with three or four interrupted, horizontal mattress 2-0 non-absorbable, braided polyester sutures oriented so that the knots are pushed down onto the sartorius muscle. The sutures are placed in a staggered fashion to avoid being placed at the same level in the ligament, which would otherwise weaken the fascia (**FIG 6**).

Placement of Drain and Closure

- If a concomitant pelvic dissection (i.e., superficial and deep lymphadenectomy) is planned, see the following text and closure is deferred until completion of that portion of the procedure.
- A flat or round closed-suction drain is routinely placed in the bed of dissection and brought out through a separate stab incision relatively close to the wound but away from the thinnest parts of the skin flaps. The incision is closed with interrupted 3-0 absorbable, polygalactin sutures for the subcutaneous tissue and a running suture of 4-0 absorbable, monofilament suture for the subcuticular skin layer. Cyanoacrylate adhesive (or equivalent) is used over the subcuticular closure for extra protection. The leg is wrapped with an Ace wrap from the level of the metatarsals to mid-thigh, and a thigh-length SCD is placed over the Ace and on the contralateral extremity. The urinary catheter, if used, is left in place at the end of the case.



A B

FIG 5 ● **A.** The appearance of the completed left inguinofemoral lymphadenectomy dissection with a view of the specimen attached only by the saphenofemoral junction *(arrow)* with the superficial femoral artery immediately lateral. **B.** The appearance of the ligated saphenofemoral junction *(arrow)* after removal of the specimen without any narrowing of the superficial femoral vein, and a view of the superficial femoral artery lateral to the vein as well as the sartorius muscle that forms the lateral boundary of the dissection.

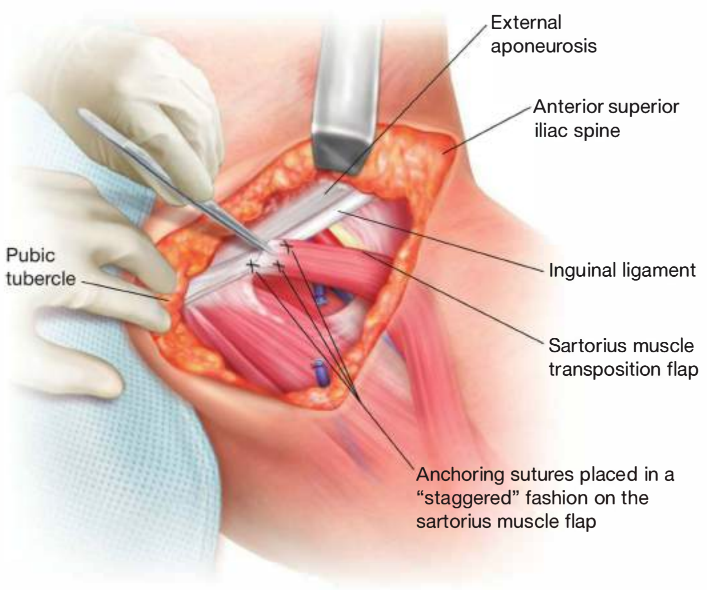


FIG 6 ● Sutures that anchor the sartorius muscle transposition flap are placed in a staggered fashion instead of being placed on a single plane in order to avoid weakening the fascia.

ILIOINGUINAL LYMPHADENECTOMY

Division of the Abdominal Wall and Retroperitoneal Exposure of the Pelvis

- When conducted as a portion of a combined ilioinguinal lymphadenectomy, the pelvic portion of the lymphadenectomy occurs through the same incision. The incision may need to be lengthened sufficiently above the inguinal crease to ensure adequate visualization (**FIG 2D**).
- The pelvic portion of the ilioinguinal lymphadenectomy involves the removal of the obturator and iliac nodes up to the bifurcation of the iliac vessels through a retroperitoneal approach. In some individuals, the common iliac nodes can be removed if grossly involved by extending the fascial incision cephalad, but para-aortic nodes are considered beyond the scope of the dissection and are rarely accessible through the retroperitoneal approach.
- Through the same skin incision used for the inguinofemoral dissection, the external and internal abdominal oblique aponeuroses are incised parallel to the direction of the fibers of the respective muscles (**FIG 7A**). The peritoneum is retracted superiorly and medially, which typically mobilizes the ureter out of the field. Retraction of the peritoneal contents superiorly and medially exposes the external iliac artery and vein with associated node-bearing tissue (**FIG 7B**).

Retrieval of Iliac Nodal Tissue

- The external iliac vessels are skeletonized over their anterior aspect. All fibrofatty and lymphatic tissue overlying the iliac vessels is retrieved from the bifurcation proximally to the posterior aspect of the inguinal ligament distally.

Retrieval of Obturator Nodal Tissue

- The external iliac vein is retracted laterally to expose the obturator space medially. Fibrofatty and lymphatic tissue is removed down to the level of the obturator nerve (**FIG 8**). Caution should be taken when dissecting medially as the obturator vessels and tributaries are difficult to visualize and can be difficult to control if injured.
- The obturator foramen and the pubic rami should be carefully inspected and palpated to ensure that nodes are not left behind in those locations.

Placement of Drain and Closure

- While not absolutely required, a second closed-suction drain can be deployed into the bed of the dissection and brought through the divided abdominal muscle fibers distally, exiting the skin through a separate stab incision. The internal and external abdominal oblique fasciae are closed with absorbable monofilament sutures. Closure then proceeds as described earlier in the inguinofemoral dissection.

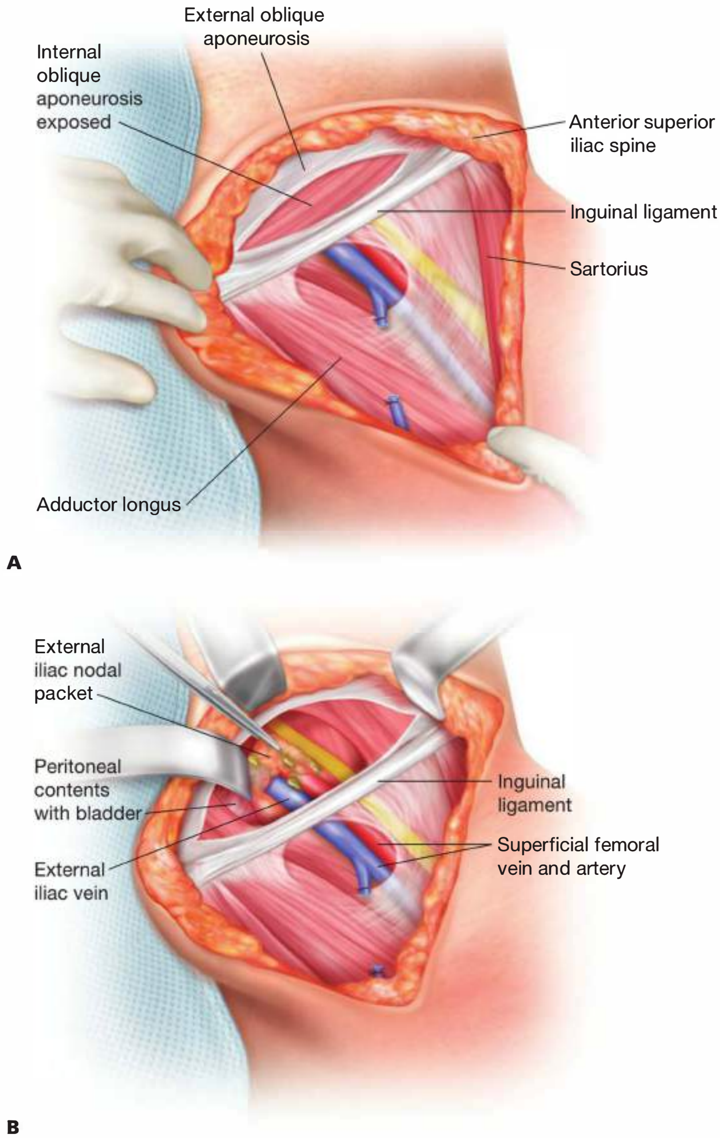

FIG 7 ● **A.** The external oblique aponeurosis has been incised in a direction parallel to its fibers, exposing the underlying internal oblique aponeurosis. **B.** Anterior view of the external iliac artery and vein with delivery of the external iliac nodal packet.

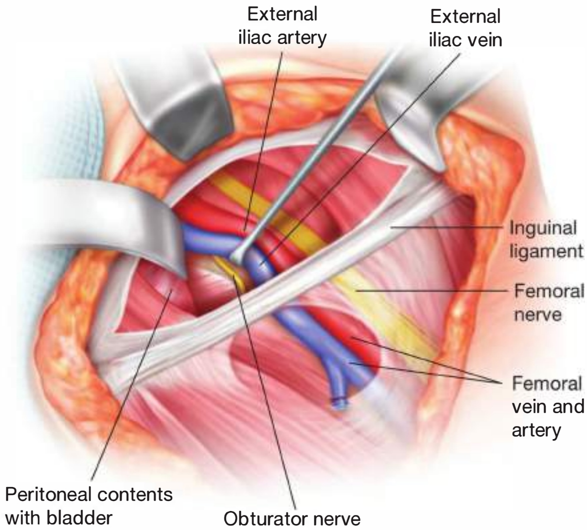

FIG 8 ● Appearance of the completed ilioinguinal dissected field with the obturator nerve exposed deep and medial to the external iliac vessels.

PEARLS AND PITFALLS

Indications	■ The diagnosis of inguinal metastasis should be made using the least invasive method possible. ■ Palpable disease should be evaluated by percutaneous fine needle aspiration or core needle biopsy rather than open biopsy whenever possible. ■ Sentinel node biopsy incisions should be fashioned while being mindful of the possibility that inguinal lymphadenectomy may be required in the future. ■ Sentinel node biopsy incisions directly in the inguinal crease are not advised due to the difficulty with the subsequent lymphadenectomy incision if necessary. ■ In cases where there is nodal disease without a known primary, a careful physical examination to identify a primary cancer is warranted, including examination of the skin of the lower body, digital rectal examination, and examination of the penis/vulva.
Placement of incision	■ Incisions should be fashioned to avoid crossing the inguinal crease where feasible.

Extent of resection	■ Saphenous vein preservation may be considered for cases being performed for micrometastatic disease and when the vein is not involved with scar or the seroma/biopsy cavity.
	■ Indications for inclusion of pelvic lymphadenectomy in the absence of clear-cut pelvic involvement have not been definitively established; but typically, scenarios for which ilioinguinal lymphadenectomy is potentially considered are the following:
	  ■ Macroscopic inguinofemoral disease
	  ■ Four or more positive nodes identified at sentinel lymphadenectomy
	  ■ Pelvic drainage observed at the time of lymphoscintigraphy with a positive inguinofemoral sentinel node

Key postoperative care	■ Patients are typically placed on bedrest overnight. ■ DVT prophylaxis is typically instituted on the evening of the procedure and continued while the patient is in the hospital unless there is clinical concern for hemorrhage. ■ Lymphedema precautions include compression with Ace wraps or fitted compression garments with aggressive institution of lymphedema therapy at the first clinical sign of lymphedema.

POSTOPERATIVE CARE

- The patient is typically kept on bedrest overnight with the urinary catheter, if used, in place, and affected extremity raised to above the level of the heart. The affected extremity is kept wrapped with an Ace from the metatarsals to mid thigh, with thigh-length SCDs in place on the contralateral extremity and over the Ace on the ipsilateral extremity.
- If the patient's physical examination and the drain output are not concerning for postoperative bleeding, prophylactic subcutaneous low-molecular-weight heparin is administered on the evening of the procedure and continued daily while the patient is hospitalized.
- On the first postoperative day, the urinary catheter, if present, is removed and the patient is encouraged to ambulate.

- After an inguinofemoral lymphadenectomy, patients are discharged after 1 or 2 nights when pain is controlled with oral analgesics.
- After ilioinguinal lymphadenectomy, patients are kept nil per os for the first night. If there is no sign of ileus, the diet can be advanced on postoperative day 1. Patients typically remain in the hospital for at least 2 nights and are discharged when pain is controlled with oral analgesics and are tolerating a diet.
- On discharge, patients are encouraged to ambulate to minimize risk of DVT, wear Ace or fitted gradient compression stockings during the day, and to elevate the operated leg above the level of the heart at night.
- At the first clinical sign of lymphedema, lymphedema therapy is ordered and verification of compliance with the fitted compression stockings is done.

OUTCOMES

- Five-year overall survival rates for melanoma metastatic to regional lymph nodes are listed below[6]:
  - Stage IIIA melanoma—1 to 3 nodes involved with microscopic disease and nonulcerated primary tumor—78%
  - Stage IIIB melanoma—1 to 3 nodes involved with microscopic disease and an ulcerated primary tumor or 1 to 3 nodes involved with macroscopic disease and a nonulcerated primary tumor—59%
  - Stage IIIC melanoma—4+ nodes involved, 1 to 3 nodes involved with macroscopic disease and an ulcerated primary tumor, matted lymphadenopathy, or disease that includes in-transit and nodal metastasis—40%

COMPLICATIONS AND RELEVANT MANAGEMENT

- Seroma—if symptomatic can be percutaneously drained; open drainage should be avoided
- Lymphedema—managed with early compression and lymphedema therapy
- Wound dehiscence—risk is minimized by confining area of the flap to the boundaries of the femoral triangle and can be managed with a wound vac device as needed
- Infection—typically managed with oral antibiotics
- DVT/pulmonary embolism—risk is minimized by the routine use of low-molecular-weight heparin prophylaxis and high index of suspicion should be maintained for early diagnosis and treatment
- Sensory deficit is common but typically does not require management unless there is a persistent neuralgia
- Recurrence

Chapter 30 Minimally Invasive Inguinal Lymph Node Dissection for Melanoma

James W. Jakub

DEFINITION

- Minimally invasive inguinal lymph node dissection (MILND) is defined as an inguinal lymph node dissection performed through trocar ports. Many names have been coined for this videoscopic approach, and unfortunately, minimally invasive has also been used by some to describe an open technique using smaller incisions.
- The terminology surrounding the inguinal node dissection can be confusing. Urologic groin dissections separate the superficial inguinal basin as anterior to the cribriform fascia and the "deep" inguinal nodes as those nodes along the femoral vessels deep to this fascial layer. Melanoma surgeons have historically referred to both of these basins as a "superficial inguinal lymph node dissection" or "inguinalofemoral" and the pelvic or external iliac/obturator lymph nodes are referred to as a "deep inguinal lymph node dissection" or "ilioinguinal." In this chapter, when we describe an inguinal lymph node dissection, it will refer to all the nodes in the groin distal to the inguinal ligament and superficial to the external oblique aponeurosis, superficial and deep to the cribriform fascia. The deep or ilioinguinal dissection is discussed in Part 5, Chapter 29.

ANATOMY

- The anatomy critical to the MILND is identical to that for the conventional open operative approach and is depicted in **FIGS 1A,B** and **2**. The superficial and deep inguinal lymph nodes are separated by the cribriform fascia, which is violated at the fossa ovalis. There are approximately 10 lymph nodes in the superficial basin and five in the deep.
- The borders of the femoral triangle are graphically depicted in **FIG 2**.

NATURAL HISTORY

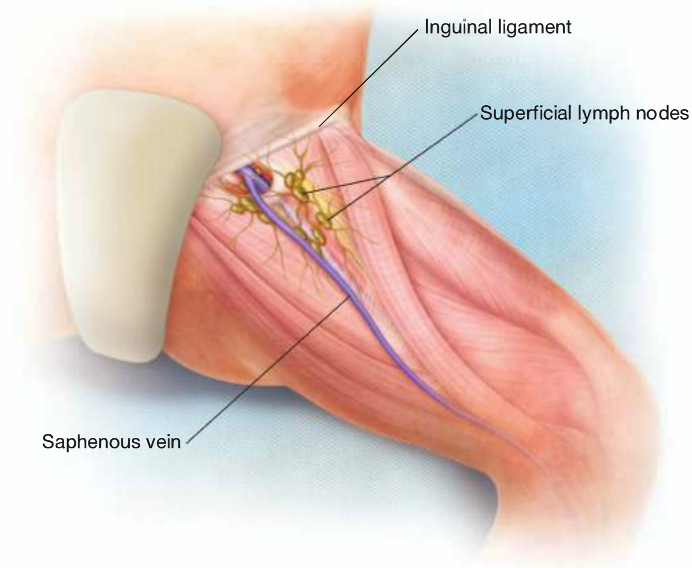
- Complete inguinal lymph node dissection is advised for any patient with melanoma metastatic to the inguinal lymph nodes in the absence of distant metastases. Microscopic and macroscopic subclassifications of stage III disease are distinguished as clinical and not pathologic entities.[1] If disease is detected by physical exam, this is considered macroscopic, whereas a positive sentinel lymph node (SLN) represents microscopic disease regardless of the tumor burden identified pathologically. Stage III melanoma patients represent a very heterogeneous cohort and prognosis varies greatly based on the number of positive lymph nodes, nodal burden in the lymph nodes, and presence or absence of synchronous in-transit metastasis. Five-year overall survival for this group of patients is approximately 50%, but based on the specific subcategory varies widely from 25% to 75%.

PATIENT HISTORY AND PHYSICAL FINDINGS

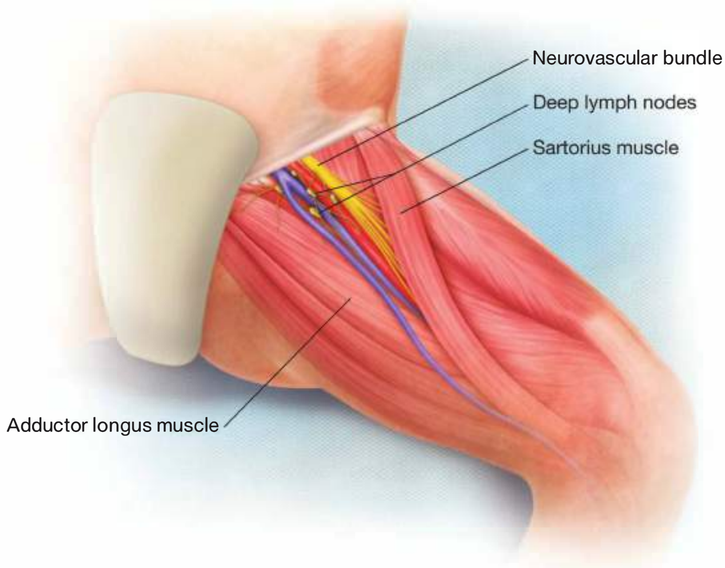
- An MILND is indicated in most cases that would be considered for traditional inguinal nodal dissection including melanoma; cutaneous squamous cell carcinoma (SCC); and some urologic (penile), gynecologic (vulvar), anal, or low-lying rectal cancers.
- Physical examination should not only evaluate the inguinal nodal basin but also identify in-transit disease between the primary and inguinal nodal basin, particularly in the case of melanoma. Radiographic or gross nodal disease can be found cephalad to the inguinal ligament and superficial to the external oblique aponeurosis, especially in cases of a truncal primary.
- For lower extremity disease, the popliteal nodal basin should be evaluated; and for disease of the trunk, consideration for contralateral inguinal or axillary drainage needs to be considered based on location of the primary.
- Physical examination should also evaluate for prior scars in the field (sentinel lymph node biopsy [SLNB] or saphenous vein harvest from prior coronary artery bypass graft [CABG]) and skin changes suggestive of cutaneous involvement. This can be direct extension with overlying cutaneous hyperemia and fixation of disease or nodularity/ulceration that is often seen in SCC. For penile primaries, the genitals and base of penis should be inspected for cutaneous involvement.
- Most frequently, an MILND will be performed for microscopic disease following a positive SLNB. In this setting, waiting a minimum of 6 weeks from the SLNB to the MILND allows time for the acute operative inflammatory changes to resolve. An MILND may be considered in selected cases of macroscopic disease. Caution and sound clinical judgment should be used to avoid violating the specimen, assuring an en bloc resection and for radiographic disease, that the identified disease to be resected will indeed be contained inside the contents of dissection.
- MILND is contraindicated in the setting of cutaneous involvement or a prior lymphadenectomy in the same field. MILND may be considered in a prior radiated field, but again, caution should be stressed.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Positive SLNB for microscopic disease
  - In general, this is a delayed diagnosis and MILND is offered as a staged procedure, as typically, frozen section is not performed on SLNs for melanoma. Even in institutions where frozen section is performed on SLNs (such as



A



B

FIG 1 ● **A,B.** Anatomy of the superficial and deep inguinal basin.

our own), there is no need to freeze the SLNs of the groin if MILND may be offered at a later date.
- The yield of systemic imaging to find clinically occult stage IV disease after a positive SLN is less than 5% and typically not warranted prior to MILND.[2–4]
- Deep pelvic (external iliac/obturator) node dissection is typically not required.

- Clinical inguinal regional nodal disease
  - In the setting of a palpable inguinal lymph node, a fine needle aspiration (FNA) to confirm the clinical diagnosis is frequently appropriate prior to embarking on an inguinal node dissection.
  - A search for systemic disease with whole-body imaging (computed tomography [CT] scan or positron emission tomography [PET]/CT) is reasonable prior to MILND as the true positive rate is above 10%.[5,6]
  - The decision to embrace a routine, selective or nihilistic, and hence, almost never approach to the pelvic basin will not be covered in this section. In general, for clinically apparent disease, I strongly consider a combined deep pelvic node dissection at the same setting.
  - There is limited data on minimally invasive approach to the pelvic lymph nodes for melanoma. Technically, it can be performed as clearly shown in clinical practice with gynecologic and urologic procedures. However, the role in melanoma is not defined. Basic questions such as, "Should an extraperitoneal versus an intraperitoneal approach be used?" and "Is converting an extraperitoneal

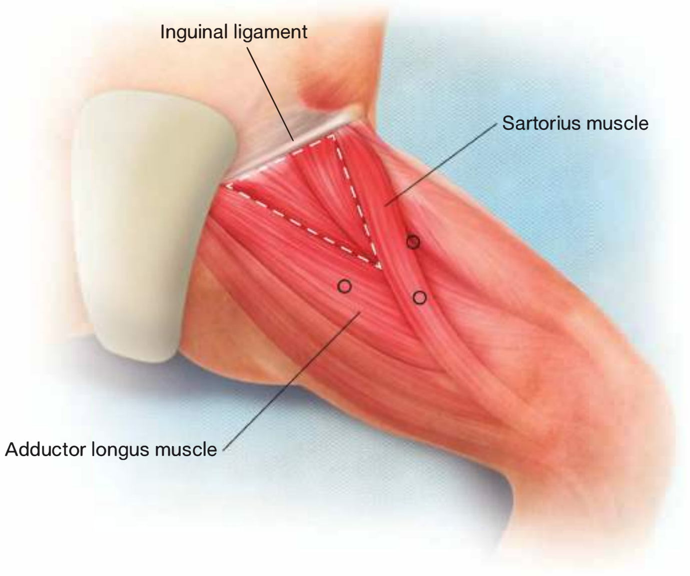


FIG 2 • Borders of the femoral triangle as well as trocar placement for MILND.

disease to an intraperitoneal operation sound?" have not been established. At the time of this writing, when performing a combined inguinal and a pelvic node dissection, I personally perform this as an open approach.

NONOPERATIVE MANAGEMENT

- The current standard, off protocol, is for a regional node dissection for all cases of a positive SLN, including immunohistochemical disease only.
- At the time of this publication, the Multicenter Selective Lymphadenectomy Trial II (MSLT II) randomizing patients with a positive SLNB to observation of the basin or standard lymph node dissection, just closed to accrual.

SURGICAL MANAGEMENT

- A word of caution: Data on short- and long-term morbidity are limited at the time of this publication.[7,8] Seromas are common and can be prolonged; wound complications requiring more than outpatient oral antibiotics are rare. Randomized single institution (Delman, personal communication, February 2013) and single-arm multi-institutional surgical trials (NCT01500304) are actively ongoing to define the short-term morbidity and surgical learning curve for this procedure. One measure of oncologic adequacy of the procedure is lymph node yield and this appears to be similar.[7,9] There is no data to date regarding oncologic outcomes and patients need to be clearly made aware, that as of the time of this publication, it is unknown if the regional control and cure rates with this approach are worse, better, or equivalent to a standard open approach. This candid discussion is necessary as part of the informed consent process (at the time of this printing one manuscript has been published).[9]

Preoperative Planning

- Preoperative baseline bilateral limb volumes should be considered.
- Brief with anesthesia and the operating room (OR) team prior to the start of the procedure:
  - Hypercarbia is to be expected. Unlike laparoscopy performed in an intraperitoneal location, this entire dissection is performed in the subcutaneous plane and much higher levels of carbon dioxide (CO_2) will be systemically absorbed. Anesthesia team needs to be aware and appropriate ventilatory modifications made to avoid the need for conversion.
  - Ensure you have towers in correct position, patient position is rehearsed, and desired equipment, including dissector and laparoscopic supplies, are in the room.
- Prophylactic antibiotics are provided.
- Mechanical venous thromboembolism (VTE) prophylaxis in the form of sequential compression devices are placed on the contralateral leg. Chemical VTE prophylaxis in the form of subcutaneous heparin is provided prior to incision and ideally prior to induction of general anesthesia.
- A Foley catheter is placed sterilely on the prepped field and sealed out of the dissection field with the genitalia by a sterile towel and Ioban.

Positioning

- In the typical setup, the patient is positioned supine with the legs split either on a split-leg table (my preference) or in the synchronous position with Yellofin gel stirrups. The operative leg is abducted and slightly flexed at the knee (**FIG 3**). If the leg is left straight, the surgeon will almost inevitably perform the dissection too lateral. The surgeon and the assistant stand so one is between the legs and the other stands lateral to the operative leg. The surgeon and the assistant may change positions during certain portions of the procedure if desired. The surgical technician stands on the opposite side of the patient's body.
- Video towers are placed at the head of the table, one above each shoulder (**FIG 3**). Minimal operative instrumentation is needed on the Mayo stand. If there is a need to emergently convert, appropriate instruments should be immediately available.

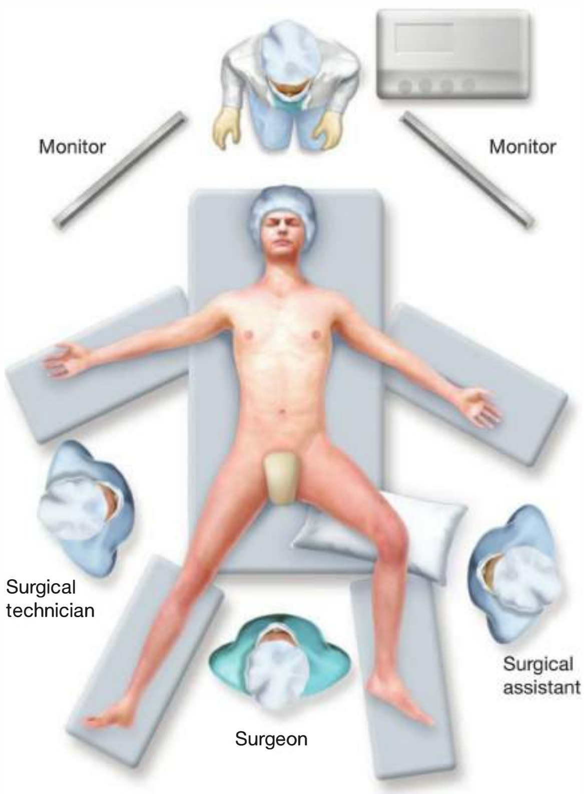

FIG 3 ● Operating theater setup and patient position.

Approach

- The current approach involves en bloc resection of the muscular fascia and saphenous vein with the lymphadenectomy specimen. The plane of dissection off the sartorius muscle and adductor may not be as apparent with a minimally invasive approach as during an open procedure, and to be clear that the dissection is in the correct plane, we have scored the fascia and visualized the underlying muscle.
- Resecting the muscular fascia is the approach initially described by Delman et al.[10] and the approach we have followed. Whenever embarking on a new procedure, it is critical that caution is exercised and the procedure is approached with this mindset, assuring that the extent of the oncologic resection is at least as complete as the traditional standard for which it is meant to replace. It is also true that the minimally invasive approach should, as much as possible, exactly mirror the technique of the open approach. As with any novel technique, this procedure will likely evolve with time, and with experience, it may be shown that a muscular fascia and saphenous vein preserving approach is as safe and oncologically sound.
- We do not excise the SLNB scar if present. We also do not make an open incision to confirm the adequacy of dissection because the videoscopic view should make this obvious. If there is any question of inadequate resection, a small proximal incision can be made and the extent of the oncologic operation should not be jeopardized because of a perceived feeling of inadequacy or failure by "converting."

MINIMALLY INVASIVE INGUINAL LYMPH NODE DISSECTION

Operating Room Setup

- In the typical setup, the patient is positioned supine with the legs split either on a split-leg table (my strong personal preference) or in the synchronous position with Yellofin gel stirrups. The operative leg is abducted and slightly flexed at the knee (**FIG 3**). The surgeon and the assistant stand so one is between the legs and the other stands lateral to the operative leg. The surgeon and the assistant may change positions during certain portions of the procedure if desired. The surgical technician stands on the opposite side of the patient's body.
- Video towers are placed at the head of the table, one above each shoulder (**FIG 3**). Minimal operative instrumentation is needed on the Mayo stand. If there is a need to emergently convert, appropriate instruments should be immediately available.
- The anatomy critical to the MILND is identical to that for the conventional open operative approach and is depicted in **FIGS 1** and **2**. The superficial and deep inguinal lymph nodes are separated by the cribriform fascia, which is violated at the fossa ovalis. There are approximately 10 lymph nodes in the superficial basin and five in the deep.
- The borders of the femoral triangle are graphically depicted in **FIG 2**.
- External landmarks are identified. Palpation is performed to identify the medial border of dissection, which is the adductor longus muscle. This is marked with a marking pen. Next, similar palpation is performed to identify the sartorius muscle and identify its medial border, which will mark the lateral boundary of the dissection. The convergents of these lines occur at the distal border of dissection, which is the apex of the femoral triangle. Proximal dissection extends 3 to 5 cm cephalad to the inguinal ligament and it includes the soft tissues superficial to the external oblique in this location.
- Next, the three trocar sites are marked. The distal most incision is marked 3 cm from the apex of the femoral triangle. The other two trocars are placed proximal to this, each 5 cm apart, one medial and one lateral (see **FIG 5A,B**). Through one of the trocar sites, blunt dissection is performed with the index finger separating along the natural avascular plain between the subcutaneous fat and underlying soft tissue. Three 10/12 mm trocars are next introduced. As a

FIG 4 ● Photo depicting trocar placement and initial CO_2 insufflation at beginning of case (image © Mayo Clinic, 2014).

result of the thin subcutaneous tissue, a leak around the trocar may be encountered. As a result, the incision should be kept to a minimum and only one trocar site should be used for the initial blunt dissection. Short trocars are ideal, and bariatric instruments should be available in order to reach the proximal most dissection. Using trocars with balloons to minimize the leak are ideal.

- CO_2 insufflation is performed. Initially, 25 mmHg for 10 minutes and then decreased to 15 mmHg for the remainder of the procedure (FIG 4).

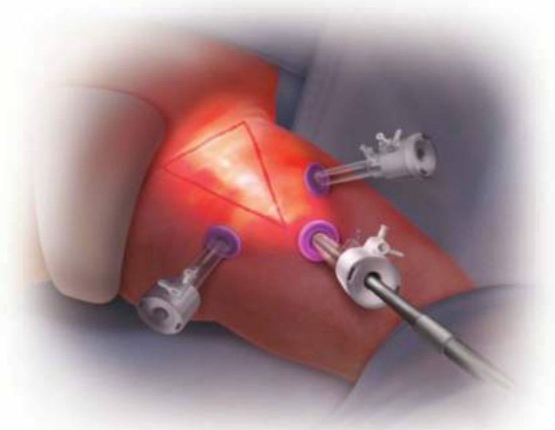
Superficial Dissection

- I perform the entire dissection with an ultrasonic dissector (personal preference) or LigaSure® device, except when freeing the tissue from the external oblique aponeurosis where I use a hook cautery.
- Camper's fascia is preserved. Dissection is performed superficial to Scarpa's fascia.
- Initial dissection starts in a space created by the digital dissection and CO_2 insufflation. The dissection is begun distally and continued proximally. The initial dissection is performed in order to create a working space between the subcutaneous tissue and underlying regional contents.
- Dissection is performed fairly superficially, superficial to Scarpa's fascia. This can be appreciated with an external view showing the transillumination of the light source through the skin (FIGS 5A,B). Dissection can be assisted by external palpation over the previously marked boundaries of the triangle. Running a finger up and down the previously drawn landmarks while viewing internally assists one in defining the borders and extent of the superficial dissection. As dissection is completed more proximally, the loose areolar tissue overlying the external oblique aponeurosis can be appreciated. The entire anterior dissection within the externally marked triangle should be completed.

Sartorius Exposure

- The next portion of the procedure is the lateral dissection to identify the sartorius muscle. Dissection is performed through the fatty tissue until the sartorius fascia is identified.

A



B

FIG 5 ● A,B. Photo and image demonstrating trocar placement, flap thickness, and drain placement. Dissection is quite superficial and this is demonstrated in these images showing how well the light transilluminates through the skin flaps (Fig. 5a © Mayo Clinic, 2014).

The fascia is divided, identifying the underlying muscular fibers of the sartorius. This is initiated distally, and once identified, you simply march proximally up this layer. The fascia is continually scored from distal to proximal as shown in FIG 6. This is continued up toward the inguinal ligament.

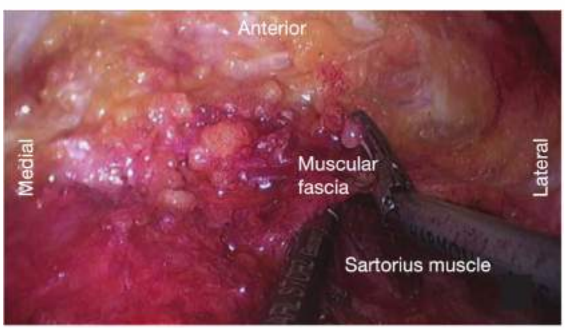


FIG 6 ● The lateral border of the deep dissection is shown here. The muscular fascia is scored from distal to proximal exposing the sartorius muscle (image © Mayo Clinic, 2014).

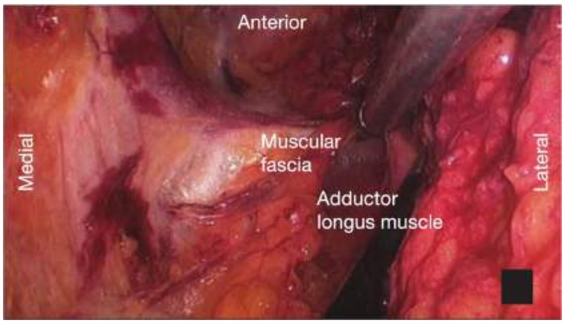

FIG 7 ● The medial border of the deep dissection is shown here. The muscular fascia is scored from distal to proximal exposing the adductor longus muscle (image © Mayo Clinic, 2014).

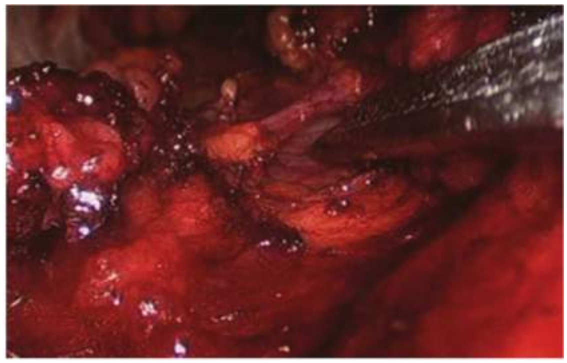

FIG 9 ● The distal saphenous vein is being divided as it crosses the adductor longus muscle (image © Mayo Clinic, 2014).

Adductor Longus Exposure

- A similar approach is taken medially to identify the adductor longus muscle (FIG 7). Because of the crossing saphenous vein, the medial dissection is started more proximal in this location. This dissection is also continued proximally to the inguinal ligament.
- The specimen is rolled laterally off the adductor. As we progress medially, the deep border of dissection becomes the pectineus muscle (FIG 8).
- It is fairly common for the knee to be "in the way" during portions of the dissection as a result of the knee bumped and the leg position. I find that I am not infrequently operating with the handle of the dissection device turned upside down to accommodate this reality.

Exposure and Division of Distal Saphenous Vein

- The next step is to identify and divide the saphenous vein distally. At this point, the dissection is begun more proximally on the adductor longus.
- The saphenous vein is identified and circumferentially dissected out. It is located two-thirds of the distance from the inguinal ligament to the apex of the triangle as the vein crosses the adductor muscle.
- The vein can be divided with an endovascular stapler, LigaSure® or ultrasonic dissector per surgeon preference and vessel caliber (FIG 9).

Apex Dissection

- Next, the apex dissection is completed. This is the remaining soft tissue between the sartorius and the adductor at the distal most aspect of the dissection.
- The contents are grasped and elevated under tension with traction in both the superficial and cephalad direction (FIG 10). This tissue is controlled with the nondominant hand, as the dissection of the remaining tissue over the apex is completed.

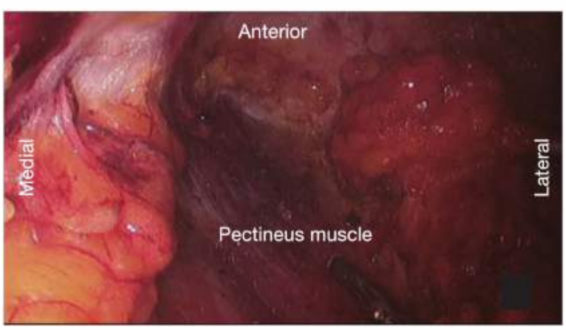

FIG 8 ● The pectineus muscle is exposed as the proximal portion of the specimen is rolled from medial to lateral off the adductor (image © Mayo Clinic, 2014).

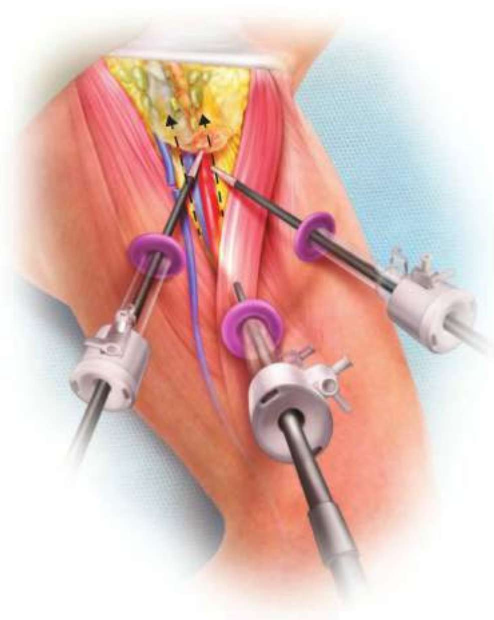

FIG 10 ● At the apex of the femoral triangle, the contents are grasped and retracted under tension by pushing the specimen anterior and cephalad.

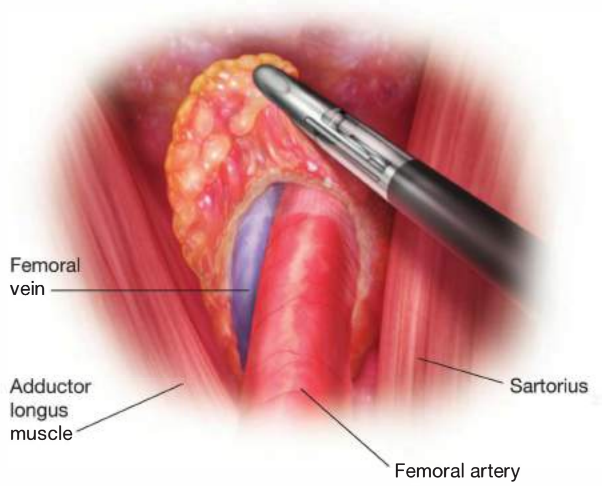

FIG 11 ● As the dissection at the apex continues deep from distal to proximal, the femoral vessels will come into view with the artery the first to be encountered.

- At this point, the dissection is performed by walking up the medial aspect of the sartorius from distal to proximal and rotating the contents medially. Because the femoral nerve lies in this location, a thin rim of fat is left on top of the nerve.
- As this process is repeated and continued, beginning at the apex and dissecting proximally, the femoral vasculature will be identified at this location (**FIG 11**).
- Because of the position of the lower extremity in abduction and flexion, the femoral artery lays directly anterior to the femoral vein. The femoral vein is deep and medial, and as we dissect proximally, the vessels will spiral and the two vessels will ultimately become parallel with each other lying in the same plain. Dissection should stay directly on the adventitia of the femoral vessels. Some prefer to use a laparoscopic Kittner for this dissection. I mainly use the dissection shears. The anterior half of the vessels are completely exposed.
- **FIG 12A,B** show the relative position change of vessels in relation to each other as we proceed from distal to proximal; this is accentuated by the leg being in a position of abduction.
- The deep inguinal lymph nodes are resected en bloc with this procedure. Our deep dissection plain is deep to the cribriform fascia. The cribriform fascia is an extension of the fascial lata. It separates the superficial inguinal lymph nodes from the deep inguinal lymph nodes. The cribriform fascia is penetrated by the saphenous vein at the fossa ovalis. The plane of dissection is depicted in **FIG 12A,B**.
- The femoral vein is appreciated deep and medial to the artery, just proximal to the apex. This is dissected out in a similar fashion. The anterior as well as the medial and lateral aspect of the vessels are skeletonized. There is no need to circumferentially dissect out these structures (**FIG 13A,B**).

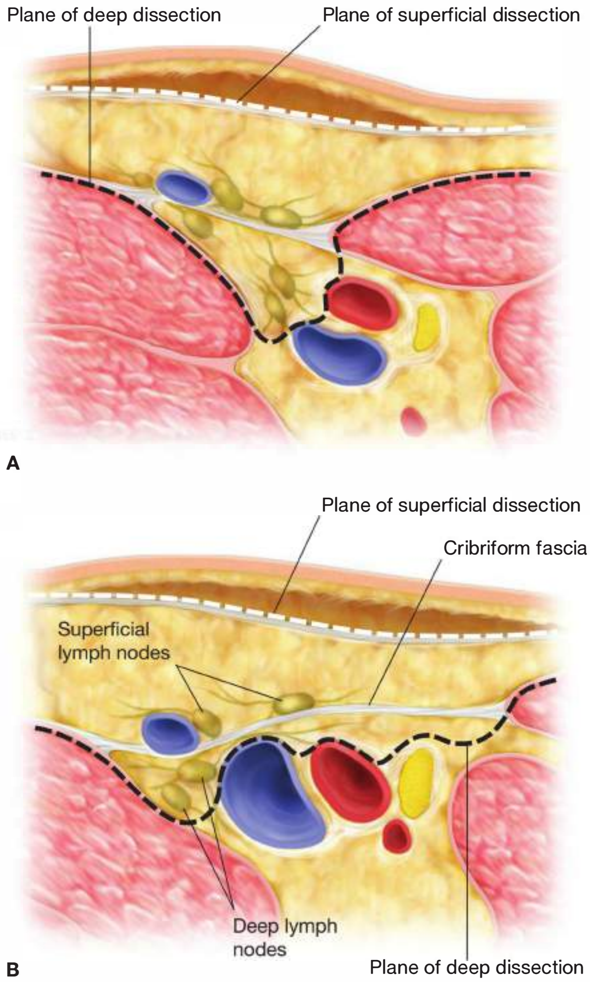

FIG 12 ● **A,B.** The superficial and deep dissection planes are graphically depicted here. These figures also demonstrate the relative position change of vessels in relation to each other as we proceed from distal to proximal, respectively.

- The femoral vein will be somewhat collapsed because of the CO_2 insufflation in this closed space. Its caliber will also be seen to fluctuate with ventilation.
- The medial dissection is completed off the adductor as we progress more proximally. As we continue our dissection, we simply walk up the adductor from distal to proximal. Continued anterior traction is applied to the specimen as we expose the vessels heading toward the inguinal ligament.

Proximal Dissection of Saphenous Vein at the Fossa Ovalis

- The medial and anterior surface of the femoral vein is skeletonized and we continue along medial aspect of this vessel under the inguinal ligament. Based on how far proximal you prefer to dissect here, Cloquet's lymph node can be removed en bloc with the specimen. If desired, a suture can be placed to mark Cloquet's node.

FIG 13 ● **A,B.** Intraoperative photos of the relationship of the vessels to each other and relative position change from distal to proximal, respectively (images © Mayo Clinic, 2014).

- The pectineus muscle can be seen here as the deep boundary of dissection. At this point, dissection is deep and proximal to the shelving edge of the inguinal ligament (**FIG 14**).
- The tissue is freed from medial to lateral off the previously exposed inguinal ligament.
- At this point, the saphenofemoral junction is identified, coming directly anterior off the femoral vein, approximately 3 cm distal to the inguinal ligament as the saphenous vein penetrates the cribriform fascia at the fossa ovalis. This will be identified as you dissect from distal to proximal along the medial surface of the femoral vein (**FIG 15**).

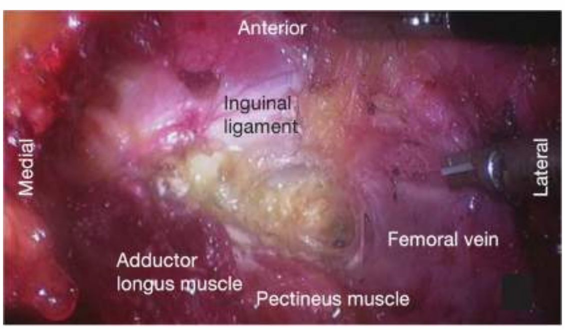

FIG 14 ● This image shows the empty space created deep to the inguinal ligament at the proximal/medial aspect of the dissection. The medial aspect of the femoral vein is skeletonized. One can choose to extend proximal to include Cloquet's lymph node with the specimen (image © Mayo Clinic, 2014).

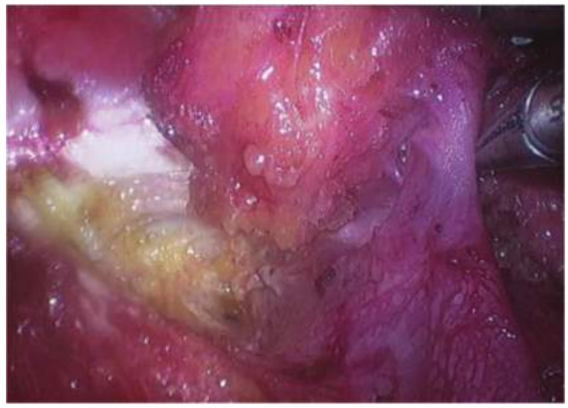

FIG 15 ● The saphenofemoral junction is identified as the dissection off the medial and anterior surface of the femoral vein is continued proximally (image © Mayo Clinic, 2014).

- The saphenofemoral junction is cleared and divided with a linear endovascular stapler (**FIG 16**). The proximal/medial tissue must first be freed off the femoral vein before this can be accomplished. It is better to complete this dissection proximal and medial to the saphenofemoral junction and make this window wider than you expect before attempting to introduce the stapler.
- The remaining proximal dissection of the femoral vessels (mostly cephalad and lateral) is then completed, removing the inguinal contents off of the remaining attachments with the femoral vessels. Short trocars and long instruments have been necessary in my experience in order to reach this proximal most dissection.
- If not already done so, any remaining soft tissue cephalad to the inguinal ligament is to be included (3 to 5 cm). This is easily peeled down off the external oblique aponeurosis, using hook cautery if desired, and included en bloc with the specimen. The remaining attachments with the inguinal ligament and external oblique aponeurosis are completed.

FIG 16 ● The intraoperative photo shows the proximal saphenous vein being divided with an endovascular stapler (image © Mayo Clinic, 2014).

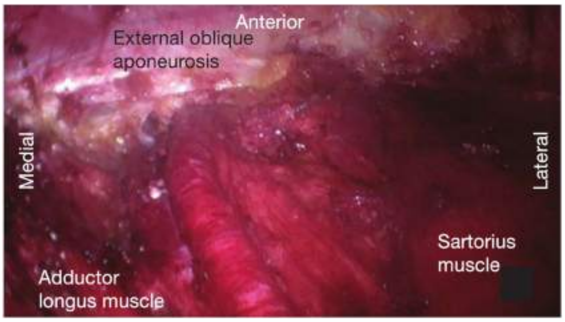

FIG 17 ● Intraoperative photo at the completion of the operation showing the musculature of the femoral triangle exposed, including the fascia overlying the external oblique aponeurosis, proximal to the inguinal ligament, and skeletonization of the anterior half of the femoral vessels (image © Mayo Clinic, 2014).

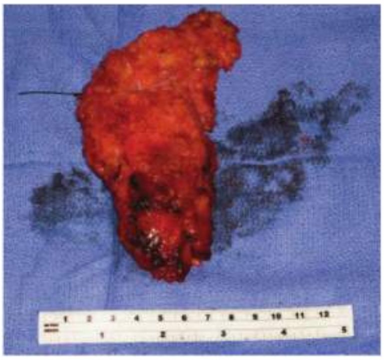

FIG 18 ● Photo of the inguinal contents after en bloc resection using the minimally invasive approach (image © Mayo Clinic, 2014).

- In a similar fashion, any remaining lateral attachments are freed off the sartorius followed by the final attachments off the inguinal ligament.

Specimen Removal

- Once the specimen is free, the contents are placed in an endobag.
- The anatomic boundaries are clearly delineated and you can visualize the soft tissue removed cephalad overlying the external oblique aponeurosis (**FIG 17**).
- Once completed, the drain is passed through the lateral trocar sites.
- The extracted specimen is depicted in **FIG 18**.
- A photo taken 1 week postoperatively is shown (**FIG 19**). It should be noted that the proximal longitudinal scar is from the original SLNB and not part of the MILND.
- At the end of the case, the genitals will be edematous from the CO_2 dissection. This is not a concern; the Foley can be removed at the end of the case and this should resolve by morning rounds. Crepitance up to the chest has been reported in some cases but has never been of clinical significance in my experience and to my knowledge. A chest strap during the operation can serve avoid this.

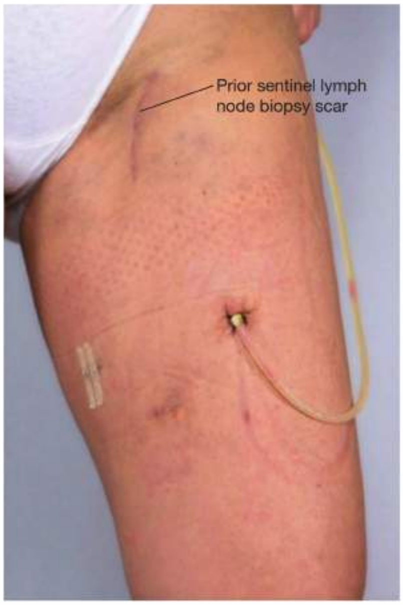

FIG 19 ● Photo of operative leg at the first postoperative visit.

PEARLS AND PITFALLS

High conversion rate	■ Embarking on this procedure without adequate training ■ Frustration and lack of patience ■ As with any new minimally invasive procedure, this should be scheduled at a date and time when there are limited other external pressures.
Unable to reach proximal dissection	■ Placing trocars too distal or instruments too short
Dissection too lateral	■ Typically, this is a result of not placing the leg in adequate abduction and external rotation prior to the start of the procedure.

Inadequate lymphadenectomy	■ Not staying within defined anatomic boundaries ■ Not dissecting anterior to Scarpa's fascia ■ Not dissecting the deep inguinal lymph nodes by staying on the adventitia of the femoral vessels (not dissecting deep to the cribriform fascia) ■ Not dissecting the tissue cephalad to the inguinal ligament
Conversion secondary to hypercarbia	■ Not briefing with anesthesia team and making appropriate minute ventilation adjustments
Constant leak during case	■ Finger dissection of more than one port site at start of case and making incisions too large
Drain not holding suction	■ Not sealing incision closed tightly around drain at end of case. There is no subcutaneous fat between trocar site and cavity, unlike an abdominal procedure or open nodal dissections in which the drain is passed through a subcutaneous tunnel, so this remains very unforgiving.
Seroma/prolonged drain days	■ See section regarding Postoperative Care

POSTOPERATIVE CARE

- Patient is admitted as an outpatient overnight and discharged within 23 hours. Drain care is reviewed in detail. Same-day discharge could be considered as pain has not been an issue.
- Regarding seromas, activity, and drain days, my practice continues to evolve. I went from limited activity to one of minimal activity and near bed rest at home until the drain comes out, and my current approach at the time of publication is back to limited activity. As a result of the malignancy, the immediate perioperative period, restricted activity to almost one of bedrest, patients were discharged home on daily low-molecular-weight heparin (LMWH), prophylactic VTE dosing. This minimal activity and compression of the surgical site did not appear to result in decreased drain days, so I have since stopped and allow limited activity. If considering home chemical VTE prophylaxis with LMWH, there is no need for a home health or visiting nurse; patients can be taught while in the hospital to self-administer this medication.
- The patients are seen prior to discharge by the physical medicine and rehabilitation lymphedema therapist. Compressive leg wrapping is applied as well as compression to the operative field (compressive biker shorts with a foam insert or sock placed directly over the basin). I have no data this decreases seroma or lymphedema or allows for earlier drain removal. Patients and family are educated on dressing changes and follow-up is arranged for the 1-week postoperative visit.
- Ensure the drain is holding suction prior to discharge.
- Redness and minor bruising of the flap is typical and noted on postoperative day 1 and on the first postoperative visit. These findings do not represent cellulitis and antibiotics are generally not indicated.
- There are two approaches to the drain removal. This is a balance between an increased risk of infection as the drain days increase versus accepting a higher seroma rate. The verdict is not out on the best approach here:
  - Remove drain at 2 to 3 weeks regardless of output and accept a seroma. Observation of the seroma is reasonable, if asymptomatic. Patients need to be educated preoperatively that a fluid collection will develop in their groin and not to be concerned.
  - Leave drain until output is less than 30 to 40 mL a day for 2 consecutive days. This often means keeping the drain up to 7 weeks.
  - As a result of the expected prolonged number of drain days (NOT flushing up the drain, just rinsing the bulb and emptying), our drain care regimen consists of rinsing the bulb with dilute Dakin's solution three times a day and placing a chlorhexidine Biopatch around the drain exit site and sealing it with a Tegaderm. The chlorhexidine disc is changed every third day and the drain site is cleaned with an alcohol wipe with each dressing change. This practice is based on Dr. Degnim's work in breast surgery and I only use for groin dissection because of the prolonged drain days.[11]

OUTCOMES

- The outcome data is limited[7,8] and frank discussion with the patient must be held explaining that this operation is being performed for malignancy, but it remains unknown if this is as oncologically sound as an open approach. The extent of resection should never be jeopardized to accomplish the procedure with the smallest incision possible. Seromas and prolonged drain days appear to be the Achilles heel thus far; we are exploring ways to combat this. Based on the limited experience worldwide, wound complications including breakdown and infections appear to be much less of an issue compared to the open approach (no big incision, no big wound problem). If lymphedema rates will be decreased is unknown at present. Major neurovascular structures are in the field and at risk. Flap necrosis can occur, but despite very thin flaps, I have not personally seen this.

COMPLICATIONS

- Seroma
- Hematoma
- Wound dehiscence
- Flap necrosis
- Major vascular injury
- Femoral nerve injury
- Drain not holding suction
- Recurrence
- Lymphedema
- Infection
- Anesthesia risks
- Hypercarbia
- Inadequate lymphadenectomy

Chapter 31 Selective Neck Dissection for Melanoma

Vasu Divi

DEFINITION

- The goal of a selective neck dissection for melanoma is the complete removal of the lymph nodes and lymphatics that drain a specific region of skin in the head and neck.
- This procedure is performed for patients presenting with clinically evident regional metastasis as well as for patients with a positive sentinel lymph node.

PATIENT HISTORY AND PHYSICAL FINDINGS

- All patients with melanoma of the head and neck should undergo palpation of the regional lymphatics, including the parotid glands and cervical levels 1 to 5.
- Melanomas at the junction of the neck and the chest, back, or shoulder should also include palpation of the axillary lymph nodes.
- All patients with melanoma, particularly those with proven regional metastases, should have a focused review of symptoms, looking for symptoms concerning for metastatic disease.
- All patients with melanoma should also have a complete skin exam, looking for second primary cutaneous malignancies.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Preoperative imaging of the neck is not necessary in patients without clinically evident neck disease.
- In patients with palpable adenopathy
  - Imaging by contrast-enhanced computed tomography (CT) scan is generally recommended to evaluate the extent of disease.
  - Fine needle aspiration is used to obtain pathologic diagnosis of the enlarged lymph node.
- In cases of distant metastatic disease, the need for selective neck dissection is balanced against the life expectancy of the patient. In many cases, achievement of regional control in the neck is preferred, given the complications of untreated disease in the head and neck.

SURGICAL MANAGEMENT

Preoperative Planning

- Determination of the type of neck dissection to be performed is based on the location of the primary tumor and location of neck disease.
- The relevant lymphatic basins of the head and neck include the parotid lymph nodes, levels 1 to 5, and the postauricular lymph nodes (**FIG 1**).
- This serves as a rough guide to when different lymphatic basins should be addressed; ultimately, the clinician should dissect all lymphatic basins that could potentially be harboring clinical disease based on an understanding of lymphatic drainage patterns.
  - The removal of the superficial lobe of the parotid gland is performed for any primary cutaneous tumor anterior to the external auditory canal and above the angle of the mandible.

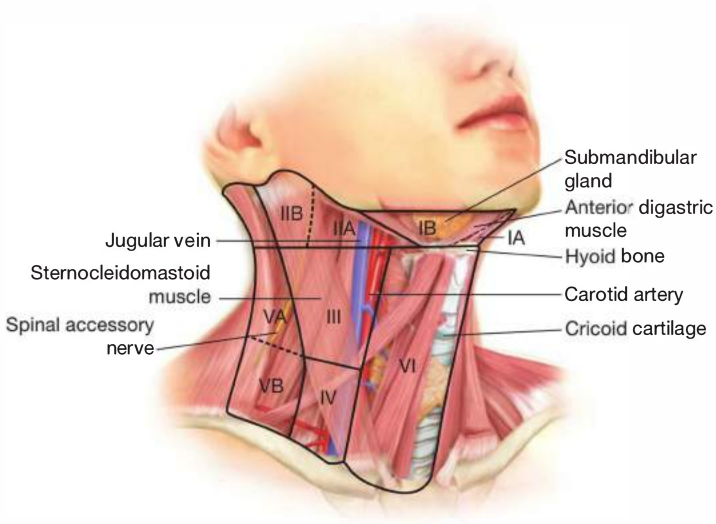

FIG 1 ● Levels of the neck. Level 1 includes all nodes between the contralateral anterior belly of the digastric, ipsilateral posterior belly of the digastric, and the inferior edge of the mandible. Level 2 includes the nodes below the skull base between the posterior belly of the digastric, posterior edge of the SCM, and above the level of the hyoid. Level 3 includes all nodes between the hyoid bone and cricoid cartilage arch, between the lateral and the internal carotid artery, and the posterior edge of the SCM. Level 4 includes all nodes between the cricoid cartilage arch and clavicle, between the lateral and the internal carotid artery, and the posterior edge of the SCM. Level 5 includes all nodes from the skull base down to the posterior border of the sternocleidomastoid muscle to the clavicle, anterior to the trapezius muscle.

- Levels 1 to 4 are dissected with any lesion involving the scalp anterior to the plane of the external auditory canal, facial skin, or anterior neck skin.
- Levels 2 to 5 are dissected with any lesion involving the scalp posterior to the plane of the external auditory canal or posterior neck skin.
- If the primary lesion is in the scalp and located very close to the plane of the external auditory canal, dissection should include levels 1 to 5.

Positioning

- Patients are placed supine with the top of the head at the edge of the surgical bed.
- A bump is placed underneath the shoulder blades to allow for extension of the neck, being careful to maintain support of the head on the operating room (OR) table.

SELECTIVE NECK DISSECTION LEVELS 1 TO 4

- A curvilinear incision is made midway between the angle of the mandible and the clavicle; the incision travels within a neck crease, extending a few centimeters from the mastoid tip toward the approximate midpoint of the thyroid cartilage (**FIG 2**).
- Skin is incised down through the subcutaneous tissue and platysma.
- Subplatysmal skin flaps are elevated to expose the deeper contents overlying levels 1 to 4 of the neck; this will extend to the mentum, along the strap musculature in the midline, to the posterior border of the sternocleidomastoid muscle (SCM), and down to the level of the clavicle (**FIG 3**).
- The marginal mandibular nerve is identified in the superficial layer of the cervical fascia near the angle of the mandible and is identified using nerve stimulation. The nerve is dissected free and elevated over the plane of the mandible (**FIG 4**).

FIG 2 ● The neck incision is marked out between the mandible and clavicle.

- The facial artery and vein are identified and ligated as they cross over the plane of the mandible.
- The tissue over the mandible is then incised from the mentum to the angle of the mandible, taking care not to injure the previously dissected marginal mandibular nerve. This tissue is pulled inferiorly, taking care to remove the perifacial lymph nodes located near the facial vessels. During this

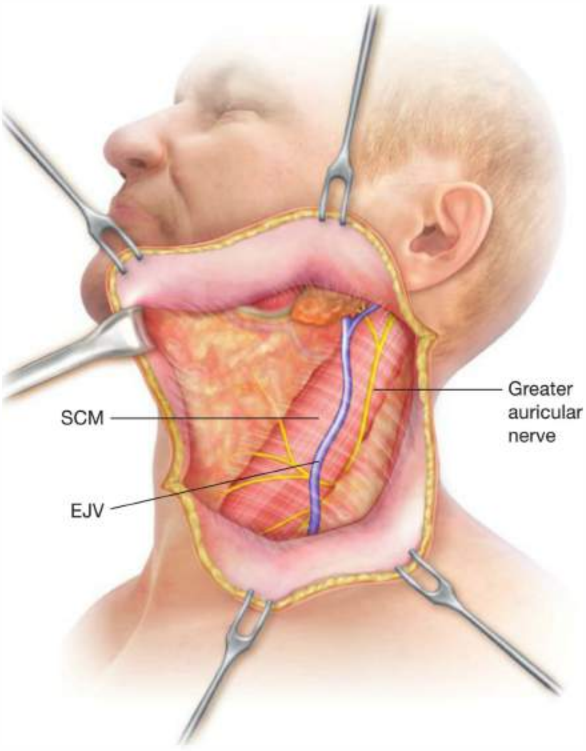

FIG 3 ● The neck incision is completed with subplatysmal flaps elevated superiorly and inferiorly.

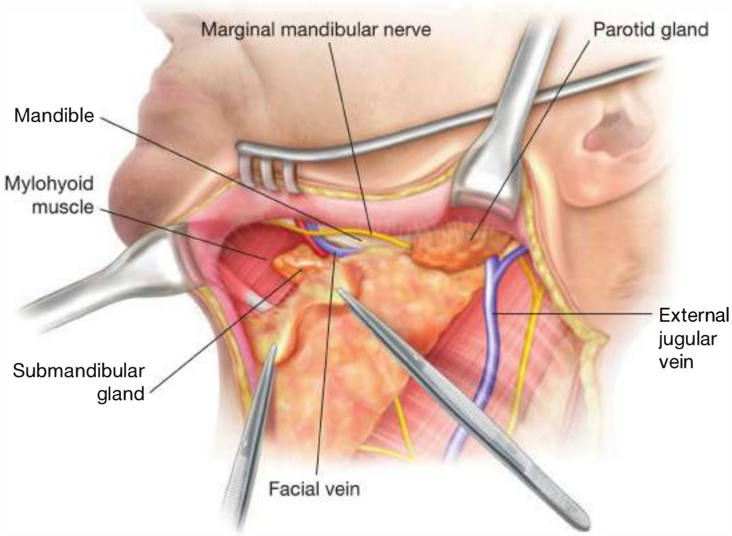

FIG 4 ● The marginal mandibular nerve is elevated over the mandible and the contents of level 1A are dissected posteriorly. Division of the facial artery and vein would occur at this point or earlier in the dissection.

dissection, the retromandibular vein may be identified and ligated as it travels through the tail of the parotid gland.

- Incise soft tissue over contralateral anterior belly of the digastric muscle from mentum down to hyoid bone.
- Begin elevating contents of level 1A by pulling tissue laterally off the mylohyoid muscle toward the ipsilateral anterior belly of the digastric muscle; this will require division of tissue along the hyoid bone inferiorly.
- Bring packet of tissue over ipsilateral digastric and back onto mylohyoid until the edge of the mylohyoid is reached see **FIG 4**.
- Retract the mylohyoid muscle medially to allow for exposure of the contents deep to the submandibular gland. This may require some blunt dissection in this area. Identify the hypoglossal nerve, lingual nerve, and submandibular duct (**FIG 5**).
- Divide the submandibular duct, taking care not to cause excessive bleeding from the nearby veins (**FIG 6**).
- Divide the submandibular ganglion and allow the lingual nerve to retract superiorly.
- Pull the submandibular gland and packet of tissue laterally, carefully dividing the tissue over the posterior belly of the digastric (**FIG 7**).
- Approximately halfway up the posterior belly, the facial artery is again seen travelling under the digastric and into the submandibular gland; divide the artery a second time.
- Trace the posterior belly superiorly, dividing the overlying tissue until the SCM is reached. If it has not already

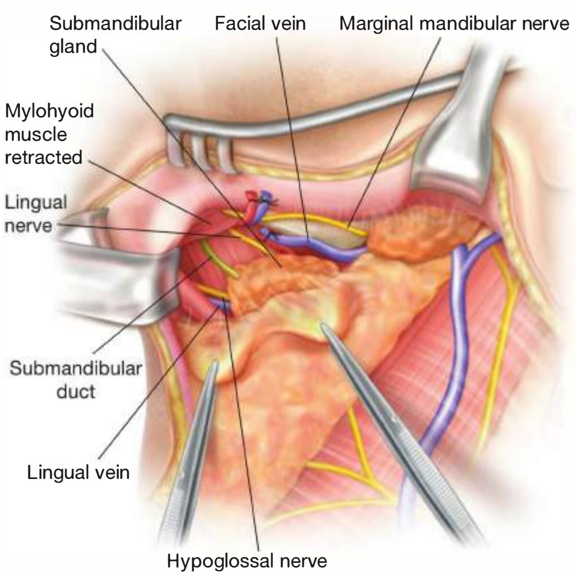

FIG 5 ● The mylohyoid muscle is retracted anteriorly exposing the lingual nerve, submandibular duct, and hypoglossal nerve. The hypoglossal nerve is in a deeper plane than the lingual nerve and is only exposed after dividing the overlying fascia.

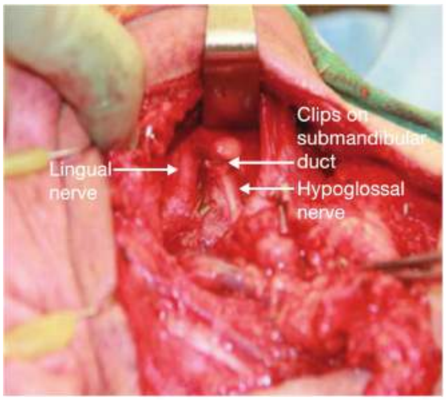

FIG 6 ● View of the right neck level 1B with the submandibular gland removed and the mylohyoid muscle retracted anteriorly. Clips are seen on the submandibular duct remnant.

been divided, the retromandibular vein is usually encountered as it exits the parotid gland near the angle of the mandible—carefully divide the vein.

- The SCM is then "unwrapped." At the posterior edge of the SCM, incise the fascia over the muscle. This will require division of the cutaneous nerves that course over the muscle; the great auricular branch to the ear as well as the external jugular can sometimes be traced out and saved.
- Pull the fascia medially to unwrap the SCM; be careful to take all tissue over the muscle because lymph nodes associated with the external jugular vein must be removed.

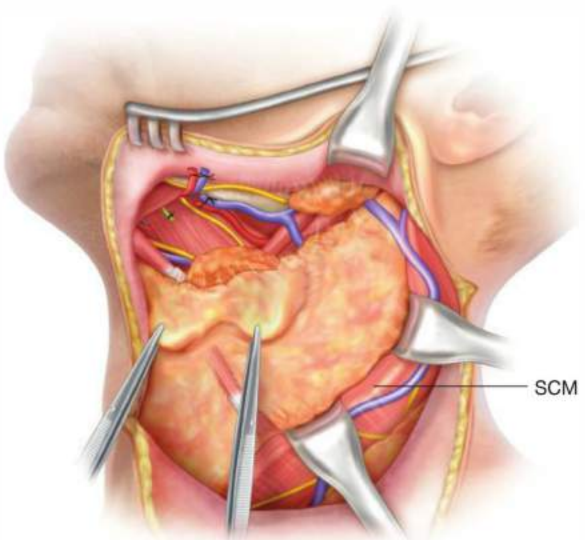

FIG 7 ● The contents of level 1B are pulled over the posterior belly of digastric. The facial artery could be dissected free from the gland (as shown) or divided a second time as it crosses under the digastric.

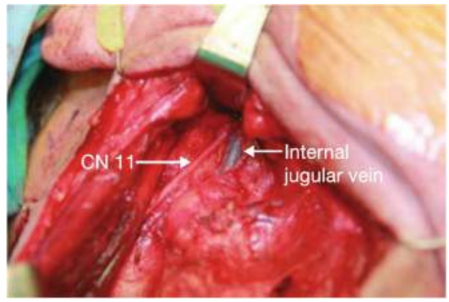

FIG 8 ● The contents of the right-sided level 2 are exposed with CN 11 in clear view as it courses over the internal jugular. The posterior belly of digastric is retracted superiorly.

- After the anterior surface of the SCM is wrapped, carefully roll the muscle outward to start unwrapping the deep surface; at the junction of the upper one-third and lower two-thirds, the cranial nerve (CN) XI (the spinal accessory nerve) will be encountered as it enters the muscle.
- Continue to unwrap and elevate the muscle of the floor of the neck until the posterior edge is reached, taking care to not stretch or injure CN XI.
- At this point, the posterior belly of the digastric should be traced underneath the SCM and then mobilized so it can be pulled superiorly.
- At the hyoid bone, the omohyoid muscle is identified and traced low into the neck to the posterior edge of the SCM. It is mobilized as well so it can be pulled inferiorly.
- Next, the posterior belly of the digastric is pulled superiorly while CN XI is traced underneath the muscle by dividing the overlying tissue until it courses over the internal jugular (IJ) vein; the nerve usually passes superficial to the vein (80%) but can also pass deep to it (20%) (**FIG 8**).
- The spinal accessory nerve is elevated off the deep neck and is circumferentially dissected up to the IJ; the wall of the IJ vein is then skeletonized (**FIG 9**).
- The transverse process of C1 is palpated on the floor of the neck. This will serve as the superior limit of dissection.
- Lymphatic tissue of level 2B is mobilized by dividing the tissue between the IJ and the posterior edge of the SCM down to the level of the floor of the neck (levator scapulae muscle). Superiorly, the contents of level 2B will need to be pulled underneath the CN XI (**FIG 9**).
- The posterior edge of dissection parallels the posterior border of the SCM. This tissue is incised down to the floor of the neck as well, taking care to not divide the cervical rootlets (**FIG 10**).
- The inferior margin of dissection is approximately at the clavicle. The omohyoid muscle can be retracted inferiorly or divided to access this area.
- Start by identifying the IJ low in neck and skeletonizing the wall. Next, divide the tissue adjacent to the IJ down to the floor of the neck. This tissue needs to be carefully ligated with sutures or clips due to the presence of the thoracic duct. The tissue is divided between the IJ and the posterior edge of the SCM.

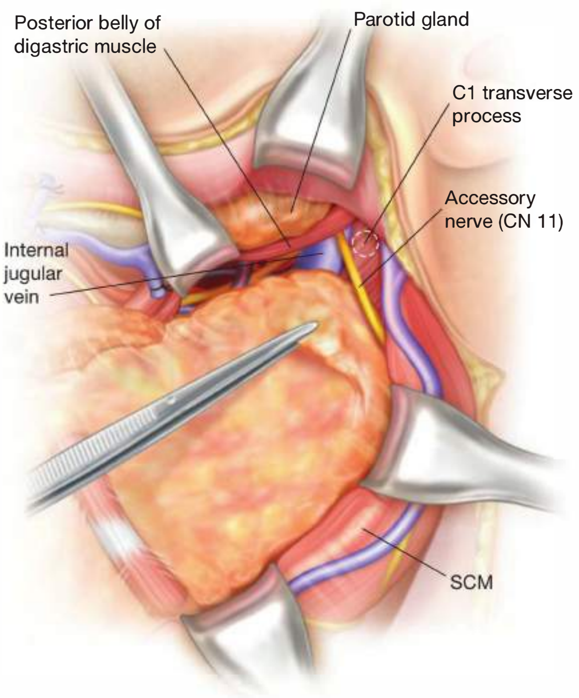

FIG 9 ● The contents of level 2B are dissected and passed underneath CN 11. The transverse process of C1 is palpable beneath the muscle.

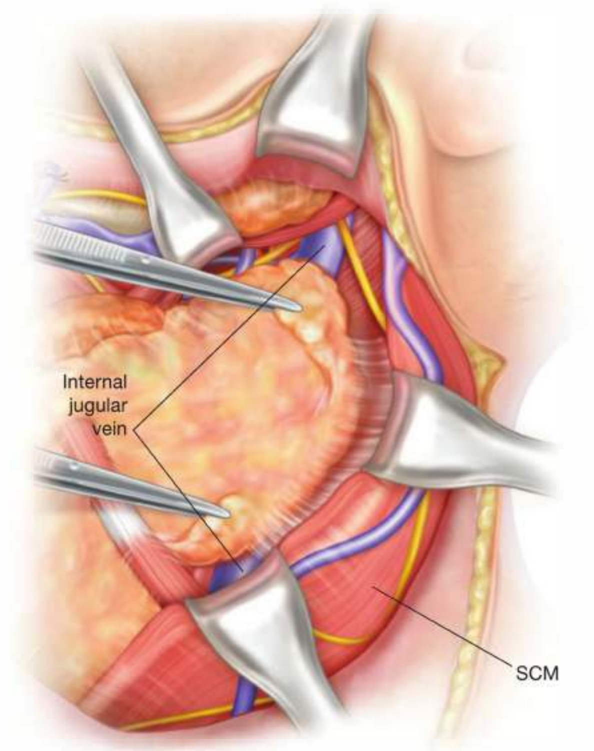

FIG 11 ● The inferior dissection at the level of the clavicle is complete, allowing the lymphatic tissue of levels 2, 3, and 4 to be elevated off the floor of the neck.

- The tissue is then brought forward off the floor of the neck onto the IJ vein (**FIG 11**). Follow the fascia of the floor without violating the fascia covering the deep neck muscles.
- The package of tissue is then brought over the IJ by entering the fascia of the carotid sheath; as the tissue is dissected off the IJ, the branches of the IJ are ligated (**FIG 12**). Once the IJ is nearly circumferentially dissected, the carotid artery is in view (**FIG 13**).

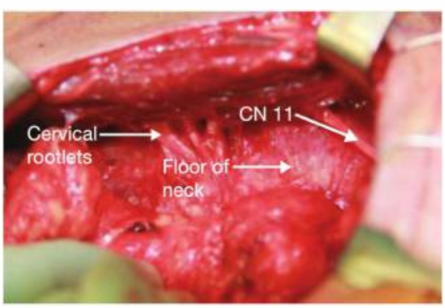

FIG 10 ● With the SCM retracted in the right neck, the contents are elevated off the floor of the neck. CN 11 is seen on the right side of the picture, and in the middle of the picture, the cervical rootlets are seen piecing the floor of the neck and wrapped around the posterior SCM.

- The hypoglossal nerve is identified underneath the digastric. This is traced posteriorly, dividing the overlying tissue and veins until the nerve travels between the carotid and IJ (**FIG 14**).
- The package is brought over the carotid until the superior thyroid artery is seen; at this point, transition is made to the fascia of the visceral space (**FIG 15**).
- The package of tissue is then truncated at the lateral border of the strap musculature.

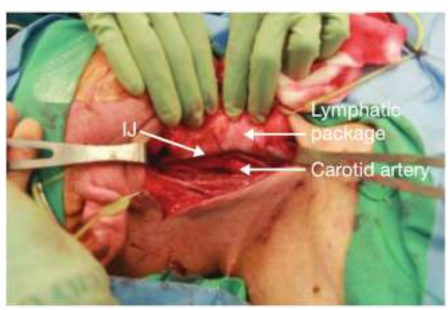

FIG 12 ● The lymphatic package is pulled medially in the right neck, still attached to the internal jugular. The package will be taken off of the IJ and onto the visceral space.

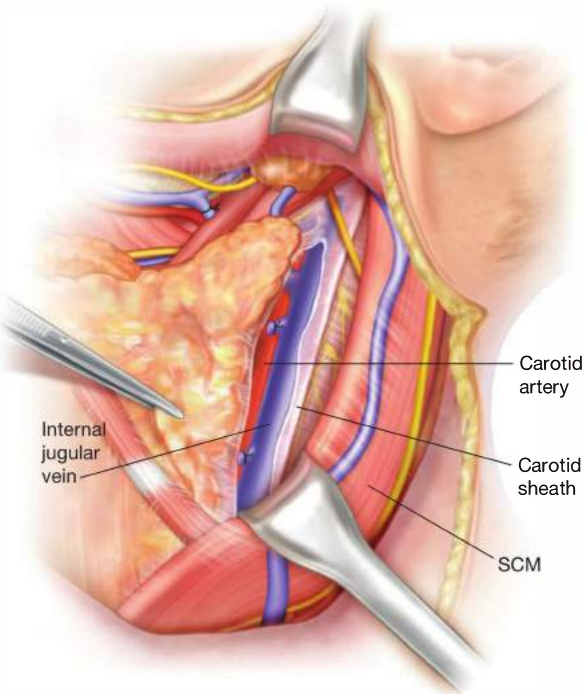

FIG 13 ● The carotid sheath is entered and the branches of the IJ are divided allowing the packet to be transitioned onto the carotid artery.

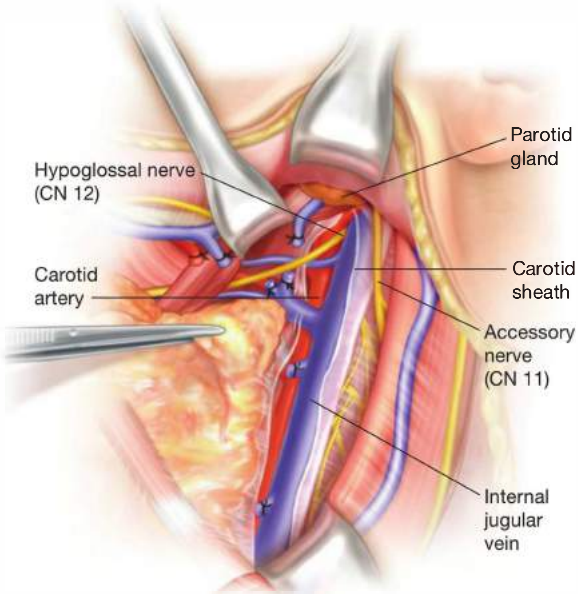

FIG 14 ● The hypoglossal nerve is traced out from where it crosses the digastric until it courses between the carotid and the IJ. The overlying veins are delicate and must be divided carefully to avoid significant bleeding which could obstruct the view of the vein.

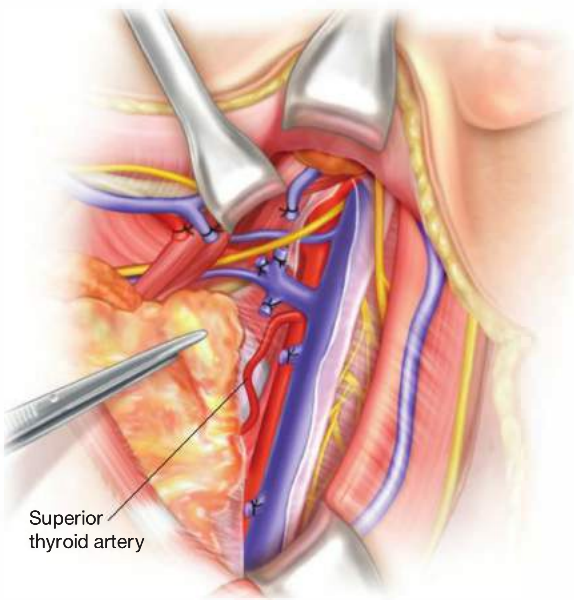

FIG 15 ● The packet is transitioned off the carotid space and onto the visceral space carefully preserving the superior thyroid artery.

TECHNIQUES

SELECTIVE NECK DISSECTION LEVELS 2 TO 5 (POSTERIOR-LATERAL NECK DISSECTION)

- The skin incision is modified from the prior procedure being located more posteriorly and travelling lower in the neck.
- Alternatively, a "limb" can be dropped down from the incision to give access to the area over the supraclavicular fossa.
- Posteriorly, the platysma is absent; therefore, the approximate plane of the superficial layer of the cervical fascia is followed.
- The skin flap is raised to the edge of the trapezius muscle posteriorly and inferiorly; the muscle edge is often not seen and therefore must be estimated.
- CN XI is located within the level 5 area. The nerve usually exits the posterior border of the SCM approximately 2 cm above where the great auricular nerve wraps around the muscle. The position is confirmed with nerve stimulation.
- Once the nerve is identified, it is traced from the posterior edge of the SCM until it travels underneath the trapezius muscle; as the nerve approaches the trapezius, it often splits into more than one branch, each of which should be preserved.
- The nerve is then mobilized and elevated from the level 5 contents.
- Next, the posterior superior edge of the SCM is skeletonized.
- This dissection is carried out to the level of the mastoid tip, where the dissection turns posteriorly until the edge of the trapezius is identified.
- In this area, the tissues are cut down to the floor of the neck until the levator scapulae muscle is identified.
- The posterior edge of the SCM and the edge of the trapezius muscle are dissected in their entirety down to the floor of the neck; care is taken to not injure CN XI as it exits and enters these muscles.
- Inferiorly, the tissue at the level of the clavicle is divided heading toward the floor of the neck; careful not to violate the fascia of the floor of the neck to avoid injury to the transverse cervical vessels or the brachial plexus.
- This dissection will connect to both the anterior SCM dissection and the posterior trapezius dissection.
- The omohyoid muscle can be divided near its insertion into the scapula.
- The contents of level 5A and 5B are now brought forward by elevating them off the floor of the neck; during this process, the sensory cervical rootlets can be dissected free and preserved or divided.
- Once the contents are brought to the posterior edge of the SCM, the contents can either be truncated at this point or tucked underneath the SCM.
- The remainder of the levels 2 to 4 neck dissection proceeds as described above; begin by identifying the posterior belly of the digastric muscle and tracing it up to the SCM.

UNIQUE SCENARIOS

- Skin involvement
  - Involvement of the skin can happen from metastatic disease in the neck or from a primary lesion in the neck.
  - Extent of involvement should be determined based on CT scan and palpation with careful attention to the platysma and dermis.
  - Mark at least 1 cm around areas of subcutaneous or dermal involvement; closure is assisted by using elliptical-shaped excisions and paying close attention to resulting skin flaps for rotation or advancement.
  - At the time of skin incision, these areas should incised down through the level of the platysma.
  - Subplatysmal skin flaps are elevated around the area of involvement, leaving the skin overlying the tumor pedicled on the tumor.
- Involvement of structures
  - Necessity for resection of the SCM, CN XI, IJ, or additional structures is based on involvement seen on imaging studies or at the time of surgery.
  - Tumor should never be violated to preserve any of these structures.

PEARLS AND PITFALLS

Communication with anesthesia	■ It is essential that the patient is not paralyzed for the operation to allow for monitoring of the marginal mandibular nerve, CN XI, and CN XII. Short-acting paralytics used for induction generally wear off by the time the incision is made.
Placement of incision	■ The incision should be about two fingerbreadths below the edge of the mandible to avoid injuring the marginal mandibular nerve during skin flap incision and elevation.
Identification of structures	■ The fascial planes provide excellent boundaries for dissection and should almost always be followed during the neck dissection.
Excision	■ If grossly positive lymph nodes are encountered, take a cuff of normal tissue to surround the node. This can involve removing a portion of the SCM or sacrificing the IJ.

Division of specimen	■ The specimen is typically divided into the corresponding levels of the neck dissection to allow pathology to separately report which levels contained positive lymph nodes.
Prior to closure	■ The level 4 area of the neck is checked for a chyle leak with a sustained Valsalva maneuver. Any evidence of clear or milky fluid should be treated by sewing over or clipping the area.

POSTOPERATIVE CARE

- Following surgery, patients are admitted to the general inpatient unit.
- Postoperative antibiotics are continued for 24 hours.
- Postoperative subcutaneous heparin is used immediately following surgery.
- Closed suction drains are used until output is less than 30 mL per day.
- Patients with extensive CN XI dissection are seen by physical therapy for arm mobilization and strengthening exercises.

OUTCOMES

- The rate of regional recurrence after selective neck dissection for melanoma depends on the extent of cervical disease at the time of resection. It is as low as 15% for micrometastatic disease and as high as 50% for macroscopic disease with extracapsular extension.
- Postoperative radiation therapy is considered for patients with extracapsular extension, a single node greater than 4 cm, three or more positive nodes, or for neck dissections following a regional recurrence.
- Recurrent neck disease after neck dissection must be carefully evaluated to determine resectability.

COMPLICATIONS

- Hematoma
- Chyle leak
- CN XI injury
- Hypoglossal injury
- Marginal mandibular weakness
- Stroke

Chapter **32**

Popliteal Dissection

Glenda G. Callender Kelly M. McMasters

DEFINITION

- Popliteal dissection, or popliteal lymphadenectomy, is the removal of all lymph node–bearing tissue from the popliteal fossa. This procedure is most commonly performed for melanoma but may rarely be performed for other cutaneous cancers or for the limited number of sarcomas that have a propensity to metastasize to lymph nodes.
- Popliteal dissection is indicated in patients with no evidence of distant metastatic disease who are found to have the following:
  - Positive popliteal sentinel lymph node biopsy (microscopic nodal disease)
  - Clinically positive popliteal lymph nodes (macroscopic nodal disease)
- Boundaries of the popliteal fossa (**FIG 1**)
  - Superomedial: semitendinosus and semimembranosus muscles
  - Superolateral: biceps femoris muscle
  - Inferomedial: medial head of the gastrocnemius muscle
  - Inferolateral: lateral head of the gastrocnemius muscle and plantaris muscle
  - Roof: skin, superficial fascia, deep (popliteal) fascia
  - Floor: popliteal surface of femur, capsule of knee joint, oblique popliteal ligament, fascia overlying popliteus muscle

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be elicited prior to treatment, including a detailed past medical and surgical history, present medications and allergies, and a personal and family history of cancer. A complete head-to-toe skin examination should be performed. All lymph node basins (cervical, supraclavicular, axillary, epitrochlear, inguinal, popliteal) should be evaluated for clinically positive lymph nodes.
- Clinically positive lymph nodes typically present as a palpable mass. However, enlarged lymph nodes in the popliteal fossa may not be easily palpable because of the thick overlying fascia. Therefore, a careful examination of the popliteal fossa is essential.
- Most patients undergo popliteal dissection because of a positive sentinel lymph node biopsy. Sentinel lymph node biopsy has now become the standard of care for evaluating regional lymph node basins in patients with cutaneous melanoma greater than 1 mm in Breslow thickness who have no evidence of distant metastatic disease (see Part 5, Chapter 27). Current standard of care for patients with positive sentinel lymph nodes includes completion lymphadenectomy of the involved lymph node basin; observation alone should be performed in the context of a clinical trial. Approximately 50% of patients with a positive popliteal sentinel lymph node biopsy will also have documented inguinal disease; therefore, popliteal and inguinal dissections are often performed concomitantly.[1,2]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A clinically positive lymph node should be evaluated using fine needle aspiration biopsy. Popliteal dissection is performed for a positive biopsy.
- For patients with clinically negative lymph nodes, preoperative lymphoscintigraphy should be performed at the time of the initial sentinel lymph node biopsy even if the primary melanoma is located on an extremity. Lymphoscintigraphy will demonstrate drainage to popliteal lymph nodes in 1% to 9% of patients with distal lower extremity melanoma (i.e., below the knee; **FIG 2**).[1–5] By far, the most common locations for primary melanomas that drain to the popliteal fossa are the posterolateral foot and posterior lower leg; however, primary melanomas of the anterior lower leg or

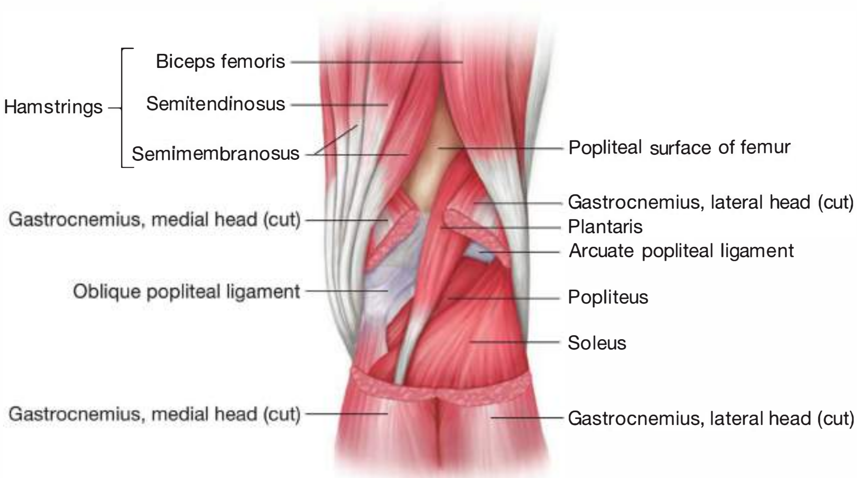

FIG 1 ● Boundaries of the popliteal fossa (right leg).

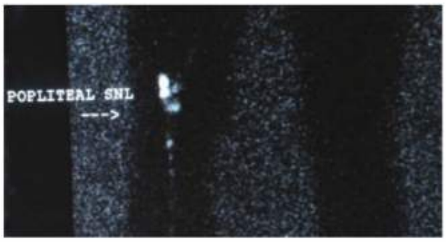

FIG 2 ● Lymphoscintigraphy demonstrating lymphatic drainage to the popliteal fossa from a primary melanoma of the distal right foot.

anteromedial aspect of the foot will also occasionally drain to the popliteal fossa.[1–4] The overall incidence of a positive popliteal lymph node is 0.3% to 2.8%.[1–3,5]

SURGICAL MANAGEMENT

Preoperative Planning

- In the preoperative area, a focused history and physical examination should be repeated, and the patient's prior pathology and imaging studies should be reviewed.
- The patient should be marked to confirm laterality.
- Although there are no data that specifically address the wound infection rate in popliteal dissection, we favor the administration of a dose of preoperative antibiotics, particularly if concomitant inguinal dissection is planned.

Positioning

- The patient is placed prone, with pressure points padded, and the operative knee slightly flexed (FIG 3). The operative leg should be prepped circumferentially from above the midthigh to below the midcalf.
- If a concomitant inguinal dissection is planned, the popliteal dissection is usually performed first.

FIG 3 ● Patient position for popliteal dissection. Note that the operative leg (right) is slightly flexed.

PLACEMENT OF INCISION

- There are two options for the incision for popliteal dissection (FIG 4). The incision should be planned such that a prior incision for sentinel lymph node biopsy can be excised.
- The S-shaped incision was described by Karakousis[6] in his initial report of the technique of popliteal dissection. This incision typically extends from approximately 10 cm proximal to the joint crease along the lateral thigh overlying the biceps femoris

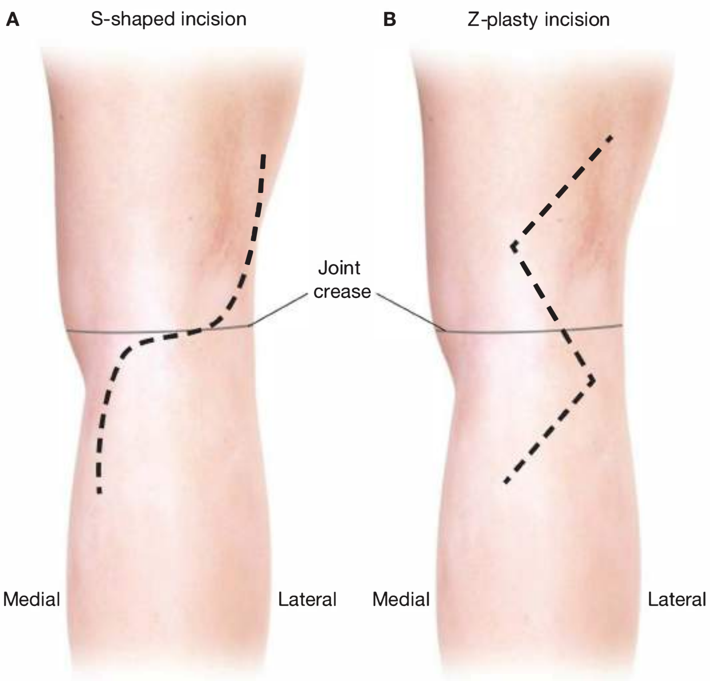

FIG 4 ● Incisions for popliteal dissection (right leg). **A.** S-shaped incision. **B.** Z-plasty incision.

muscle, crosses the joint transversely, and extends approximately 10 cm distal to the joint crease along the medial calf overlying the medial aspect of the gastrocnemius muscle (**FIG 4A**). A mirror image of this incision, extending from the medial thigh to the lateral calf, is also acceptable and may be preferable depending on the orientation of the incision used to perform the sentinel lymph node biopsy.

- We prefer a Z-plasty incision that allows for optimal exposure and heals without joint contracture.[7] Again, the orientation is typically superolateral to inferomedial. The width and length of the Z is relative to the size of the lower thigh, usually with an interior angle ranging from 100 to 120 degrees (**FIG 4B**).

SKIN INCISION AND RAISING OF FLAPS

- The incision is created and dissection is carried down through the subcutaneous tissue. Medial and lateral flaps are raised while traction is maintained with skin hooks. The flaps should expose all of the boundaries of the popliteal fossa, remaining above the deep fascia.
- The lesser saphenous vein is exposed inferiorly; it should be ligated and divided (**FIG 5**).

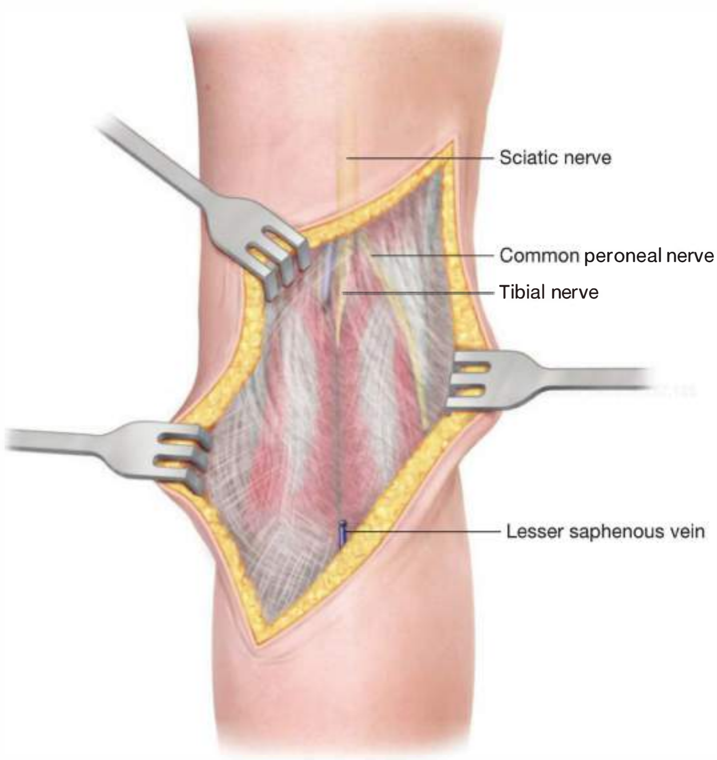

FIG 5 ● Medial and lateral skin flaps are raised, and the lesser saphenous vein is divided (right leg).

INCISION OF THE DEEP FASCIA AND IDENTIFICATION OF STRUCTURES TO BE PRESERVED

- The deep fascia is incised vertically with great care not to injure underlying structures; the nerves are very superficial (**FIG 6**).
- The common peroneal nerve runs laterally in the field, just medial to the biceps femoris muscle. The lateral sural nerve branches medially from it and eventually connects inferiorly with the medial sural nerve to form the sural nerve. The lateral sural nerve may be sacrificed if necessary; no significant deficit is appreciated as long as the medial sural nerve remains intact.
- The tibial nerve is the most superficial midline structure. It lies lateral to the popliteal vessels at the superior aspect of the popliteal fossa then courses anterior to the vessels and lies medial to them at the inferior aspect of the popliteal fossa. The medial sural nerve branches off of the tibial nerve and descends in the groove between the heads of the gastrocnemius muscle to where it connects inferiorly with the lateral sural nerve. The medial sural nerve should be preserved if possible; however, it can be divided if greater access to deeper structures is needed. The patient will experience sensory loss along the lateral aspect of the ankle and foot.
- The popliteal vessels are ensheathed; upon opening the sheath, the popliteal artery will be located slightly medial and deep to the popliteal vein (**FIG 7**). The popliteal vein has several small tributaries below the level of the lesser saphenous vein branch, which can cause bothersome bleeding.

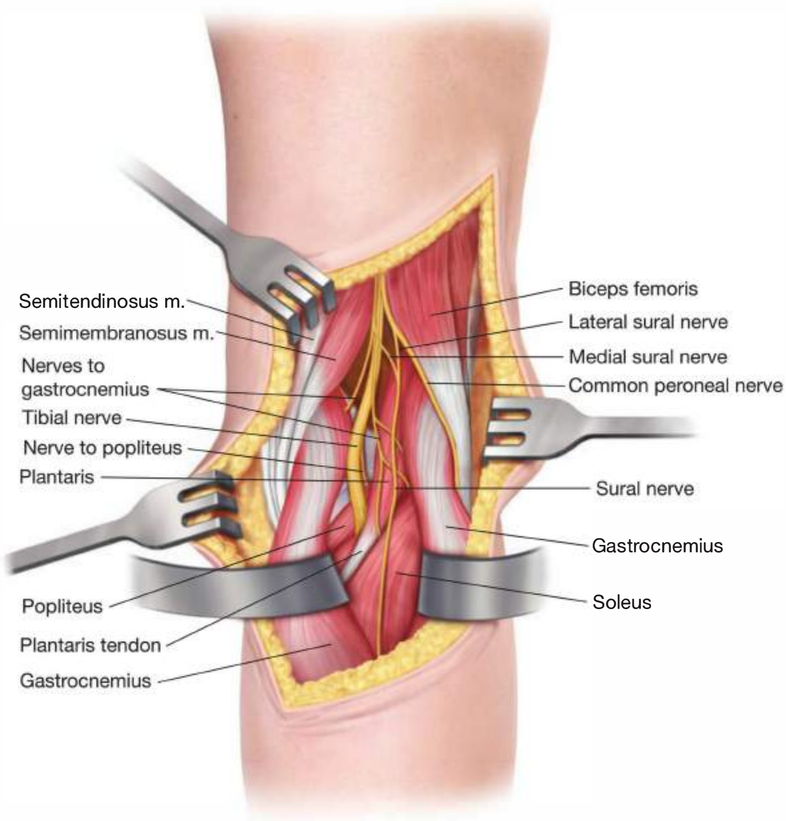

FIG 6 ● Upon opening the deep fascia and entering the popliteal fossa, the nerves are exposed (right leg).

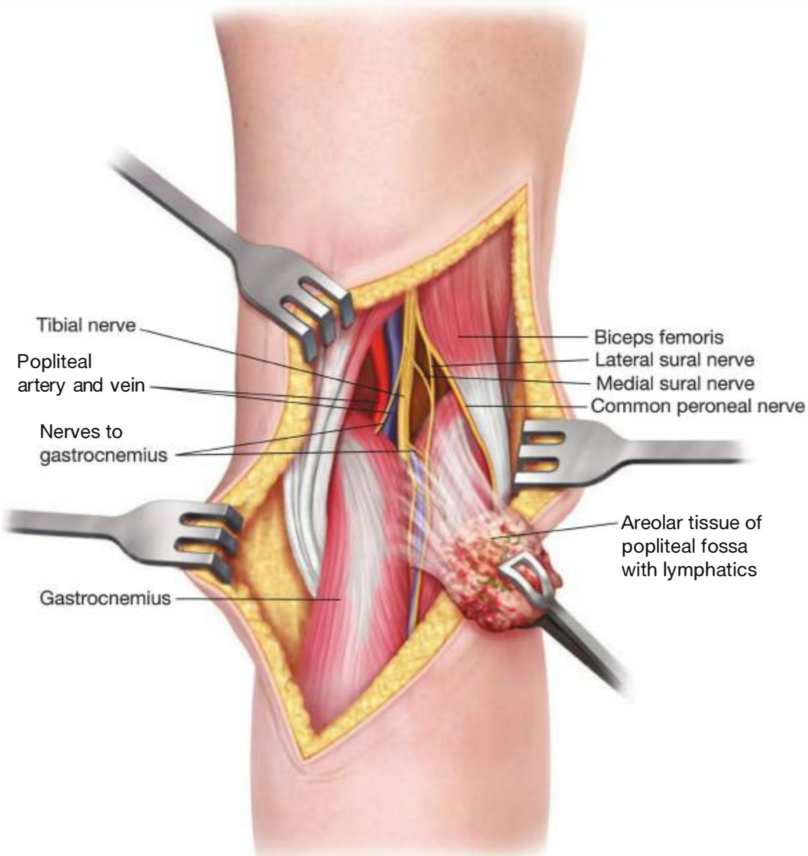

FIG 7 ● The nodal specimen is swept away from the nerves and vessels (right leg). Careful attention must be made to the space between the popliteal vessels and the knee joint (anterior/deep to the vessels) as one to two lymph nodes are commonly located here and are easily overlooked.

DISSECTION OF FIBROFATTY NODE–BEARING TISSUE AWAY FROM NERVES AND VESSELS

- The fibrofatty node–bearing tissue is dissected sharply away from the nerves and vessels and is removed in continuity, with care to preserve all important structures (**FIGS 7** and **8**).
- It is important to recognize that one or two lymph nodes are frequently located in the space between the popliteal artery and the knee joint (i.e., anterior to the popliteal artery from the anatomic perspective or deep to the popliteal artery from the perspective of the operating surgeon). These lymph nodes are often overlooked; this space should be carefully dissected so as to not leave lymphatic tissue behind.
- After removal of the specimen, the popliteal fossa should be evaluated thoroughly by inspection and palpation to ensure that all lymphatic tissue has been resected.
- The specimen is sent to pathology for permanent section.

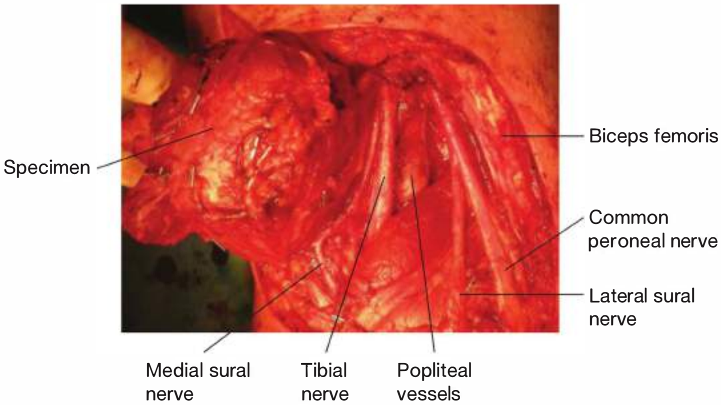

FIG 8 ● Photograph depicting resection of bulky disease in the popliteal fossa (right leg). Skin and subcutaneous tissue were resected en bloc with the specimen, and plastic surgical reconstruction was required for closure.

CLOSURE

- Hemostasis is achieved. The wound is irrigated copiously with saline.
- A 15-Fr round fluted, closed suction drain is placed into the wound and brought out through a separate stab incision (usually inferiorly; **FIG 9**).
- The incision is closed using absorbable suture for the deep dermis and a subcuticular stitch for the skin. A sterile dressing is applied.

FIG 9 ● The drain is brought out through a separate stab wound inferiorly (right leg).

PEARLS AND PITFALLS

Indications	■ Clinically palpable lymph nodes may be difficult to appreciate in the popliteal fossa because of thick overlying fascia. ■ Most patients undergo popliteal dissection because of a positive sentinel lymph node biopsy.
Incision	■ Options are S-shaped and Z-plasty to preserve joint function. ■ Orient incision so that prior sentinel lymph node biopsy scar is excised (usually superolateral to inferomedial).

Raising of medial and lateral flaps	■ Extend flaps to boundaries of popliteal fossa. ■ Ligate and divide lesser saphenous vein inferiorly.
Incision of the deep fascia and identification of structures to be preserved	■ Take care as fascia is incised; important structures lie directly beneath it. ■ Identify common peroneal nerve, tibial nerve, medial sural nerve, lateral sural nerve, popliteal artery, and popliteal vein. ■ Division of lateral sural nerve alone results in no significant deficit. ■ Division of medial sural nerve results in sensory loss.
Dissection of fibrofatty node–bearing tissue away from nerves and vessels	■ Remember to dissect the space between the popliteal artery and the knee joint (i.e., anterior or deep to the artery), as one or two lymph nodes are frequently identified in this location and are easily overlooked.
Closure	■ Place a drain.

POSTOPERATIVE CARE

- The patient remains hospitalized at least overnight, but perhaps for several days, depending on the extent of other lymphadenectomies that may have been performed during the same operation. A posterior knee splint (knee immobilizer) is used for the first few postoperative days to allow for wound healing prior to returning to full mobility. Ambulation is often initially difficult; physical therapy is useful. The drain may be removed when output falls below 30 mL per day; typically, this is a relatively short interval compared with drain times for axillary or inguinal dissections.

OUTCOMES

- Lymphedema is rare after popliteal dissection, and the functional outcome of the knee is usually excellent.
- The popliteal fossa is historically reported to contain 6 to 7 lymph nodes.[6] However, contemporary experience suggests that finding far fewer nodes is more common.[7] In a recent study of 15 patients who underwent popliteal sentinel lymph node biopsy, the mean number of popliteal lymph nodes harvested was 1.4 (range was 1 to 3); however, in 6 patients who subsequently underwent completion popliteal dissection, the mean number of lymph nodes in the popliteal dissection specimen was 0.3, with 4 of the 6 patients' specimens yielding no additional (nonsentinel) lymph nodes.[2]
- Overall, the 5-year survival for patients with stage III melanoma (lymph node–positive disease) ranges widely (14% to 85%), with the 5-year survival of a patient with a single microscopically positive lymph node approximating 70%.[8–10] It is difficult to determine whether the presence of a positive popliteal lymph node carries a different prognosis when compared with the presence of a positive lymph node in one of the more commonly involved regional lymph node basins (i.e., axillary, inguinal, cervical). Because popliteal disease is overall quite rare, the literature contains only case reports and small case series, most of which include both patients with micrometastatic disease and patients with clinically palpable disease.[1,3] A relatively large contemporary study in the literature reports on 15 patients who underwent popliteal sentinel lymph node biopsy; 8 patients had a positive sentinel lymph node. At an average follow-up of 64 months, 3 (37.5%) patients had died of melanoma, 1 (12.5%) was alive with disease, and 4 (50%) had no evidence of disease.[2] Given the very small numbers, these statistics are likely similar to overall 5-year survival rates for patients with positive nodes in the more commonly involved regional lymph node basins.

COMPLICATIONS

- Common complications of popliteal dissection include wound infection (cellulitis or abscess), seroma, and hematoma.
- Injury to the common peroneal nerve results in postoperative foot drop and sensory loss or paresthesias over the dorsum of the foot (including the space between the great and second toes) and lateral shin.
- Injury to the tibial nerve results in postoperative loss of plantar flexion of the foot, loss of flexion of the toes, weakened inversion of the foot, and sensory loss or paresthesias over the posterior aspect of the leg and the sole of the foot.

Chapter 33 Isolated Limb Infusion

Jeffrey J. Sussman Joseph S. Giglia

DEFINITION

- *Isolated limb infusion* is the term that is commonly used to indicate a minimally invasive, low flow rate, nonoxygenated perfusion of an extremity with chemotherapy to effect control of a cancer within that extremity[1] (**FIG 1**). It is a more recent modification of a more traditional technique commonly referred to as *isolated limb perfusion* (see Part 5, Chapter 34), which uses higher flow rates and an oxygenated circuit to perfuse the chemotherapy through the extremity where vascular control is obtained during an open procedure and is often combined with a formal node dissection. Comparatively, isolated limb infusion is a shorter, better tolerated, less complex procedure, not requiring a perfusionist, an oxygenator, nor blood products to prime the extracorporeal circuit.[2,3] Proponents of limb perfusion claim a higher response rate, particularly in bulky disease; however, the techniques have not been compared in a randomized fashion.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The most common indication for this procedure is a patient with in-transit melanoma restricted to an extremity whose lesions are too numerous or recurrent to be amenable to simple excision. It should be thought of as a limb salvage technique to treat regionally advanced disease and has no proven systemic benefit. Therefore, it is not commonly used in the face of distant metastasis unless regional control/palliation is the central goal.
- Common malignancies treated in this manner include melanoma and Merkel cell carcinoma. Other histologies treated less commonly include squamous cell carcinoma and sarcoma.
- A through history and physical should be performed with attention to documenting location and extent of extremity disease, limb function, edema, vascular exam, and evaluation of draining nodal basins.
- Limb volume is estimated by water displacement.
  - Sequential circumferential measurements or computed tomography (CT) volumetric measurements have been described as alternatives.
  - The contralateral limb should be measured if the involved limb is edematous.
  - The limb is submerged in a water tank up to level anticipated to be at bottom of tourniquet. The water level is marked and then after removal of the limb, the tank is filled with a measured amount of water to reach the marked level.
- Patients should have nonoccluded arterial and venous systems to allow catheter placement and chemotherapy infusion.

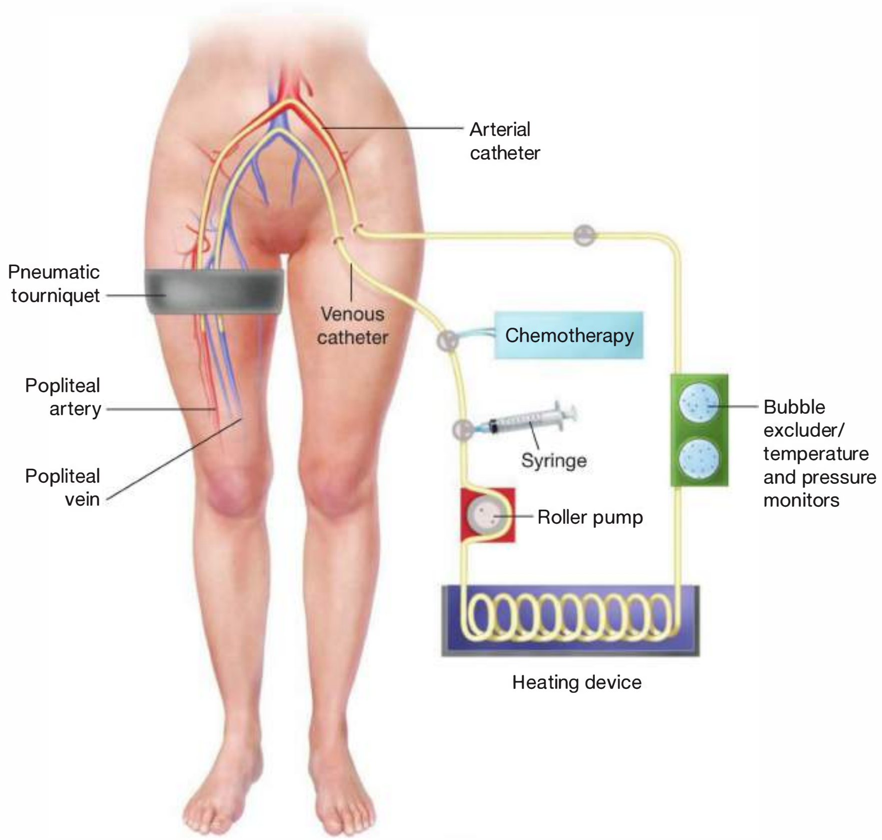

FIG 1 • Schematic of circuit used for isolated limb infusion. Roller pump is optional.

- The extent of disease needs to be distal enough in the extremity to be able to place a tourniquet proximally.
  - In selected cases, this may require resection of limited more proximal disease combined with infusion of greater distal disease burden distally.
  - Isolated limb infusion can be combined with a lymph node dissection with direct placement of the catheters in the exposed vessels.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Arterial and venous duplex ultrasound to establish arterial and venous patency. With adequate collaterals, limb infusion has been described even when superficial vessels are occluded.
- Imaging to evaluate limb disease burden if lesions are deep seated and difficult to quantitate on exam
- Imaging to evaluate for distant disease including brain magnetic resonance imaging (MRI); whole body positron emission tomography (PET)/CT; and/or chest, abdomen, pelvis contrast-enhanced CT scans

SURGICAL MANAGEMENT

- Patients should be discussed in multidisciplinary fashion to consider alternatives to isolated infusion including isolated limb perfusion; intralesional therapy; simple excision; radical excision, including circumferential excision and grafting or amputation; radiation; or systemic cytotoxic, immunotherapeutic, and other biologic therapies as well as clinical trial eligibility.

Preoperative Planning

- Who and where vascular access is to be obtained should be determined preoperatively and may be institution specific. Possible methods include the following:
  - Interventional radiology. Vascular access can be performed in the interventional radiology suite, with the patient then transported to the operating room (OR) with the arterial and venous catheters in place.
  - Vascular surgery. Some vascular surgeons have the training, experience, and interest to perform the vascular access as an alternative to the interventional radiologist. Access can be obtained in the OR directly if appropriately equipped with fluoroscopic capabilities. Although additional OR time is required if done in the OR, the catheters can more easily be manipulated later, as needed. Moreover, access can be obtained under general anesthesia and risk of dislodgement during transport/bed transfer is eliminated.
  - Chemotherapy. Melphalan and dactinomycin are prepared just prior to the procedure. The calculated drug dosage is often reduced if the patient's actual body weight exceeds ideal body weight by multiplying the calculated drug dose by the ratio of ideal to actual body weight.
  - Melphalan dose is 7.5 mg/L volume for lower extremity infusions (maximum dose of 100 mg) or 10 mg/L volume for the upper extremity (maximum dose 50 mg).
  - Dactinomycin dose is 1% of the melphalan dose (maximum 0.5 mg).
  - The drugs are mixed together in 400-mL normal saline lower extremity (200 mL upper extremity) and delivered to OR for administration.

FIG 2 ● Exposed affected limb with tourniquet proximally.

Positioning

- The patient is positioned supine on a fluoroscopy-capable OR bed for vascular access or in case catheter manipulation is needed.
- The room should be prewarmed.
- A heated circulating water blanket is placed around the affected extremity or an external radiant heater utilized (**FIGS 2** and **3**).

FIG 3 ● Affected limb wrapped in water blanket.

- Heated air blankets are placed on the patient's trunk and head or an external radiant heater is used.
- A pneumatic tourniquet is placed on the proximal aspect of the extremity with the lower edge marked with a radiopaque hemostat. For distal-only infusions, the tourniquet can be placed lower.
- Needle temperature probes are inserted into deep and superficial locations within the proximal and distal limb locations.
- Baseline activated clotting time (ACT) is obtained.

VASCULAR ACCESS

- Venous and arterial access is obtained in the uninvolved lower limb using the Seldinger technique with ultrasound and fluoroscopic guidance.
- After placing a vascular access sheath, a 5- or 6-Fr 100-cm catheter is introduced into the external iliac artery retrograde and manipulated across the iliac bifurcation and down the index limb arterial system to a point beyond the lower edge of the tourniquet. Similarly, a 7- to 8-Fr catheter is placed thru the venous system and positioned below the tourniquet (**FIG 4**).
- The patient is heparinized at 200 to 300 units/kg to obtain an ACT of 400.

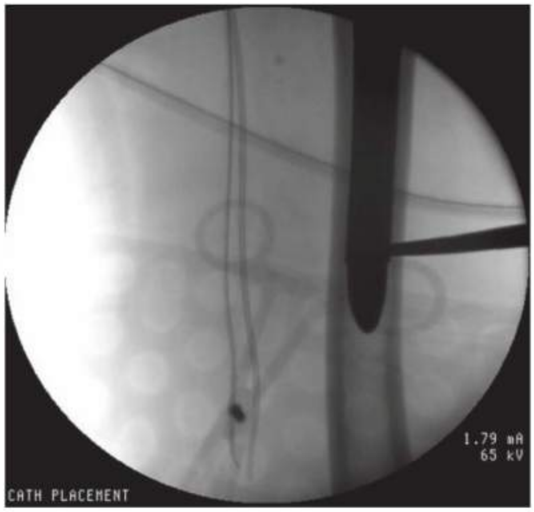

FIG 4 ● Radiograph of extremity with catheters in place below lower edge of pneumatic tourniquet. Note, wire in arterial catheter will be removed prior to infusion.

INFUSION CIRCUIT

- The catheters are connected to sterile ¼″ pump tubing with high-flow stopcock connectors and a 20-mL syringe as a hand pump or thru a single roller pump (**FIGS 5** and **6**).
- The circuit then passes through a heat exchange unit or heated water bath set to heat the fluid to 41°C followed by a bubble excluder before connecting to the arterial catheter. The circuit is primed with saline.
- Inflate the tourniquet to 250 to 300 mmHg.
- Adequate flow is obtained by hand pumping the syringe and using the three-way stopcock to pull from the venous catheter and infuse toward the arterial catheter. Alternatively, a roller pump can be used at rate approximately 100 mL per minute.

FIG 5 ● Photograph of roller pump workstation with temperature monitors, heat exchanger (water bath not depicted), ACT monitor, pressure gauge, and patient in background.

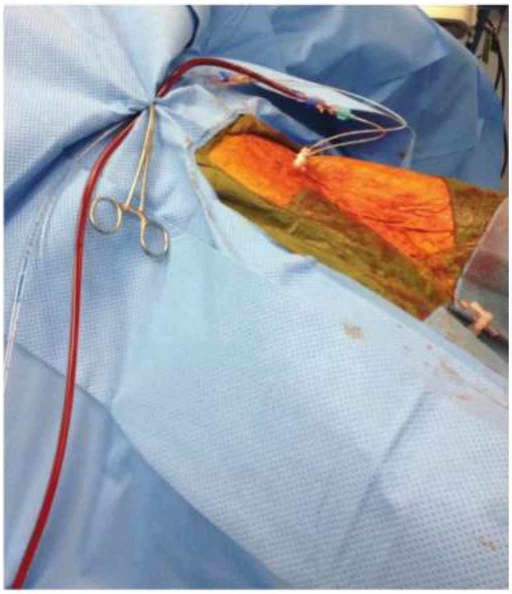

FIG 6 ● Contralateral groin with catheters in place connected to infusion circuit.

CHEMOTHERAPY INFUSION

- If the hand or foot is not to be perfused, an Esmarch bandage is tightly wrapped around the hand or foot to exclude the chemotherapy.
- Papaverine (60 mg for the lower extremity, 30 mg for the upper extremity) is infused into the circuit.
- The chemotherapy drug and dosage is double checked and then infused into circuit.
- Chemotherapy and blood are circulated for 30 minutes by hand pump syringe or roller pump method.
- Temperature, flow rate, pressure, and extremity are monitored. Blood gas and ACT are checked at 10- to 15-minute intervals.

CHEMOTHERAPY WASHOUT

- The venous tubing is disconnected from circuit and allowed to gravity drain blood into a waste container.
- One liter of lactated Ringer's solution (500 mL upper extremity) is infused into the arterial circuit.

CONCLUSION

- The tourniquet is released after notification to anesthesiologist of possible electrolyte and volume changes.
- The catheters are removed while leaving sheaths in place. Esmarch bandage, if used, is removed.
- Vascular exam of infused extremity is assessed and, if baseline, protamine is given to reverse the heparin.
- Once ACT is corrected, the sheaths are removed with pressure applied for hemostasis at the vascular puncture sites.

PEARLS AND PITFALLS

Drug dosing	■ If no ideal body weight correction, overall response rate may be increased; however, toxicity is also increased without clear improvement in complete response rate.
Poor venous return	■ Catheter may be up against valve, vein sidewall, or pulled back under tourniquet. ■ With heating, limb may vasodilate leading to relative intravascular volume loss. Infusing an extra 500-mL saline into limb through arterial circuit may help.
Proximal disease	■ An Esmarch bandage can be used as a tourniquet high on the limb to allow for greater volume of leg infused.

Limb temperature	■ Pumping heated blood through circuit prior to chemotherapy administration can heat up limb internally to greater than 37°C in 5 to 15 minutes.
Antiemetics	■ Steroids should not be used as antiemetics during or after anesthesia as they have an unknown effect on response rate.
Residual melanin pigmentation	■ Response may continue over several months. In-transit lesions may flatten but retain pigment. Biopsy may indicate melanin-laden macrophages without viable tumor.

POSTOPERATIVE CARE

- The patient is routinely extubated and admitted to an appropriate care unit capable of frequent neurovascular extremity monitoring for first 24 hours. Baseline serum creatinine phosphokinase (CPK), complete blood count (CBC), and chemistry panel are obtained.
- The extremity should be elevated when in bed, but the patient is allowed to get out of bed after 24 hours if extremity toxicity is not evident.
- Twice-daily physician examination should be performed, checking for vascular access complications, vascular and neurologic exam, and for compartment syndrome. Daily CPK is obtained, as muscle injury will routinely occur to some extent.
- CPK levels are expected to rise, peaking on postoperative days 4 and 5. Once levels begin to decrease and the extremity is stable, then the patient may be discharged. If the patient is reliable and has immediate health care access, it may be possible to discharge patient sooner with careful outpatient follow-up and instructions as the inpatient care after the first day is for toxicity monitoring.
- If the CPK levels rapidly rise sooner than day 4 and/or exceed 1,000 IU/L, then the patient is in danger of developing a compartment syndrome and potential limb loss. Steroids can ameliorate associated inflammation and decrease risk of requiring operative intervention. Dexamethasone can be given at 4 mg every 6 hours with rapid taper when the CPK drops below 1,000 IU/L.

FIG 7 ● **A.** Photograph of limb with in-transit disease. **B.** Photograph of same limb 4 weeks following isolated limb infusion.

OUTCOMES

- A complete clinical response is seen in 30% to 40% of patients after a single isolated limb infusion with another 30% to 50% of patients experiencing a partial response.[4–7] Complete responses are often durable, whereas partial responses are usually not (**FIGS 7A,B**). Response may take 2 to 6 weeks to be seen clinically. Limb salvage is obtained in the vast majority of patients, whereas 5-year overall survival is approximately 30% due to distant disease progression. Nearly all patients will develop some side effects from the procedure including skin erythema and lymphedema. Approximately half of patients will report return to baseline limb function by 3 months and the remainder by a year.
- Isolated limb infusion is better tolerated with less toxicity as compared to isolated limb perfusion, is technically easier to perform, and appears to have similar response rates.

COMPLICATIONS

- Potential complications related to vascular access include hematoma, pseudoaneurysm, dissection, and embolization. Stroke can be a complication of upper extremity arterial access.
- Toxicity from the isolated limb infusion of chemotherapy into the extremity skin and soft tissue are classified by the Wieberdink grading scale (Table 1).[8] Grade V or limb loss occurs in less than 1% of cases.
- Systemic toxicity from the chemotherapy should be rare but might include nausea and bone marrow suppression.

Table 1: Wieberdink Extremity Toxicity Scale

Grade I	No reaction
Grade II	Slight erythema and/or edema
Grade III	Considerate erythema and/or edema with some blistering; slightly disturbed motility permissible
Grade IV	Extensive epidermolysis and/or obvious damage to the deep tissues, causing definite functional disturbances; threatening or manifest compartmental syndromes
Grade V	Reaction that may necessitate amputation

Chapter 34 Isolated Limb Perfusion

Omgo E. Nieweg   Oscar E. Imhof   Bin B.R. Kroon

DEFINITION

- Compared to other cancer types, melanoma has a particular biology in various respects. In-transit dissemination is typical of this disease and occurs in a few percentage of patients. In-transit metastases grow from tumor cells that are stuck in a lymph vessel in the skin or in the subcutaneous tissue. Such metastases are preferably excised but they tend to recur in larger numbers (**FIG 1**). Isolated perfusion can be considered when they are situated on a limb and their number is too great or they recur too frequently.
- Isolated limb perfusion (ILP) enables treatment of an arm or leg with a high dose of chemotherapy without exposing the remainder of the body to the drug(s). This is accomplished by isolating the limb from the body's circulation and creating a separate oxygenated blood circuit. This is in contrast to isolated limb infusion (ILI), a low-flow, nonoxygenated perfusion that is described in Part 5, Chapter 33. ILP and ILI are therapeutic options for patients with locally or regionally advanced melanoma that would otherwise require a more debilitating operation, for example, amputation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- After treatment of their primary melanoma, patients are instructed to regularly examine the scar of the excision for local recurrence and to check the skin and subcutaneous tissue around this area up to the regional lymph node basin for visible or palpable satellite and in-transit metastases. The physician who follows the patient inquires about new regional lesions. Patients themselves detect about half of the recurrences, but at an early stage, they can look quite innocuous. The detection of the more subtle ones requires the expertise and suspicious mind of an experienced surgeon.
- A detailed history should be obtained to assess the general condition of the patient and to be informed about other relevant ailments, allergies, and medication.
- Physical examination of melanoma patients is aimed at detecting a local recurrence, satellite metastases, in-transit metastases, regional lymph node involvement, and a subsequent primary melanoma. A detailed examination of the skin, the regional subcutaneous tissue, and the regional node field is warranted.
- The vascular situation of the limb is assessed. The presence of peripheral arterial pulsations needs to be sufficient to allow for ILP.

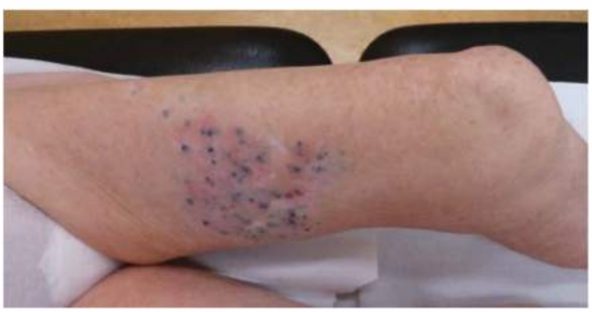

FIG 1 ● Extensive in-transit metastases on the left thigh.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The presence of advanced melanoma in the extremity should be confirmed by biopsy.
- In addition to the routine preoperative tests, screening for metastases elsewhere is appropriate as their presence may change the treatment plan. Whole body positron emission tomography (PET) or computed tomography (CT) and magnetic resonance imaging (MRI) of the brain are frequently recommended for this purpose.
- Arteriography is indicated if the arterial blood supply is questionable. A complete obstruction in the target artery or a major impediment downstream renders perfusion impossible. Extensive arterial calcification per se is not a contraindication.
- An elevated tumor marker such as the TA90 glycoprotein antigen or the S100 protein provides an opportunity to monitor the course of the disease.

SURGICAL MANAGEMENT

Rationale and Contraindications

- Extensive involvement limited to a certain region is typical for melanoma.
- The rationale for ILP is that melanoma is sensitive to cytotoxic drugs but effective treatment requires a higher dosage compared to various other cancer types. In contrast to the vital organs, the normal tissues in the extremities tolerate such a high dose. ILP with cytotoxic medication may improve regional tumor control while limiting the systemic side effects.
- The procedure makes it possible to vary physiologic conditions such as blood flow, temperature, and oxygenation.
- Prophylactic ILP is not indicated in patients with excised high-risk primary melanoma without evidence of regional metastases.[1]
- The contraindications are listed in Table 1. A major vascular obstruction may prevent access to the artery and precludes the operation.
- Diabetes mellitus with severe peripheral vascular disease is a contraindication.
- ILP should not be performed in children as it may damage the epiphyseal plates.
- Previous radiotherapy is a relative contraindication as perfusion may cause necrosis of prior irradiated skin.
- A large superficial tumor with major tendon involvement is a relative contraindication.

Table 1: Absolute and Relative Contraindications to Isolated Limb Perfusion

Absolute contraindications
Obstruction of major artery
Diabetes with serious peripheral vascular disease
Child with open epiphyseal plates
Relative contraindications
Previous radiotherapy
Large superficial tumor with major tendon involvement
Brain metastases
Infected wound or ulcer

- Brain metastases tend to bleed and their presence is a relative contraindication.
- An infected wound or ulcer is another relative contraindication.
- ILP can be carried out safely at an advanced age.[2] The presence of regional node involvement is not a contraindication, as this procedure can be combined with a regional node dissection. In the presence of distant metastases, systemic therapy is a reasonable first option, but perfusion can provide good regional palliation in the presence of refractory bloodborne metastases.

Anatomy

- For advanced disease of the leg, ILP can be performed at the femoral or iliac level. The arm can be treated at the brachial level or through the axilla.

Preoperative Planning

- ILP requires cooperation of the surgeon, the perfusionist, and the nuclear medicine worker in addition to the customary operating room team.
- Melphalan is the standard drug used in current practice. The dosage of the drug is adjusted to the need of the individual patient. The volume of the extremity is an often used parameter to calculate the required melphalan dose. The volume can be determined using a water reservoir (FIG 2). Adjustments to the dosage can be made based on risk factors for regional toxicity like female gender and obesity.

FIG 2 ● Water reservoir for measuring the volume of a limb. On the right is the elevator to bring the patient up to the required height. The elevator handle is on the left.

- ILP requires sophisticated technology. The surgeon should verify the availability of the required drug(s) and make sure that the necessary equipment and materials are present and in good working order.
- General anesthesia is required. Epidural anesthesia is to be avoided as it induces vasodilation and predisposes to leakage of blood from the systemic circulation to the perfusion circuit.
- Preoperative antibiotics are not necessary.

TECHNIQUES

ISOLATED FEMORAL PERFUSION

Positioning

- The patient is placed on the operating table in a supine position. The leg may be slightly exorotated.
- The leg is prepped and draped in a sterile fashion in its entirety.
- A pneumatic tourniquet is positioned around the upper thigh, but it is not inflated yet.
- A heating blanket is wrapped around the knee and the lower leg.
- A cotton doughnut is positioned underneath the heel to prevent decubitus.
- The operating table is tilted toward the surgeon.

Incision

- A longitudinal incision of approximately 10 cm is made starting just below the pneumatic tourniquet (FIG 3). The incision runs over the sartorius muscle. The skin and the subcutaneous tissue are divided and, subsequently, the fascia. Adson retractors are placed (FIG 4).

Access to the Superficial Femoral Vessels and Cannulation

- The external femoral vessels run behind the sartorius muscle. The vessels are reached either medially or laterally from the muscle. The thin fascia covering the vessels (FIG 5) is incised, exposing the superficial femoral artery. The artery is mobilized over the exposed length (FIG 6). Small arteries branching from the superficial femoral artery are ligated and divided. A vessel loop facilitates the dissection. The accompanying vein is identified when the artery is pulled aside (FIG 7). The vein is mobilized over the exposed length. Attributing branches are ligated at the confluence and divided.
  - Heparin is administered in a quantity of 150 units/kg body weight.

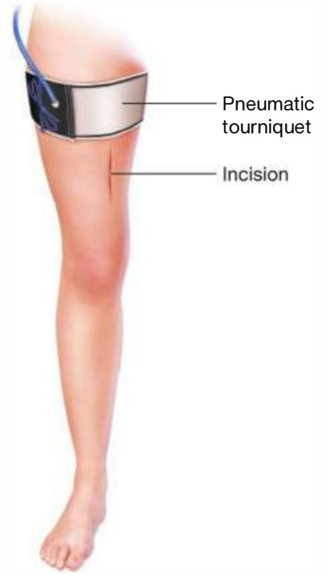

FIG 3 ● The incision is made over the inner thigh just below the pneumatic tourniquet.

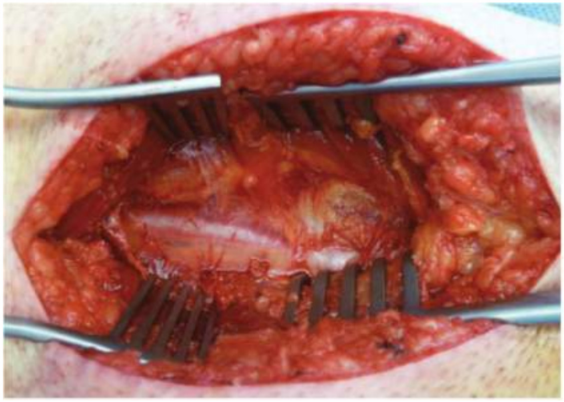

FIG 5 ● The superficial femoral artery can be seen through the thin fascia that covers the vessels.

- Open access to the saphenous vein at the level of the ankle is gained to measure the venous pressure. The venous pressure is monitored throughout the procedure and should not deviate more than 10 mm H_2O from the initial assessment. An increase is associated with postoperative morbidity.
- The appropriate diameter of arterial and venous cannulae for the perfusion is determined. The cannulae are tunneled subcutaneously underneath the tourniquet to the open wound to prevent kinking.
- The vein is clamped cranially and caudally. A transverse venotomy of a few millimeters is performed.

FIG 6 ● The superficial femoral artery is mobilized.

FIG 4 ● The long adductor muscle **(above)** and the sartorius muscle **(below)** are exposed. The superficial femoral vessels lie behind the sartorius muscle.

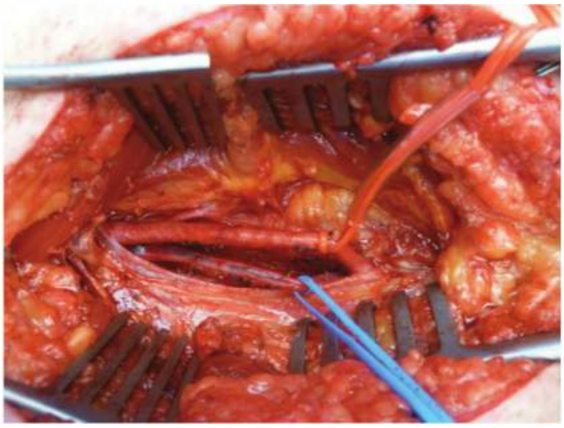

FIG 7 ● The superficial femoral artery is pulled aside (red vessel loop) and the accompanying vein is identified and dissected (blue vessel loop).

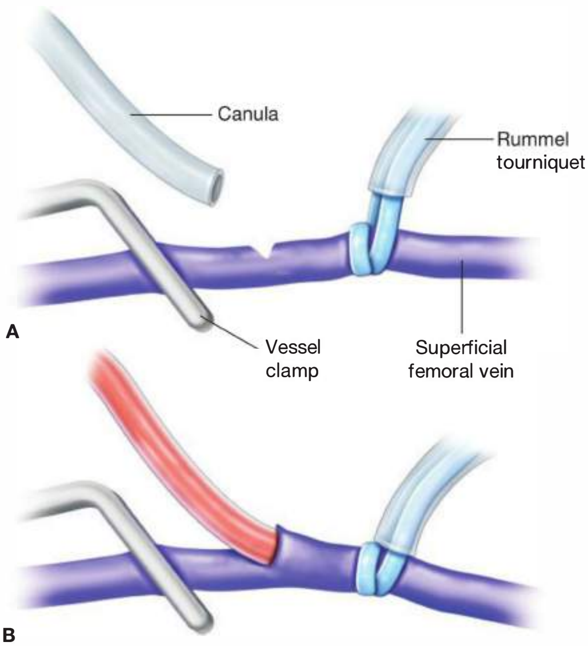

FIG 8 ● **A,B.** Insertion of cannula in superficial femoral vein.

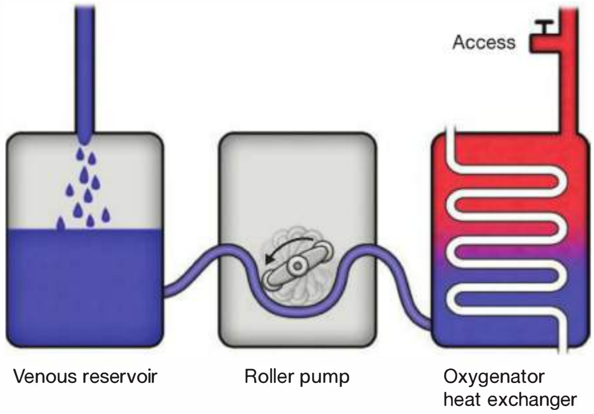

FIG 10 ● The perfusion device contains a venous inflow reservoir, a roller pump, an oxygenator annex heat exchanger, and access to the circuit for tapping blood and administration of drugs.

The cannula is inserted caudally and secured with the vessel loop (**FIG 8A,B**). The cannula is hooked up to the extracorporeal circuit and 300 mL of blood is tapped for the perfusion circuit. Subsequently, the arteriotomy is performed in a similar fashion and the arterial cannula is introduced and secured, and the circuit is completed (**FIG 9**).

Establishing the Perfusion

- The perfusion device consists of a reservoir to collect the venous blood, an oxygenator, a heat exchanger and a roller pump (**FIG 10**). In addition to the patient's own blood, the perfusion fluid consists of 100 mL of a crystalloid solution (lactated Ringer's solution), 200 mL 6% hydroxyethyl starch solution (HES) and 2,500 units of heparin. The hematocrit is approximately 30%. The flow should be generous, but it should not increase the venous pressure in the limb. The flow is typically 30 to 60 mL/L lower extremity volume/min. The venous blood is recollected by gravity.
- Thermistor probes are inserted in the subcutaneous tissue and a muscle compartment of the lower leg and the thigh. At this point, the leg is found to be around 34°C.
- The heating blanket is another tool to attain the desired temperature of 37°C.
- The tourniquet is inflated to a pressure of 350 mmHg, if necessary higher. This occludes the collateral vessels to and from the systemic circulation in the skin, the subcutaneous tissue and muscles. **FIG 11** shows the setup at this point.
- Escape of the drug(s) from the limb to the main circulation is to be avoided. Leakage can be monitored continuously by administering a small dose of a radiopharmaceutical such as technetium 99m-labeled serum human albumin to the perfusion circuit.[3] An even smaller background dose is administered intravenously into the systemic circulation. A gamma-ray detector is placed over the heart (**FIG 12**). The percentage of leakage can be calculated when the number of counts increases after correction for the physical half-life of the radionuclide (**FIG 13**).
- Substantial leakage either way can also be detected by assessing the fluid level in the venous return reservoir.
- The drug is administered when the flow and venous pressure are stable, when the tissue temperatures are around 37°C, and there is no leakage. Melphalan has always been the drug of choice. The dosage is 10 mg/L of perfused volume with adjustments based on risk factors for morbidity. The dose should not exceed 150 mg.
- The limb is exposed to the melphalan for 1 hour.
- The temperature in the various tissues is kept between 37°C and 38°C.

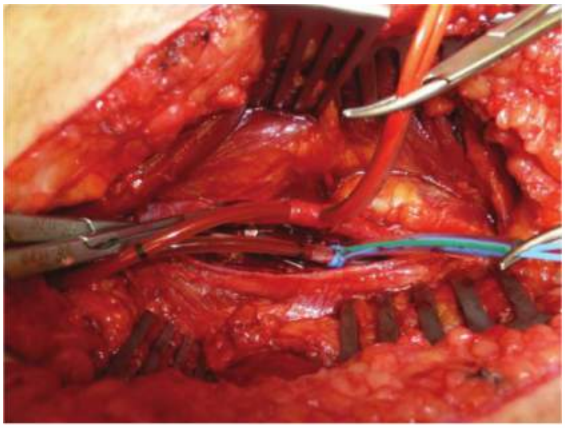

FIG 9 ● The cannulae in the superficial femoral artery and vein are secured with vessel loops tightened through Rummel tourniquets.

FIG 11 ● From top to bottom, note the cotton doughnut under the heel to prevent decubitus, the thermistors with the white cords to monitor the tissue temperatures, the blue warming blanket that is folded open for the picture, the open wound that would normally be covered with a wet gauze to prevent the vessels from drying out, the pneumatic tourniquet around the root of the thigh, and the arterial **(left)** and venous cannulae tunneled subcutaneously underneath the tourniquet.

- Tumor necrosis factor-α induces apoptosis of tumor endothelial cells and is beneficial in patients with bulky tumor nodules.[4] It causes thrombosis and increased melphalan penetration. A dose of 3 mg is given 30 minutes preceding the melphalan administration. When tumor necrosis factor is used, the temperature of the leg is increased from 37°C to 39°C to 40°C in the last half hour. At this time, most of the melphalan has been accumulated in the tissues, which limits potential heat-induced toxicity.
- Parameters to monitor are flow, venous and arterial blood gas values, venous and arterial pressure in the perfusion circuit, leakage to or from the systemic circulation, and venous pressure and tissue temperature in the limb.
- There is considerable variation in the perfusion technique between institutions. Some surgeons use body weight (0.5 to 1.5 mg/kg) or another parameter to calculate the melphalan dose instead of the volume of the leg. Some surgeons use other drugs than the ones described here, such as dactinomycin or cisplatin. Tumor necrosis factor is not registered throughout the world. If available, the dosage used ranges between 0.5 and 4 mg. Despite its obvious advantages, few surgeons use autologous blood for the perfusion circuit. Temperatures up to 43°C have been used for the leg, but these higher temperatures tend to severely increase the postoperative morbidity. The venous pressure is not always measured to guide the flow. The duration of the perfusion in different institutions ranges from 45 to 90 minutes. Judging by the published response rates, one technique is not necessarily better than another.

FIG 12 ● Mobile gamma-ray detector with screen to assess leakage.

Terminating the Perfusion

- After the leg has been exposed to the drug for the intended duration, the perfusate is washed from the leg using a colloid or a similar fluid followed by a lactated Ringer's solution. Massaging the leg helps to clear the less well-perfused tissues. The leg will be seen to turn pale.
- Meanwhile, the temperature probes and the venous pressure cannula are removed. The saphenous vein is ligated.

FIG 13 ● The *green* curve reflects the leakage. Note steep increase when background radiopharmaceutical is administered to the systemic circulation and subsequent two bumps up when the main dose initially passes through the perfusion circuit. The curve is flat thereafter, indicating adequate isolation during the perfusion.

- The flushing is terminated when the fluid that comes back from the leg is clear. The tourniquet is deflated and taken off. The cannulae are removed from the superficial femoral artery and vein and the distal vessel clamps are reapplied.
- The vein is closed with a running Prolene 6-0 suture (**FIG 14**) and the clamps are removed. The artery is closed with horizontal mattress sutures using double-armed Prolene 6-0 (**FIG 15**).

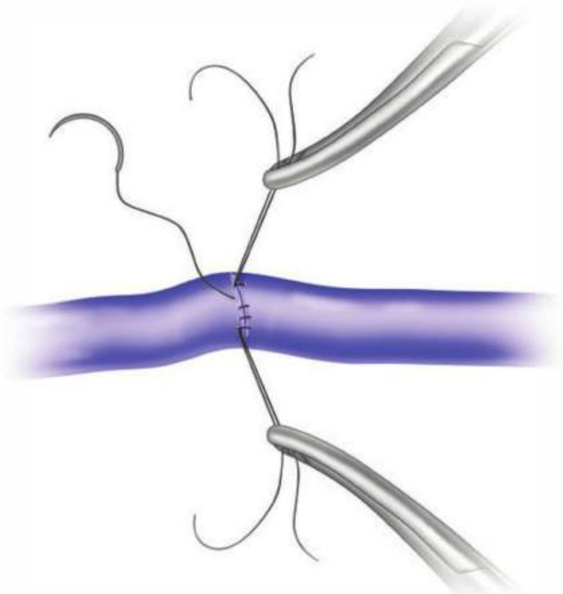

FIG 14 ● The vein is closed with a running Prolene 6-0 suture.

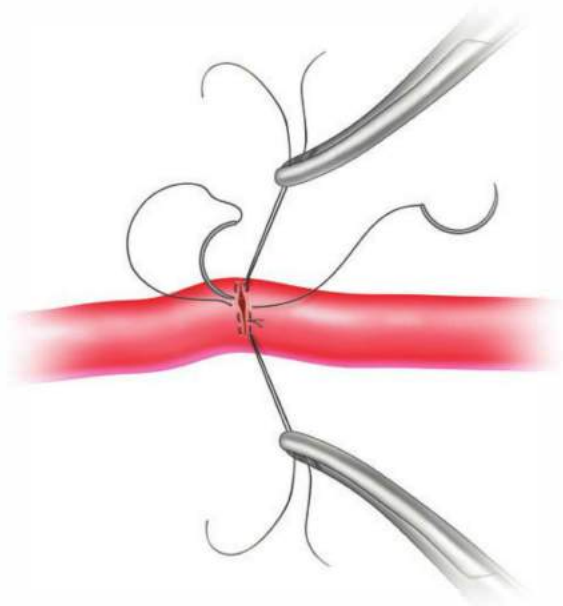

FIG 15 ● The artery is closed with double-armed Prolene 6-0. Horizontal mattress sutures evert the edges of the arterial wound in order to appose the endothelium layers.

- The clamps from the artery are removed and the leg assumes a pinkish hue. The nuclear medicine worker will now see an upward turn in his curve and the leakage, which typically is 0% during the perfusion, ends up being 2% or 3%.
- A vacuum drain is inserted and the wound is closed in layers.
- Protamine administration to counter the heparin is optional.

ISOLATED ILIAC PERFUSION

Aspects Specific to Isolated Iliac Perfusion

- Isolated perfusion at the external iliac level is performed if the disease involves the upper thigh. Specific points inherent to this procedure that are different from femoral perfusion are described here.
- The approach to the external iliac vessels is extraperitoneal. The Bookwalter retractor provides an excellent exposure. An external iliac and obturator lymph node dissection is carried out first (see Part 5, Chapter 29, Inguinal Lymph Node Dissection). These nodes may contain metastasis, but even if this is not the case, their dissection is worthwhile because they can become involved later on and a retroperitoneal approach is challenging after perfusion. Also, an iliac and obturator node dissection results in little morbidity.
- Arterial branches and venous tributaries of the external iliac vessels are ligated and divided. The obturator artery and vein are ligated and also other vessels that connect to the thigh. The internal iliac vessels may be clamped temporarily.
- The tips of the cannulae are positioned in the common femoral vessels.
- Because the diameter of the iliac vein is generous, a longitudinal venotomy can be performed without fear of stenosis after suturing.
- Occlusion of collateral vessels is obtained by wrapping an Esmarch rubber bandage around the thigh through the groin, anchored by a Steinmann pin in the iliac crest. The Steinmann pin is inserted before the heparin is administered.
- Prolene 5-0 is used for closing the vessels.

ISOLATED BRACHIAL PERFUSION

Aspects Specific to Isolated Brachial Perfusion

- Isolated perfusion at the brachial level is performed if the disease is limited to the forearm. Some specific points inherent to this procedure are described here.
- The patient is placed on the operating table in a supine position. The arm is placed in 90% abduction.
- A pneumatic tourniquet is wrapped around the proximal upper arm.
- An 8-cm longitudinal incision is made over the medial aspect of the upper arm, caudally from the tourniquet.
- Microvascular instruments are used.
- The cannulae are led through a subcutaneous tunnel underneath the tourniquet to avoid kinking.
- Both veins may be cannulated if the venous return from a single one is insufficient.
- The quantity of autologous blood needed to prime the extracorporeal circuit is 200 mL.
- Venous pressure measurement is performed using the cephalic vein at the wrist (FIG 16).
- The tourniquet is inflated to a pressure of 250 mmHg.
- The dosage of melphalan is 13 mg/L of perfused volume if the volume of the arm exceeds 3.5 L, with adjustments based on risk factors for morbidity. Otherwise, 10 mg/L of perfused volume is given. The dosage of tumor necrosis factor is 2 mg.
- Prolene 6-0 sutures are used for closing the vessels. Alternatively, the vein(s) may be ligated because there is sufficient collateral circulation.

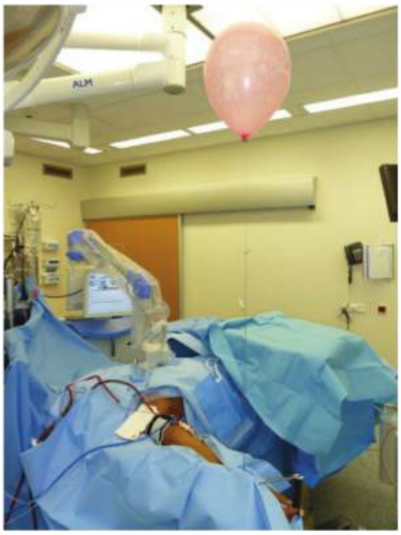

FIG 16 ● Helium-filled balloon keeping up the venous pressure line in a brachial perfusion.

ISOLATED AXILLARY PERFUSION

Aspects Specific to Isolated Axillary Perfusion

- Isolated perfusion at the level of the axilla is performed if the disease involves the upper arm. Some specific points inherent to this procedure and differing from the brachial perfusion are described here.
- The axilla is approached via an incision along the lateral margin of the major pectoral muscle. Axillary lymph node dissection is optional (see Part 5, Chapter 28, Axillary Lymph Node Dissection for Melanoma).
- The axillary vein is exposed and dissected. The axillary artery lies amidst the brachial plexus and is mobilized. Branches are ligated and divided.
- Occlusion of collateral vessels is obtained by wrapping an Esmarch rubber bandage around the upper arm through the axilla anchored by a Steinmann pin in the humeral head. A cotton pad underneath the bandage protects the brachial plexus from undue pressure.[5]

PEARLS AND PITFALLS

Volume measurement	■ If the limb is edematous, the volume of the contralateral limb—if normal—should be measured to guide the melphalan dosage.
Drug dosage	■ A sufficient dose for the desired effect is warranted but an excessive dose can be associated with limb-threatening morbidity. The surgeon threads a thin line and this implies a careful calculation of the drug dose and attention to the details of the procedure.
Prevention of systemic side effects	■ Extremely high doses of cytotoxic drugs are used and the toxicity in case of leakage of the drugs to the systemic circulation can be life threatening. Therefore, painstaking occlusion of collateral vessels and meticulous measuring of leakage are of the essence.
Insertion of the cannula in the femoral vein	■ Valves in the femoral vein may prevent accurate positioning of the venous cannula. A high arterial inflow and temporary clamping of the vein create a generous outflow, which opens the valves and facilitates advancing the cannula. Alternatives are abduction of the leg or cannula insertion over a Fogarty catheter.

Perfusion	■ The hand and foot are particularly sensitive to the side effects of melphalan. Their exposure to the drug can be limited by temporarily excluding them from the perfusion circuit. This can be accomplished by wrapping the hand or foot in a tight Esmarch rubber bandage for the first 30 minutes of the melphalan perfusion.
Major tendon involvement is a contraindication	■ A large superficial tumor mass with substantial tendon involvement intuitively appears as an appropriate indication for perfusion. However, a complete response will lead to necrotic tendons that may necessitate amputation.
Autologous blood	■ Most surgeons use allogeneic blood, but autologous blood obtained at the beginning of the procedure is cheaper and safer.
Elderly patients	■ In contrast to what is often suggested in the literature, advanced age is not a contraindication, as ILP is effective and quite safe in elderly patients.[2]
Palliation	■ In the presence of refractory blood-borne metastases, ILP can provide valuable palliation for patients with otherwise unmanageable limb disease that is bothersome because of pain, recurrent bleeding, or fungating infection.

POSTOPERATIVE CARE

- Overnight monitoring of the distal arterial pulsations is obligatory as arterial occlusion at the level of the sutured arteriotomy is a complication that is threatening in the first few hours.
- Postoperatively, the leg is kept elevated on a Braun frame to limit development of edema. The vacuum drain is removed the next day. Patients experience surprisingly little pain. Muscle-setting exercises are performed, but bed rest is maintained until the inflammatory signs subside.
- Creatine phosphokinase is checked daily. An increase in the first few days is normal but an excessive level may indicate muscle necrosis due to a compartment syndrome.
- An anticoagulant is given for the duration of 3 months.
- Responding dermal in-transit metastases may be seen to wrinkle, shrink, and develop a crust. Subcutaneous metastases typically soften and show fluctuation on physical examination.
- The patient is mobilized when the inflammatory signs subside. The patient is discharged when fully mobilized, usually after 7 to 10 days.

OUTCOMES

- There appears to be no relationship between limb toxicity and tumor response to the treatment.[6]
- A response may become evident as early as on the operating table but may also take up to 9 months. Remaining lesions can be excised later in case of a partial response. ILP results in a complete response in 54% of the patients.[7] The complete response is durable in half of them. In an additional 30% of patients, a partial response is obtained. The complete response rate when tumor necrosis factor is used is around 70%,[8] but the end result is not better than with melphalan alone. Ten-year survival in patients with a complete response is 49%.[9]
- Long-term survivors have a better quality of life than comparable control individuals.[10]
- The Wieberdink classification is used to quantify the limb morbidity (Table 2).[11]
- Acute regional toxicity determines long-term morbidity. One year after treatment, 44% of the patients show some degree of morbidity: recurrent infections, 3%; neuropathy, 4%; pain, 8%; muscle atrophy or fibrosis, 11%; limb malfunction, 15%; or lymphedema, 28%.[12] The lymphedema can be attributed to concomitant lymph node dissection.
- Postoperative toxicity necessitates amputation in 0.9% of the patients.[13] Amputation for intractable recurrence is required in 2.4% of the patients.[14]

COMPLICATIONS

- Perioperative mortality is less than 1%.[13,15]
- If tumor necrosis factor is used, some of the drug inevitably remains in the body and may cause a slight fever immediately after the operation.
- Serious postoperative complications associated with ILP are rare but they demand urgent intervention. Arterial thrombosis looms in the first few hours and requires thrombectomy. A venous patch is often necessary to ensure a sufficient flow.
- Excessive swelling of the muscles in the limb compresses the vessels, which may decrease the blood supply and lead to a compartmental syndrome. Excruciating pain suggests this diagnosis and it can be confirmed by measuring the intracompartmental pressure. Timely fasciotomy of the involved muscle compartments prevents permanent damage.
- In the first few days, an inflammatory response typically develops and the leg becomes red, warm, and slightly edematous.
- Over a period of 2 to 3 weeks, the edema and redness subside and give way to a tan discoloration that gradually disappears over the course of several months.

Table 2: Wieberdink Classification of Postoperative Limb Morbidity

1	No skin reaction
2	Redness, edema
3	Blisters
4	Superficial necrosis, damage to deep tissues causing functional disturbance, threatening or manifest compartmental syndrome
5	Necrosis requiring amputation

Wieberdink J, Benckhuysen C, Braat RP, et al. Dosimetry in isolation perfusion of the limbs by assessment of perfused tissue volume and grading of toxic tissue reactions. Eur J Cancer Clin Oncol. *1982;18:905–910.*

Chapter 35

Thyroid Lobectomy

Amy C. Fox   Paul G. Gauger

DEFINITION

- Total thyroid lobectomy is defined as the surgical removal of an entire thyroid lobe and isthmus. It can be used as a diagnostic or a therapeutic procedure.
- Thyroid disease requiring a lobectomy is most often due to the presence of a thyroid nodule. Palpable thyroid nodules are common and occur in 4% to 7% of the general population with an increased incidence with advanced age.[1]
- The most common indications for a thyroid lobectomy are the following:
  - A thyroid nodule with diagnostic uncertainty
  - A symptomatic thyroid nodule (e.g., compressive unilateral goiter or autonomous toxic nodule)

DIFFERENTIAL DIAGNOSIS

- Benign thyroid nodule
- Toxic adenoma
- Thyroid cancer
- Intrathyroidal parathyroid adenoma
- Lymph node

PATIENT HISTORY AND PHYSICAL FINDINGS

- Although thyroid nodules are common, the vast majority of them are benign. A thorough patient history can assist the clinician in determining which thyroid nodules may require surgical management. Previous radiation to the neck, a rapidly growing mass, hoarseness, associated lymphadenopathy, or a family history of cancer may raise the suspicion of malignancy. Dysphagia, choking, or intolerance to things around the neck may suggest local compressive symptoms from a large thyroid nodule.
- The physical exam should focus on characteristics of the thyroid such as size, firmness, and the presence of nodules. The neck should be palpated for associated lymphadenopathy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- **Thyroid function studies.** A thyroid-stimulating hormone (TSH) can assess the biochemical status of the patient's thyroid. A TSH should be obtained prior to any fine needle aspiration to ensure the patient is not hyperthyroid.
- **Ultrasonography.** Neck ultrasound is a user dependent but highly sensitive adjunct in the evaluation of the thyroid and cervical lymphadenopathy. It can also assist in fine needle aspiration of thyroid nodules. A high-frequency probe of 7.5 MHz to 10 MHz is required.
- **Biopsy.** Fine needle aspiration can help determine benign from potentially malignant nodules. It is often done using ultrasound guidance. The cytopathology results can be categorized according to the Bethesda system.[2] These categories are associated with varying risks of malignancy allowing for different proposals for clinical management (Table 1).[3]
- **Computed tomography (CT).** A preoperative neck or chest CT is usually not necessary except in specific situations:
  - Malignancy—A neck CT may suggest local invasion of the thyroid into surrounding structures such as the carotid artery, internal jugular vein, or trachea which could potentially modify the operative approach. A CT scan of the neck can also provide a detailed map of cervical lymphadenopathy. A chest CT can evaluate for metastatic disease.
  - Large goiters—A neck and chest CT scan can help determine the degree of tracheal obstruction or substernal extension of large goiters. Patients with clinical evidence of airway obstruction should have a CT to provide anatomic information to help manage a potentially difficult airway.
- **Laryngoscopy.** Flexible laryngoscopy should be performed on all patients with hoarseness or a previous history of neck surgery. This provides a current assessment and baseline evaluation of bilateral vocal cords prior to surgery.

SURGICAL MANAGEMENT

- Thyroid lobectomy is therapeutic for patients with a unilateral goiter or a solitary toxic nodule which is symptomatic.
- Thyroid lobectomy is diagnostic and can potentially be therapeutic for patients with indeterminate thyroid nodules such as those categorized as "follicular lesions of undetermined significance," "follicular neoplasms," or "suspicious for malignancy."
- Although thyroid malignancy often warrants surgical intervention, thyroid lobectomy is typically not the standard of care. Total thyroidectomy is recommended for most thyroid malignancies greater than a centimeter in size. A thyroid lobectomy may sometimes be appropriate for very small (less than a centimeter) well-differentiated thyroid cancers in select patients.
- In any thyroid lobectomy, the patient and surgeon should be prepared for the conversion to a total thyroidectomy if intraoperative findings dictate this need. If the patient was

Table 1: Thyroid Fine Needle Aspiration Classification Scheme and Clinical Management

Category	Risk of Malignancy	Suggested Management
Nondiagnostic		Repeat FNA under ultrasound
Benign	<1%	Monitor
Follicular lesion of undetermined significance (e.g., atypia)	5%–10%	Repeat FNA or thyroid lobectomy
Follicular neoplasm	20%–30%	Thyroid lobectomy
Suspicion for malignancy	50%–75%	Thyroid lobectomy or total thyroidectomy
Malignant	100%	Total thyroidectomy

FNA, fine needle aspiration.
From Cibas ES, Ali SZ. The Bethesda system for reporting thyroid cytopathology. Thyroid. *2009;19(11):1159–1165; Baloch ZW, Cibas ES, Clark DP, et al. The National Cancer Institute thyroid fine needle aspiration state of the science conference: a summation.* Cytojournal. *2008;5:6.*

not counseled of this possibility, the surgeon should complete the lobectomy and defer definitive management until appropriate consent from the patient.

Preoperative Planning

- Thyroid lobectomy is performed under a general anesthesia, but locoregional anesthetic with sedation may be adequate for lobectomy in select patients.
- Routine use of preoperative antibiotics is not common as wound infections after thyroid lobectomy are rare.[4]

Positioning

- The patient is placed in the supine position with the arms padded and tucked at the side (**FIG 1**). A roll can be placed under the shoulders to help extend the neck; however, extreme extension should be avoided as this can cause postoperative discomfort.

FIG 1 ● Patient positioning. The arms should be padded and can be tucked to the side with a sheet using a towel clip.

SKIN INCISION AND FLAP CREATION

- A low collar incision is placed symmetrically across the neck despite only removing a lobe. The incision is ideally located about two fingerbreadths above the sternal notch or 1 cm below the cricoid cartilage (**FIG 2**). This location provides good exposure to the entire thyroid gland and particularly the superior pole.
- Placing the incision in a skin crease can provide excellent cosmetic results. If no skin crease is appropriate, Langer's lines provide an adequate guide.

FIG 2 ● Incision anatomy. The sternal notch and cricoid cartilage are palpated to help determine the incision site.

GLAND EXPOSURE

- The incision is carried through the subcutaneous tissue and platysma. Subplatysmal flaps are created to enhance mobility from the incision (**FIG 3**). These flaps should extend to the thyroid cartilage superiorly and the suprasternal notch inferiorly. The assistant should retract the skin to help create the plane of dissection. The anterior jugular veins will remain down on the strap muscles if the correct plane is dissected.
- The midline raphe between the strap muscles is opened and dissection extends down to the level of the isthmus (**FIG 4**).
- The sternohyoid and, subsequently, the sternothyroid muscles are dissected off the thyroid and reflected laterally.
- The thyroid lobe is then retracted medially with a finger or hemostatic clamp. The space between the thyroid and the carotid sheath is opened bluntly until the prevertebral fascia is encountered (**FIG 5**). During this portion of

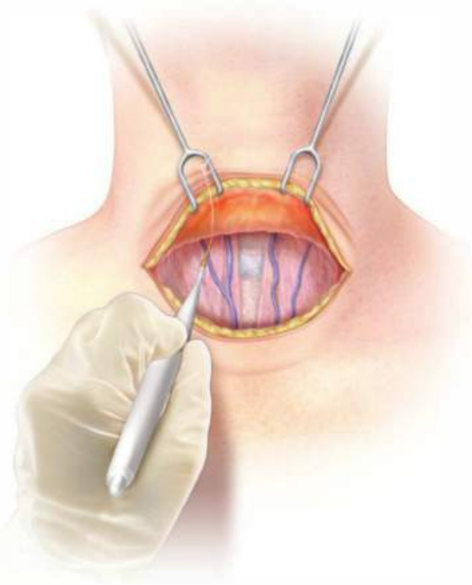

FIG 3 ● Creation of subplatysmal flaps. Adequate retraction helps creation of the subplatysmal flaps and prevents buttonholing the skin.

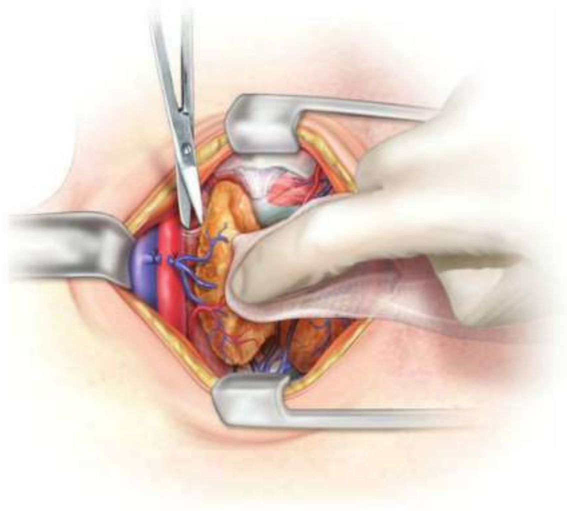

FIG 5 ● Exposure of the posterior thyroid. The thyroid is retracted toward the midline and the middle thyroid vein is divided. The areolar tissue behind the thyroid can be bluntly dissected with scissors.

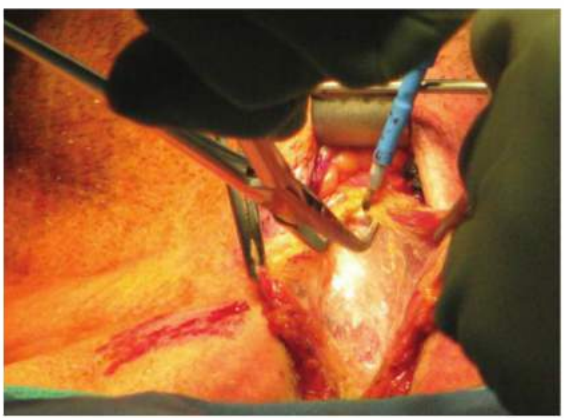

FIG 4 ● Exposure of the thyroid. The midline raphe between the strap muscles is avascular and provides access to the thyroid when opened.

the dissection, the middle thyroid vein should be controlled and ligated.

- Dissection of the isthmus can help mobilize the thyroid gland. The superior suspensory ligament and associated vessels at the superior border of the isthmus should be divided. A pyramidal lobe can be dissected and divided if present.
- The inferior vessels and attachments to the trachea along the inferior border of the isthmus should also be divided.
- The contralateral thyroid lobe can be palpated to ensure no abnormalities; however, formal dissection on the contralateral side should be avoided to prevent scar formation.

SUPERIOR POLE DISSECTION

- The cricothyroid space is an avascular space between the cricothyroid muscle and thyroid gland. This space can be bluntly opened all the way to the prevertebral fascia. Retraction of the superior pole of the thyroid in the inferior and lateral directions can facilitate this dissection (**FIG 6**).
- The external branch of the superior laryngeal nerve may be identified during this dissection and should be preserved. The nerve is vulnerable to injury as it crosses the vessels close to the superior pole of the thyroid prior to its insertion into the muscle. The anatomic variations of the nerve in relation to the superior thyroid vessels are best described by Cernea et al.[5] (**FIG 7**).
- The superior pole vessels are divided at the level of the thyroid capsule to prevent injury of the nerve (**FIG 6**). This dissection should proceed from medial to lateral.
- A superior parathyroid gland may be identified in this area and should be dissected off the gland.

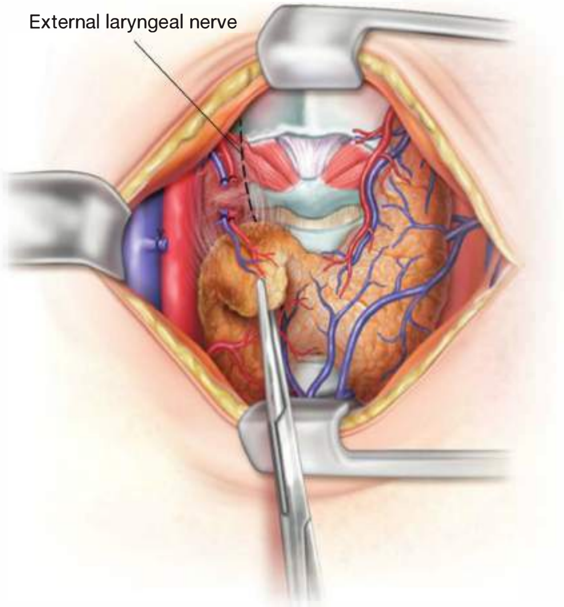

FIG 6 ● Exposure of the superior pole. The cricothyroid space is opened up bluntly. Retraction of the superior pole in a lateral and inferior direction helps to minimize the risk of injury to the external branch of the superior laryngeal nerve *(dotted line)*.

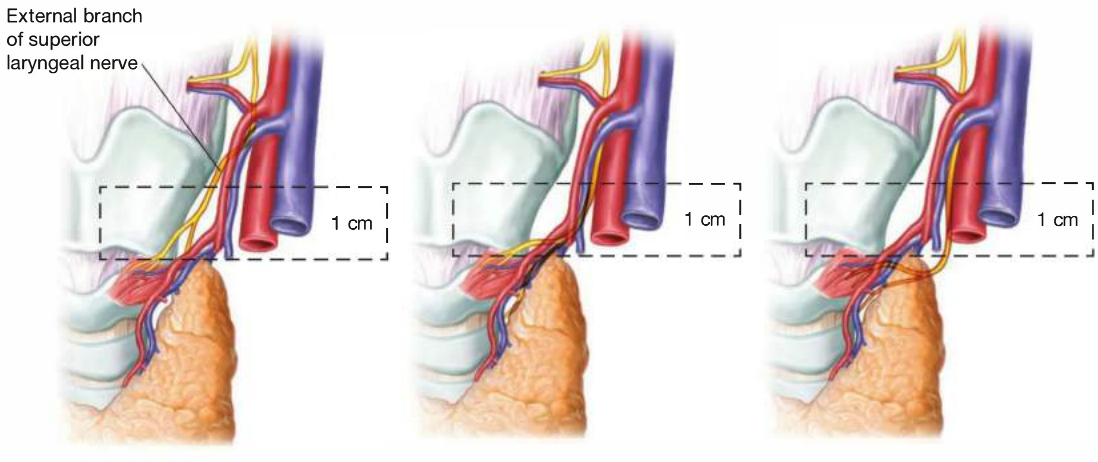

FIG 7 ● Anatomic variations of the external branch of the superior laryngeal nerve. The nerve crosses the vessels greater than a centimeter from the superior pole in type 1 anatomy. Type 2 anatomy places the nerve at higher risk of injury during dissection because it crossed less than a centimeter from the superior pole (type 2a) or even below it (type 2b). (From Cernea CR, Ferraz AR, Nishio S, et al. Surgical anatomy of the external branch of the superior laryngeal nerve. *Head Neck*. 1992;14:380–383.)

LATERAL LOBE DISSECTION

- Once the superior pole is mobilized, the lateral and inferior aspect of the thyroid can be dissected. The thyroid lobe should be retracted medially or elevated out of the wound. An assistant should retract the carotid sheath laterally to open up the lateral space.
- The identification and preservation of the recurrent laryngeal nerve is critical to the dissection. The nerve should be identified early and can often be found where it passes inferior to the inferior thyroid artery. Once the nerve is found, the dissection proceeds along the course of the nerve up to its cricothyroid insertion. The nerve is most vulnerable in this area.

- The tertiary vessels of the inferior thyroid artery are divided at the level of the thyroid capsule (**FIG 8**). This capsular dissection helps decrease the risk of nerve injury and devascularization of the parathyroid glands.
- The attachments of the thyroid to the trachea are freed by dividing the ligament of Berry.

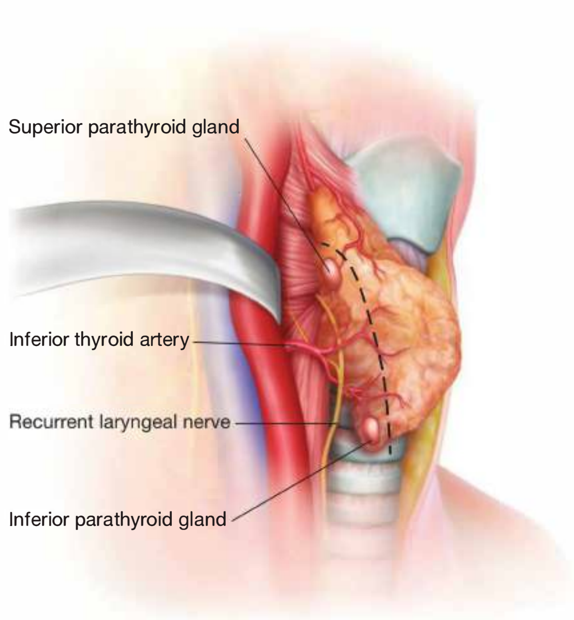

FIG 8 ● Division of the inferior thyroid artery. The tertiary branches of the inferior thyroid artery are ligated at the thyroid capsule to prevent injury to the recurrent laryngeal nerve and the blood supply to the parathyroid glands. The *dotted line* denotes the area of dissection.

PARATHYROID PRESERVATION

- The inferior and superior parathyroid glands should be identified and preserved. This is accomplished by careful dissection and reflection of them in a posterolateral direction away from the thyroid. The main trunk of the inferior thyroid artery should not be ligated as it typically provides the blood supply to both parathyroid glands.

TRANSECTION OF THE THYROID

- A thyroid lobectomy requires transection of the thyroid at the junction of the isthmus and contralateral lobe. If this junction is small, a Harmonic scalpel can transect this area while providing good hemostasis. If the area is bulky or a Harmonic scalpel is not available, a clamp can be placed across the area of transection. A knife is then used to transect the thyroid and the specimen is removed (**FIG 9**). A running absorbable suture can be placed as a hemostatic stitch underneath the clamp.

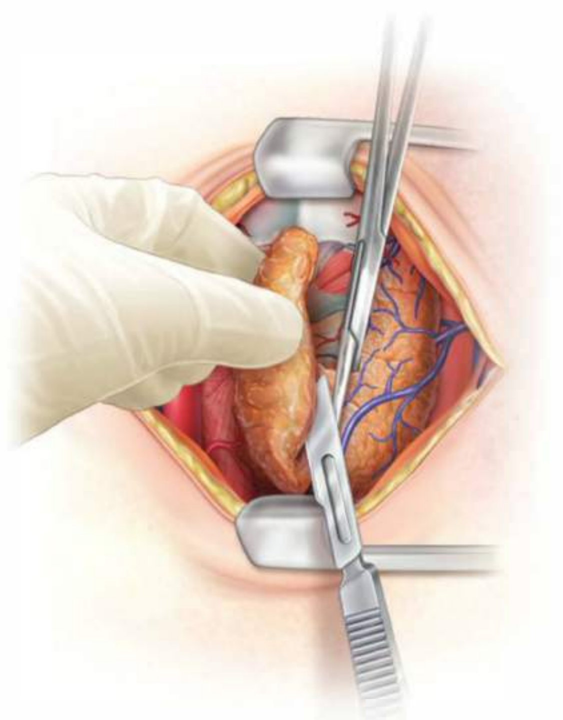

FIG 9 ● Transection of the thyroid. The junction between the isthmus and contralateral lobe is transected to remove the specimen.

CLOSURE

- Prior to closure, the surgical field is meticulously evaluated for hemostasis. Small occult bleeding can lead to clinically significant neck hematomas if not controlled.
- The parathyroid glands are evaluated once more for viability. Additionally, the lobectomy specimen should be examined for the inadvertent removal of a normal parathyroid gland. If either situation arises, the parathyroid gland should be minced up and implanted into the ipsilateral sternocleidomastoid.
- The recurrent laryngeal nerve is examined with visual inspection or nerve monitoring to ensure an intact circuit.
- After adequate hemostasis and inspection, the strap muscles are reapproximated with absorbable interrupted sutures (FIG 10). Placement of these sutures requires care to avoid injury to the anterior jugular veins.
- The platysma is reapproximated with buried interrupted sutures.
- The skin can be closed in a variety of ways. If the wound appears to be under tension during closure, removal of the shoulder roll can help. Our practice is to close the skin with a knotless running subcuticular Prolene stitch followed by the placement of skin glue. Once the glue dries, the Prolene is removed and Steri-Strips are placed as a dry dressing over the incision. Other alternatives to reapproximate the skin include the use of a running absorbable suture or the use of skin glue exclusively.

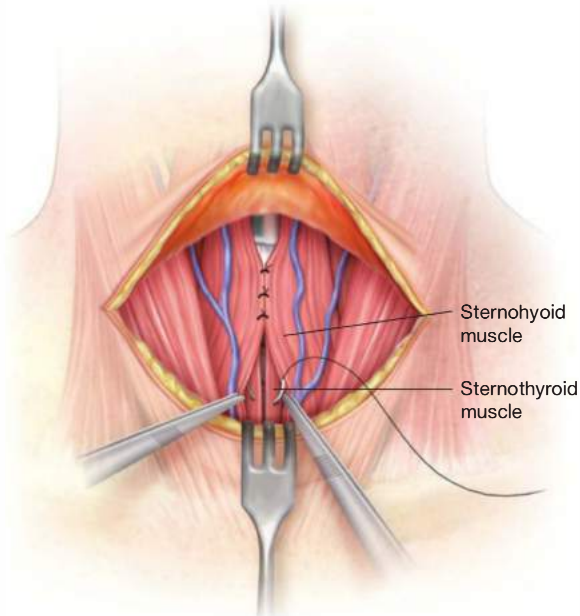

FIG 10 ● Closing the strap muscles. The strap muscles are reapproximated with interrupted sutures.

PEARLS AND PITFALLS

Incision aesthetics	■ A natural skin crease should be used if present. ■ An incision too cephalad is very noticeable with normal clothing. ■ An incision too caudal can increase the risk of keloid formation.
Parathyroid preservation	■ If a parathyroid gland cannot be preserved, it should be placed into cold saline for preservation. ■ A small portion of the parathyroid gland should be sent for frozen section to confirm normal parathyroid tissue. ■ The gland should then be minced into small pieces and implanted into the ipsilateral sternocleidomastoid. ■ A clip or permanent suture can mark the autograft sites.
Hemostasis	■ Hemostasis can be evaluated under Valsalva maneuver to look for occult bleeding. ■ Drains are rarely needed and are never a substitute for adequate hemostasis. ■ Electrocautery should be avoided in the area of the recurrent laryngeal nerve.
Large substernal goiter	■ Most substernal goiters located above the brachiocephalic vein can be removed through a cervical incision. ■ Dissection of the superior pole and early transection of the isthmus can provide added mobility needed to pull up a goiter from behind the sternum. ■ The patient should be counseled and the chest prepped in case a mini-sternotomy is needed.

POSTOPERATIVE CARE

- The patient should be monitored in the postoperative area for a few hours to ensure no significant hematoma develops.
- An ice pack may be placed over the neck to assist with pain and swelling. Once the patient is sufficiently awake, the diet may be advanced as tolerated.
- After a period of monitoring, most patients may be safely discharged home after a thyroid lobectomy. Patients should expect to resume their normal activities within a few days of surgery.
- Most patients will not require thyroid hormone replacement after a lobectomy if the remaining lobe is normal. Thyroid hormone levels should be checked about 2 months after surgery to ensure the other lobe is adequately functioning.

COMPLICATIONS

- Hematoma
- Hypocalcemia
- Hoarseness
- Vocal cord paralysis
- Wound infection

Chapter 36 Total Thyroidectomy

Saïd C. Azoury Martha A. Zeiger

DEFINITION

- Total thyroidectomy involves removal of all thyroid tissue, including both lobes and isthmus, while preserving the parathyroid glands, the recurrent laryngeal nerve (RLN), and the external branch of the superior laryngeal nerve.

ANATOMY

- The thyroid gland typically weighs 20 g and has a right and left lobe bridged by a narrow isthmus.
- The thyroid gland is located in the central compartment of the anterior neck below the thyroid cartilage.
- The thyroid cartilage forms the laryngeal prominence or the "Adam's apple."
- The thyroid lobes lie medial to the carotid sheaths and sternocleidomastoid muscles.
- The anterolateral surface of the gland is covered by the sternothyroid and sternohyoid muscles (**FIG 1**).
- The "thyroid sheath" is a connective tissue expansion of the pretracheal fascia and envelops the thyroid, condensing posteromedially into the ligament of Berry.
- The thyroid gland receives its blood supply from the superior and inferior thyroid arteries.
- The superior thyroid artery arises from the ipsilateral external carotid artery and the superior thyroid vein runs with the artery.
- The middle thyroid vein drains into the ipsilateral internal jugular. The inferior thyroid artery originates from the thyrocervical trunk. The left RLN arises from the vagus at the level of the aortic arch and loops around the ligamentum arteriosum; the right RLN loops around the right subclavian artery (**FIG 2**).

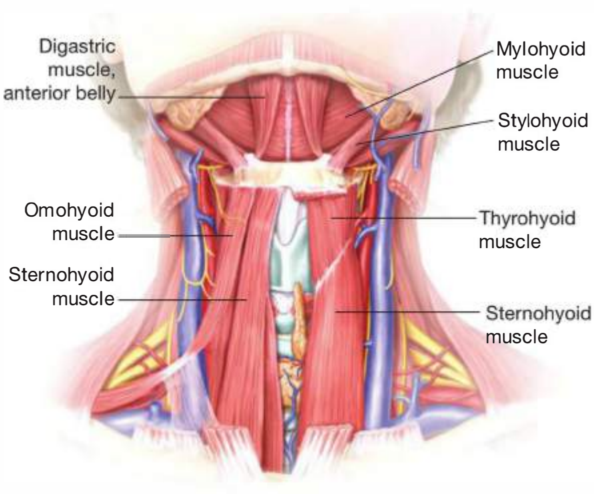

FIG 1 • Strap muscles of the neck.

- The right RLN may be nonrecurrent in 0.5% to 1% of individuals.
- The RLN innervates all the intrinsic muscles of the larynx except the cricothyroid muscles.
- The internal branch of the superior laryngeal nerve is the sensory nerve for the supraglottic larynx. The external branch of the superior laryngeal nerve lies on the inferior pharyngeal constrictor muscle and descends alongside the superior thyroid vessels before innervating the cricothyroid muscle.
- The superior parathyroid glands are generally located posterior to the superior thyroid lobe and the RLN. The inferior parathyroid locations are more variable but oftentimes are located anterior to the inferior thyroid lobes and RLN or on the inferolateral aspect of the lobes.

INDICATIONS FOR TOTAL THYROIDECTOMY

Graves' Disease[1–3]

Thyroid Cancer

- In general, total thyroidectomy is indicated for follicular or papillary thyroid cancer.[4–6] Patients may also need a concomitant central lymph node dissection.[4–6] Total thyroidectomy with central lymph node dissection is typically indicated for medullary thyroid cancer.[7]

Multinodular Goiter

- Total thyroidectomy is indicated for symptomatic multinodular goiter (MNG) or for patients who have suspicious or indeterminate thyroid nodules on fine needle aspiration biopsy (FNAB).[8–10]

PATIENT HISTORY AND PHYSICAL FINDINGS

History

- Thyroid cancer is more common in extremes of age, younger than 20 or older than 60 years.
- Most thyroid nodules are asymptomatic, and most patients are euthyroid.
- Thyroid nodules are more common in females, but there is a greater risk of malignancy in males.
- One must inquire about a history of radiation therapy and family history of thyroid cancer: Nearly 90% of radiation-associated thyroid cancers are papillary.
- Personal or family history of other endocrine disorders such as a history of thyroid cancer, primary hyperparathyroidism, pancreatic islet cell tumors, pituitary tumors, or adrenal tumors is essential to understand a patient's risk.
- Medullary thyroid cancer is a known component of multiple endocrine neoplasia 2 (MEN2).
- Weight gain, fatigue, depression, constipation, dry skin, and brittle nails are symptoms of hypothyroidism; weight loss, weakness, anxiety, palpitations, and diarrhea are symptoms of hyperthyroidism; both are key elements of the review of systems portion of a history.

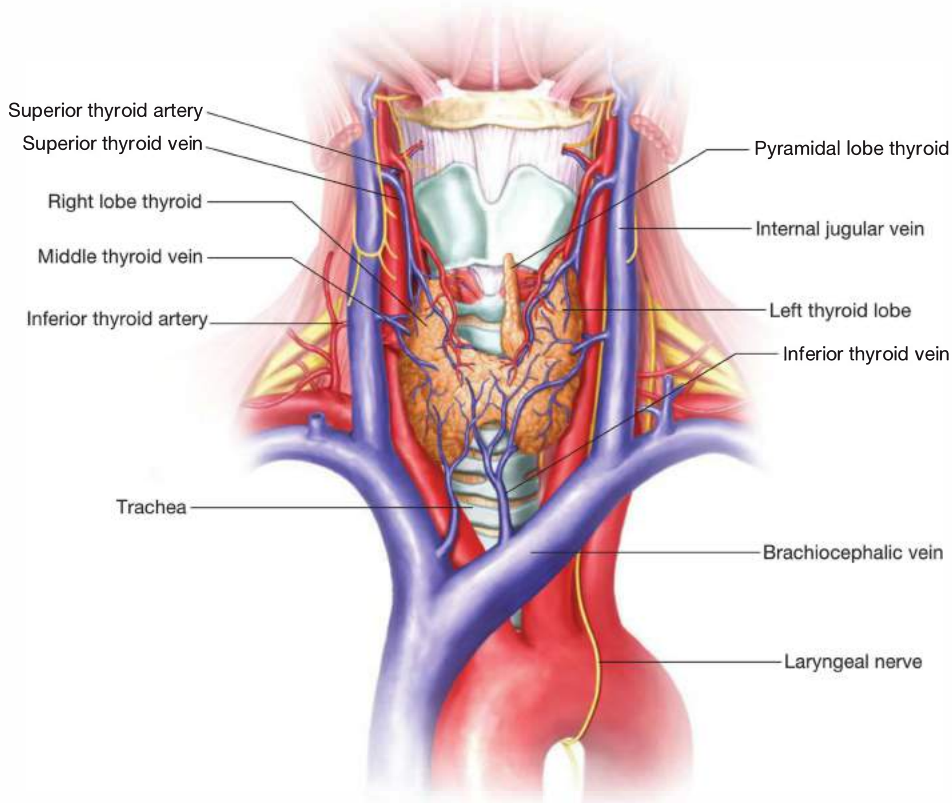

FIG 2 ● Anatomic location of thyroid gland and vascular anatomy.

- One should inquire about symptoms of dysphagia, dyspnea, voice change, cough, or trouble breathing.

Physical Exam

- Size of thyroid nodules, firmness of the nodules, and the presence of substernal extension are important to assess.
- Findings suggestive of cancer include nodule fixation, hard texture, and associated cervical lymphadenopathy.
- Important eye signs include stare, lid lag, dryness, diplopia, or exophthalmos (**FIG 3**); all of which can suggest Graves' disease.

FIG 3 ● Graves' ophthalmopathy: prominent stare.

- Extremities should be examined for pretibial myxedema (waxy, discolored induration, and swelling) that can be associated with severe hypothyroidism.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Thyroid-Stimulating Hormone (Normally 0.5 to 5 μU/mL)

- A serum thyroid-stimulating hormone (TSH) should be measured to determine if the patient is hypo-, hyper-, or euthyroid. There is an inverse relationship between the free thyroxine (T4) level and the TSH concentration.

Free Thyroxine (Normally 12 to 28 pmol/L)

- Free T4 is a sensitive and accurate measurement of biologically active thyroid hormone.
- In early hyperthyroidism, total T4 levels are normal but free T4 levels are elevated.
- Hyperfunctioning nodules are much less likely to harbor malignancy.

Serum Thyroglobulin

- Thyroglobulin is primarily used to detect recurrent thyroid cancer.

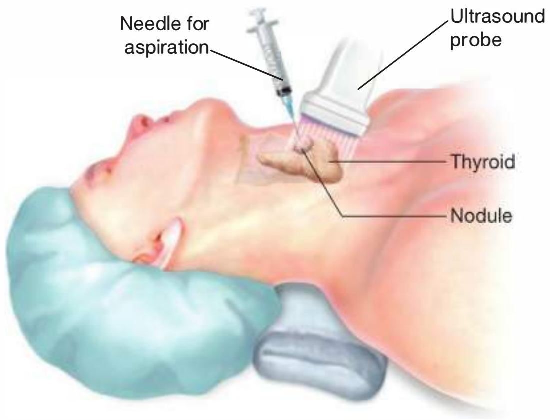

FIG 4 ● FNA of thyroid nodule.

Fine Needle Aspiration Biopsy

- Ultrasound-guided needle aspiration is performed using 23- to 27-gauge needles and a 10-mL syringe (FIG 4).
- FNAB specimens are classified as malignant, benign, indeterminate (atypical cells of undetermined significance, suspicious for follicular or Hürthle cell neoplasm, or suspicious for malignancy), or insufficient for diagnosis.
- Overall sensitivity of FNAB is 95% to 98%.[7]

Iodine Scintigraphy

- Elevated iodine uptake with diffuse uptake and enlargement is consistent with Graves' disease.
- The risk of malignancy in "hot" lesions is extremely low. Iodine scintigraphy should only be used if the patient is hyperthyroid and has nodular disease to determine if a nodule is responsible for the hyperthyroidism.

Antithyroglobulin and Antithyroid Peroxidase Antibodies

- Anti-thyroid peroxidase (anti-TPO) antibodies are associated with Hashimoto's thyroiditis. Antithyroglobulin (anti-Tg), if present, makes following patients with thyroid cancer for Tg elevation unreliable.

High-Resolution Ultrasonography

- Ultrasound is recommended to determine the number, size, and characteristics of the thyroid nodules.
- Increased intranodular vascularity, irregular margins, the so-called "halo sign" or anechoic rim, microcalcifications, and hypoechogenicity are generally associated with a malignancy.
- Cervical ultrasound to assess for lymphadenopathy is recommended for suspicious or malignant thyroid nodules.

Computed Tomography

- Computed tomography (CT) imaging is indicated for substernal goiters or if a cancer is large or appears fixed to surrounding anatomic structures.

NONOPERATIVE MANAGEMENT

Antithyroid Drugs: Propylthiouracil and Methimazole

- When used for Graves' Disease, generally, propylthiouracil (PTU) (100 to 300 mg three times daily) or methimazole (10 to 30 mg three times daily) are the antithyroid drugs of choice.
- Both drugs inhibit the organic binding of iodine and thyroperoxidase coupling of iodotyrosines. PTU also inhibits the peripheral conversion of T4 to triiodothyronine (T3).

Radioactive Iodine Therapy

- Radioiodine therapy has been the preferred treatment for most patients with Graves' disease.
- Radioiodine therapy is indicated postoperatively for patients with thyroid cancer who have a high risk of recurrence.

Close Follow-up

- Patients with asymptomatic and benign thyroid nodules should be followed with serial neck ultrasounds and repeat fine needle aspiration (FNA) as needed.
- Patients may need longitudinal neck ultrasounds and repeat FNA.

SURGICAL MANAGEMENT

- The use of total thyroidectomy for benign disease has increased over the last 15 years in the United States from 17.6% (1993–1997) to 39.6% (2003–2007) compared with 82.4% and 60.4% for partial thyroidectomy over the same periods.[11]
- Total thyroidectomy for Graves' is the gold standard advocated by endocrine surgeons.
- In one study of patients with Graves' disease, reasons for having thyroid surgery were persistent disease despite medical therapy (46.6%), patient preference (24.1%), MNG/cold nodules (20.3%), failed radioactive iodine (RAI) treatment (16%), and ophthalmopathy (12.1%).[12]
- In general, the indication for total thyroidectomy should be considered in cases of suspicious or definite malignant nodules; the presence of thyroid nodules; and a history of head and neck irradiation, Graves' disease, large or substernal goiter, or symptomatic goiter (dysphagia, pressure, dyspnea).
- The most important goals of surgery for MNG are to prevent recurrence after surgery and to definitively diagnose thyroid nodules that were indeterminate or suspicious preoperatively.
- The advantage of total thyroidectomy, compared to subtotal thyroidectomy, for treatment of Graves' is the avoidance of recurrent hyperthyroidism, which has been reported to be as high as 22% following subtotal thyroidectomy.[7,13,14]
- Advantages of total thyroidectomy over thyroid lobectomy for well-differentiated thyroid carcinoma (WDTC) include the fact that papillary thyroid cancer can be multifocal, facilitation of radioiodine imaging and ablation for residual metastatic disease, and the use of serum thyroglobulin for postoperative disease surveillance.
- Surgery is often recommended for patients with severe ophthalmopathy; this condition can be worsened by RAI.
- Surgery is appropriate in children and in pregnant women with Graves' disease.[15]
- Surgery is indicated for a substernal goiter because these are usually symptomatic and substernal nodules cannot be assessed by FNA.

Preoperative Planning

- Thyroid scintigraphy is only indicated in a subset of patients with hyperthyroidism.
- FNA under ultrasound guidance is the gold standard when there is a suspicion for thyroid cancer and should be performed if a nodule is found to be greater than 1 cm and/or if the nodule has suspicious ultrasound characteristics.[7] FNA provides quick and specific information that helps to guide definitive surgical management.
- High-resolution ultrasound of the neck can be used to evaluate for cervical lymphadenopathy.
- Laryngoscopy is often used before surgery whether for benign or malignant disease, especially for patients with voice changes, to determine the extent and any involvement of surrounding structures including the RLN.

Intraoperative Positioning of the Patient

- Patient is placed in supine position with arms tucked at the sides.
- A soft roll is placed lengthwise beneath the shoulders to extend the neck, and a soft foam "donut-shaped" rest is used to stabilize the head.
- Patient is further placed in a *semi-Fowler's position*, with the head of the bed at approximately 30 degrees (**FIG 5**).

FIG 5 ● Semi-Fowler's position.

FIG 6 ● RLN nerve monitoring wires anchored to the patient's shoulder, out of the way of the neck and the sterile operating field.

- The RLN nerve monitoring wires are anchored to the patient's shoulder, out of the way of the neck and the sterile operating field (**FIG 6**).

Approach

- During surgery, great care should be taken to identify the recurrent and superior laryngeal nerves, the parathyroid glands, and their vascular supply. Parathyroid glands can be distinguished from surrounding structures by their fine surface vascular pattern and brown hue.
- Intraoperative nerve monitoring with electrode attached to endotracheal tube allows for stimulation and detection of the RLN and superior laryngeal nerves.
- Due to the vascularity of the thyroid gland, many surgeons use LigaSure rather than bipolar cautery, ties, or clips.[16] The duration of the procedure with the use of the LigaSure is significantly shorter, and there are fewer complications compared to the classic "tie and knot" technique.[16]
- There is no statistical difference noted in the literature when comparing suture tying and Harmonic scalpel complications.[17,18]
- Clips can also be used for hemostasis on the specimen side.

TOTAL THYROIDECTOMY

- With the patient lying supine in a semi-Fowler's position with the arms tucked at the sides, the anterior surface of the neck is prepped and draped, exposing the anterior neck from the sternal notch to the chin and from both anterior borders of the sternocleidomastoid muscles (**FIG 7**).
- Transverse curvilinear collar incision is made approximately two fingerbreadths above the sternal notch, along a normal skin crease. The length of the incision varies depending on the patient's body habitus and the size of the thyroid gland (**FIG 8**).
- The subcutaneous tissue and platysma are divided, and skin flaps are raised in a subplatysmal plane from the sternal notch inferiorly to the level of the thyroid cartilage superiorly and the sternocleidomastoid muscles laterally. Skin hooks aid with the exposure and flap elevations (**FIG 9**).
- Strap muscles are separated in the midline from the thyroid cartilage to the sternal notch and are reflected laterally (**FIG 10**).

FIG 7 ● Patient prepped and draped, with thyroid cartilage and sternal notch anatomic landmarks marked out as well as the proposed incision.

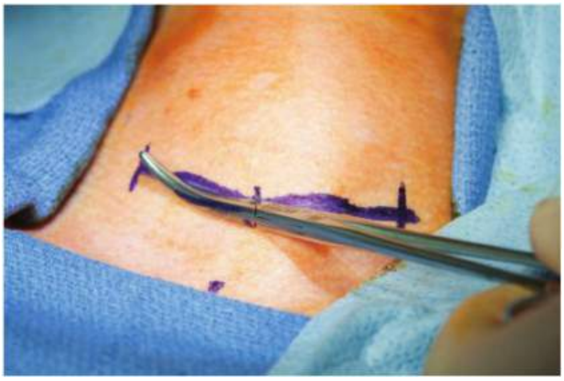

FIG 8 ● Incision marking.

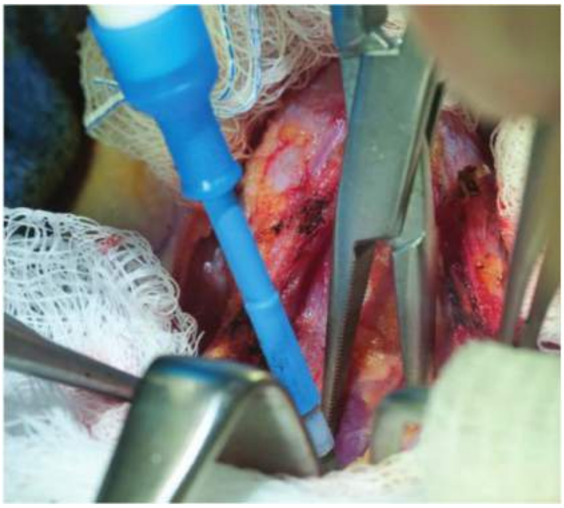

FIG 10 ● Strap muscles are separated in the midline from thyroid cartilage to the sternal notch using electrocautery.

- Horizontal division of the sternohyoid and sternothyroid muscles may be necessary to fully expose a large thyroid gland (**FIG 11**).
- If the pyramidal lobe is easily identified during this phase of the operation, it can be dissected free from its attachments and ligated to allow for greater mobility of the gland (**FIG 12**).
- Typically, the middle thyroid veins are the first vessels identified in the dissection and are ligated and divided (**FIG 13**).
- Superior pole vessels are then identified by exerting traction on the upper pole of the gland, oftentimes using a Babcock clamp to aid with the retraction. The superior thyroid vessels are individually ligated, and we typically use the LigaSure for this (**FIG 14**).

FIG 9 ● Skin hooks aiding with the exposure and flap elevations to allow for subplatysmal dissection.

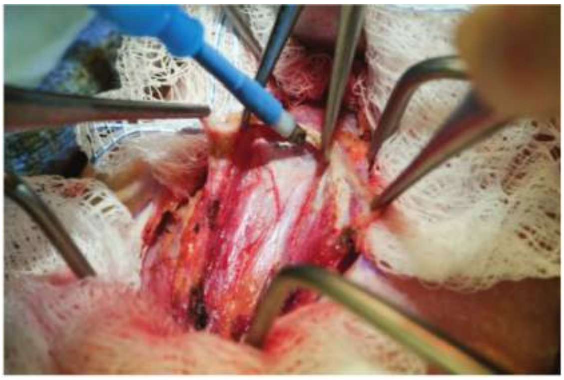

FIG 11 ● Division of sternothyroid muscles helps to fully expose the thyroid gland.

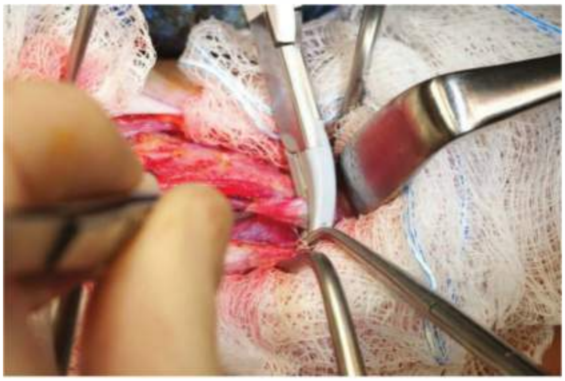

FIG 12 ● Dissection and mobilization of the pyramidal lobe and ligation of its attachments.

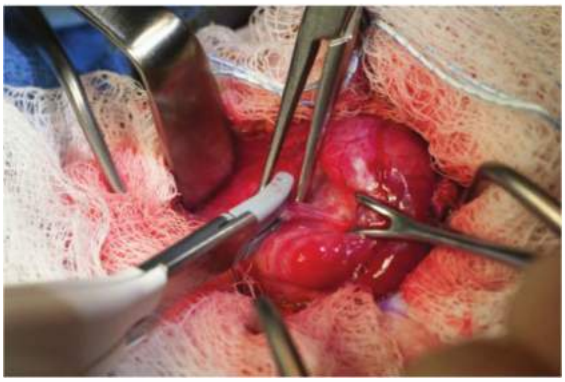

FIG 13 ● Ligation of the middle thyroid vein.

FIG 14 ● Superior pole vessels are identified and individually ligated.

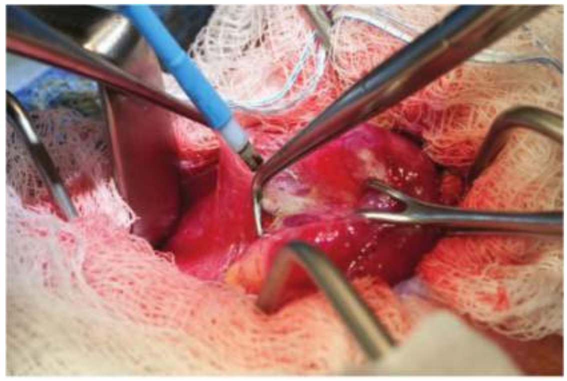

FIG 15 ● Subcapsular dissection is carried close to thyroid gland to avoid injury to the external branch of the superior laryngeal nerve.

- Subcapsular dissection is carried close to thyroid gland to avoid injury to the external branch of the superior laryngeal nerve (**FIG 15**).
- Areolar tissue between the common carotid artery and the thyroid lobe is dissected using a combination of blunt dissection, electrocautery, and LigaSure, helping to facilitate anteromedial thyroid lobe rotation (**FIG 16**).
- The inferior thyroid artery is identified, and its close proximity to the RLN then allows for easy identification of the nerve. The RLN is then traced through its entire course and preserved (**FIG 17**).
- Intraoperative nerve monitoring is often used to help confirm the location and integrity of the nerve (**FIG 18**).
- The inferior pole of the thyroid gland is mobilized once the RLN is identified, and this is done by ligating the branches of the arteries and veins close to the thyroid

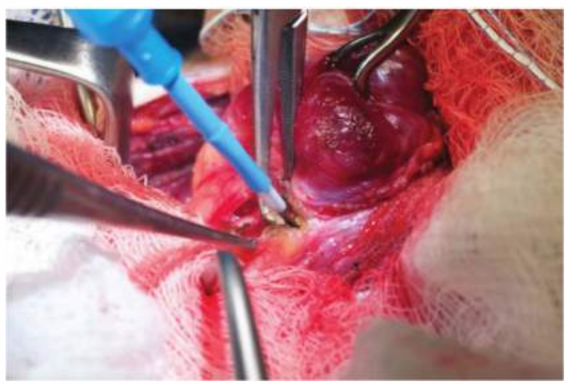

FIG 16 ● Areolar tissue between the common carotid artery and thyroid lobe is dissected with electrocautery.

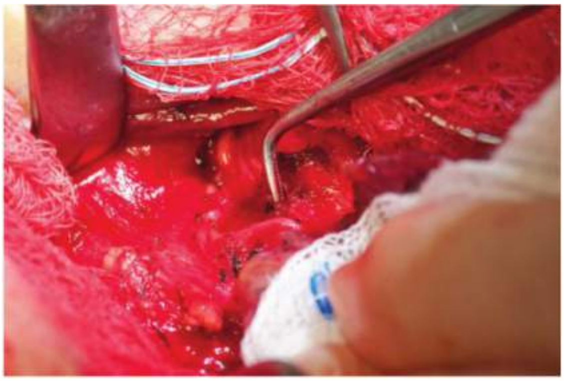

FIG 17 ● The thyroid gland is rotated anteromedially, and the recurrent laryngeal nerve is traced along its entire course. Note the RLN at the tip of the right angle.

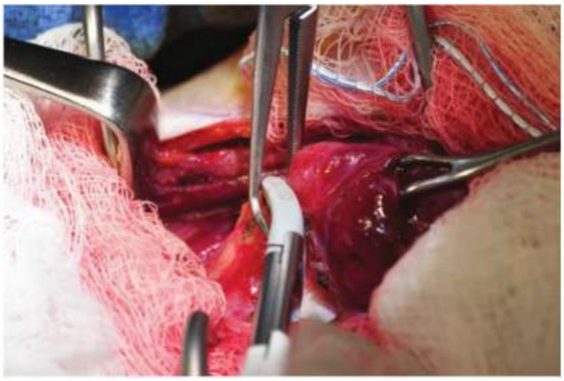

FIG 19 ● Ligation of the inferior thyroid vessels close to the gland.

gland. By ligating the vessels close to the gland, the blood supply to the inferior parathyroid gland is therefore preserved (**FIG 19**).

- The anterior surface of the trachea is then exposed (**FIG 20**), and simultaneous anteromedial retraction of the superior and inferior poles of the thyroid enhances the exposure of the RLN (**FIG 21**).
- The remaining branches of the inferior thyroid artery are ligated and divided close to the thyroid parenchyma using various techniques including surgical clip and tie or LigaSure (**FIG 22**).
- The remaining thyroid lobe and ligament of Berry are separated from the RLN, preserving the blood supply to the superior parathyroid gland (**FIG 23**).
- Once the lobe of the thyroid gland has been separated from the RLN, the remainder of the ligament of Berry can be divided, separating the isthmus form the trachea (**FIG 24**).

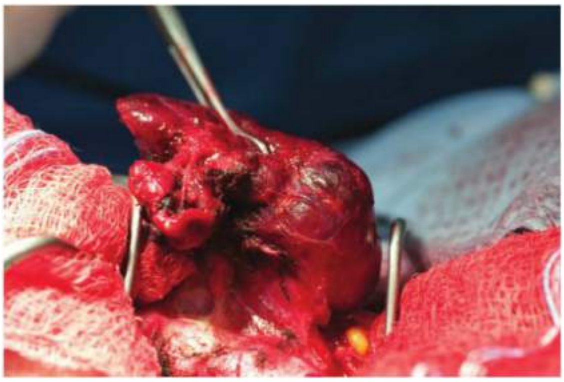

FIG 20 ● Anterior surface of the trachea exposed.

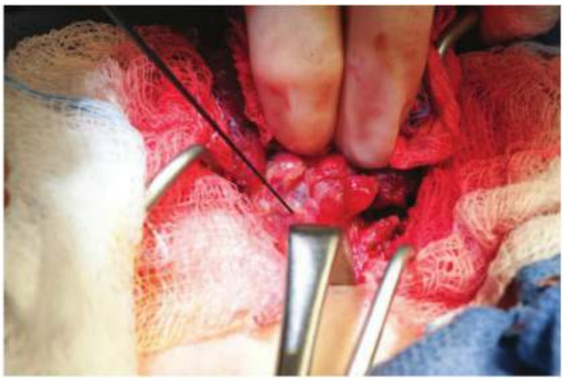

FIG 18 ● Intraoperative nerve monitoring being used to help with identifying the RLN and confirming its integrity.

FIG 21 ● RLN exposed, with the gland anteromedially retracted and countertraction applied to the trachea.

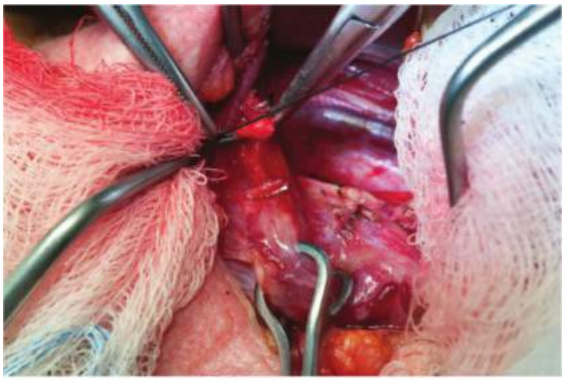

FIG 22 ● Inferior thyroid pole vessels are ligated and divided close to the thyroid gland, with careful attention paid to the blood supply of the parathyroid glands.

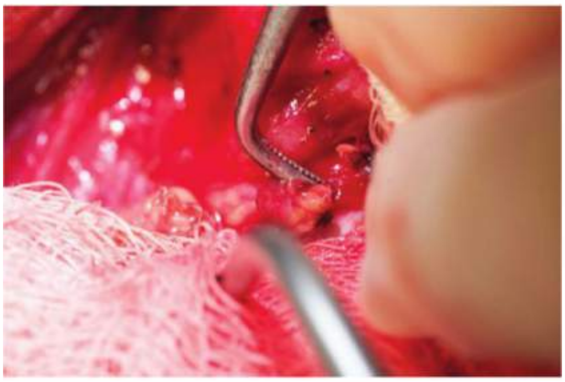

FIG 23 ● Parathyroid gland dissected free and preserved with its blood supply seen at the tip of the right angle.

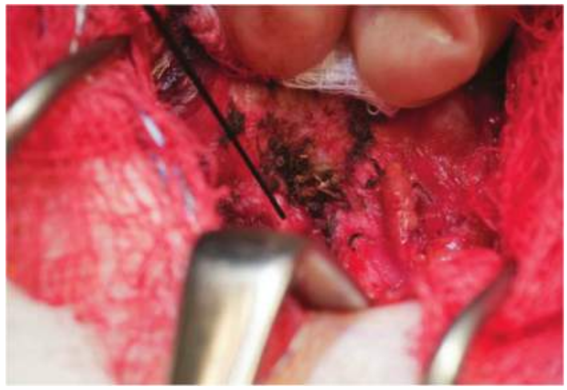

FIG 25 ● Integrity of the RLN is confirmed, both by visual inspection and with the nerve probe.

- The contralateral lobe is resected in an identical fashion, and after complete removal, the integrity of the RLN is confirmed, both by visual inspection and with the nerve probe (**FIG 25**).
- The trachea is left exposed and hemostasis is then attained, followed by irrigation with normal saline (**FIG 26**).
- The sternohyoid muscles are reapproximated in the midline using a running or locking suture, through only fascia and not muscle. The inferior aspect is left open over a distance of 1 to 2 cm to allow blood to decompress into the subcutaneous space if bleeding develops (**FIG 27**).
- The platysmal muscle layer is then reapproximated using simple interrupted suture (**FIG 28**).
- A subcuticular running suture technique, with a free knotless tail left on either end of the incision, is used to closely reapproximate the skin. Careful attention is paid to the cosmesis of the closure (**FIG 29**).
- A single Steri-Strip is placed horizontally in the direction of the incision, and a suture tail is left free on either end of the incision (**FIG 30**).

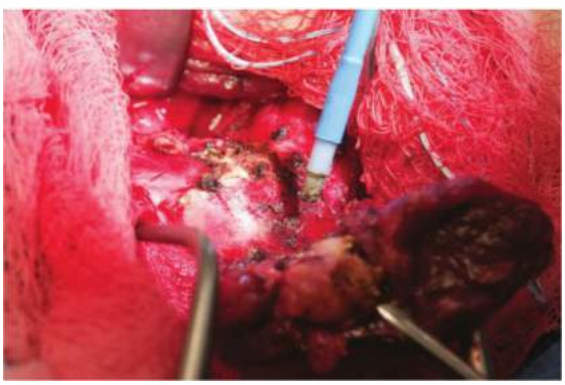

FIG 24 ● Traction placed on the thyroid gland as the ligament of berry is divided, thereby releasing the gland from its tracheal attachment.

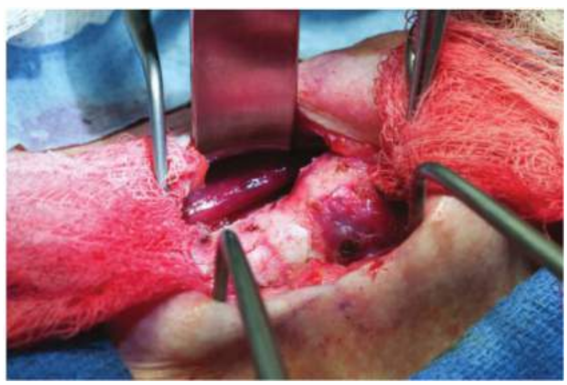

FIG 26 ● The trachea is left exposed and hemostasis is then attained, followed by irrigation with normal saline.

FIG 27 ● Sternohyoid muscles reapproximated in midline with inferior margin left open.

FIG 28 ● Platysmal muscle layer reapproximated in the midline with simple interrupted suture.

FIG 29 ● Subcuticular running suture technique.

FIG 30 ● Steri-Strip applied along the length of the incision.

PEARLS AND PITFALLS

Subcapsular dissection	■ A subcapsular dissection, in close proximity to the thyroid capsule, is the approach of choice, taking meticulous care to preserve blood flow to parathyroid glands, and identify the RLNs, protecting them all the way to their insertion in the cricopharyngeus muscle. This approach helps minimize the risk of postoperative hypocalcemia and nerve injury.
Gentle retraction	■ This simple subtlety of surgeon's technique helps to avoid nerve injury and preserve vascular supply to the parathyroid glands.
Intraoperative nerve monitoring	■ Easy to setup and aids with the identification of the RLN, oftentimes before visualization. It allows for functional assessment of an anatomically intact RLN and also permits vagal nerve identification to confirm RLN function when visual identification is difficult. Pitfall of this is that it is expensive, requires a learning curve, and may be associated with false-positive or false-negative nerve signals if not properly interpreted.
Vessel ligation	■ The Harmonic scalpel and LigaSure have been shown to result in decrease length of operation.
Closure of strap muscles	■ Strap muscles are approximated in the midline with a running, locking suture, and 1 to 2 cm is left open at its inferior margin. This will allow blood to escape into the subcutaneous space in the event of a postoperative hemorrhage, so that pressure against the airway is minimized. Platysmal muscles are reapproximated using a simple interrupted technique; again, in the event of a hematoma, the individual sutures can be cut to allow for simple evacuation.
Use of a neck drain	■ Drains are almost never used.
Skin closure	■ A 4-0 subcuticular stitch is used. A suture tail is left at the corner of each end of the skin incision, and piece of Steri-Strip is applied horizontally along the incision. If the wound needs to be redressed, the original dressing is removed, and the two ends of the sutures can be used to produce countertraction on either end of the incision and a new Steri-Strip can then be neatly applied.

POSTOPERATIVE CARE

- Total or ionized calcium are checked on the morning of postoperative day 1, as some reports have shown that nearly one-third of patients will have mild temporary hypocalcemia within the first 1 to 2 days after surgery.[9]
- Calcium supplementation is administered based on how low the postoperative calcium level is and as needed for any numbness or tingling.
- Levothyroxine (1.6 μg/kg/day) is prescribed and started 3 days after surgery, unless the patient is already on supplementation or is hyperthyroid; TSH suppression with levothyroxine is thought to improve recurrence and survival rates in cancer patients.
- Laryngoscopy is indicated postoperatively if the patient complains of hoarseness or for any voice changes in order to assess for RLN or vocal cord damage.
- For those with locally advanced disease or with macroscopic residual tumor, radioactive ^{131}I therapy is given adjuvantly. Serum thyroglobulin is followed postoperatively to detect persistent or metastatic disease.
- For patients with WDTC that is greater than 1.5 cm, RAI remnant ablation is oftentimes recommended, especially if there is residual remnant tissue, nodal metastasis, extrathyroidal extension, or distant disease.
- Ultrasonography is indicated yearly for the first 2 years after treatment; thyroid function is measured directly by free T4 and indirectly by TSH.

OUTCOMES

- MNG is more likely to recur after bilateral subtotal thyroidectomy than after total or near-total thyroidectomy, with relapse rates after subtotal thyroidectomy reported to be as high as 9% to 43%; and the risk of malignancy in remaining thyroid tissue, 4% to 17%.[9]
- It is important to emphasize that reoperative thyroid surgery is associated with more risk of complications that the first operation.

COMPLICATIONS

- Transient or permanent RLN injury
- Bilateral RLN injury
- Transient or permanent hypoparathyroidism
- Injury to the external branch of the superior laryngeal nerve
- Postoperative neck hematoma
- Surgical site infection

Chapter **37**

Thyroidectomy for Substernal Goiters

Andrew G. Shuman Ashok R. Shaha

DEFINITION

- A goiter refers to any abnormal thyroid enlargement secondary to nutritional deficiency, endocrine disease, or neoplasm. In general terms, substernal goiter applies to conditions in which the majority of the thyroid volume lies below the thoracic inlet.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A comprehensive medical history is obligatory, including assessment of the indications for surgery, consideration of medical comorbidities, and ensuring that patients are medically optimized and risk-stratified for surgery. Any prior operative records and pathology reports should be reviewed in advance.
- A detailed physical examination is mandatory, including consideration of upper airway patency and visualization of the larynx to assess vocal fold mobility.
- Flexible fiberoptic laryngoscopy is helpful in evaluating glottic function and assessing the airway.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Cross-sectional imaging (usually computerized tomography) is invaluable in defining the intrathoracic anatomic extent of the mass and its relationship to critical cervical and intrathoracic structures.[1]
- Intravenous contrast may delay the ability to use radioactive iodine but should be used whenever anatomic considerations may affect the surgical planning or technique.
- Ultrasound may also be employed but is of limited use in assessing the intrathoracic extent of disease.
- A thoughtful approach to the airway is necessary. In addition to history, physical examination, and imaging studies, exclusion of cardiopulmonary factors affecting respiration is important.
- Spirometry and flow-volume loops are useful adjuncts in order to understand the underlying respiratory physiology. However, surgical decisions are made based on functional and anatomic considerations rather than strictly physiologic tests.
- Preoperative laboratory studies should include thyroid function testing and thyroglobulin.
- In the case of a thyroid mass or nodule, fine needle aspiration (preferably image-guided) with cytologic evaluation should be attempted prior to surgery.

SURGICAL MANAGEMENT

- Consideration for removal of substernal goiters is multifactorial.[2]
- Indications for an operation may relate to the need to make a diagnosis, extirpate malignancy, ameliorate compression of the upper aerodigestive tract, or relieve venous outflow obstruction (superior vena cava syndrome).
- In most patients meeting criteria for surgery, medical options other than watchful waiting are limited.
- Given that most goiter operations are elective, prudent and deliberate preoperative planning and counseling are essential. The indications, risks, benefits, and alternatives of surgery versus expectant management should be discussed.

Preoperative Planning

- Preoperative communication with anesthesia is critical. Although most patients can be readily intubated, airway compression or deviation must be considered. Atraumatic intubation is necessary.[3]
- The endotracheal tube cuff should be well below the vocal folds to avoid both glottic trauma and inadvertent extubation, as the endotracheal tube has a tendency to be displaced with movement during surgery.
- Thoracic surgeons should provide preoperative input and be available to assist in cases in which their presence may be needed.
- Options such as small endotracheal tubes, endotracheal tubes facilitating nerve monitoring, and/or fiberoptic bronchoscopy/intubation should be discussed prior to induction with anesthesia.
- Fiberoptic intubation is rarely necessary, although adjunctive technologies, such as the GlideScope®, may be useful.

Positioning

- The patient is positioned supine with gentle neck extension. Effort should be made to prepare and drape in a manner that facilitates some movement of the head and neck while preserving the sterile field.
- Overextension of the neck may put the recurrent laryngeal nerves (RLNs) under tension and make them more difficult to identify.
- Even if sternotomy is not planned, the chest should be prepped for access in case of either an emergency or the inability to free the gland transcervically.

Anatomy

- The tuberculum of Zuckerkandl is a posterolateral prominence of thyroid tissue that frequently approximates the location of the RLN.[4]
- Berry's ligament is a condensation of the pretracheal fascia that attaches the thyroid to the airway. Small vessels run along the ligament, and it may be in close proximity to the RLN, requiring careful attention in order to ensure preservation of the nerve when the thyroid is being mobilized.
- In general, the substernal component of the thyroid gland originates from one lobe. Left substernal goiters are anteriorly displaced by the aortic arch. Right substernal goiters are frequently nestled between the superior vena cava and the prevertebral muscles (**FIG 1**).
- Posterior mediastinal goiters are rare, but when present, the RLN may be anteriorly displaced.
- In rare cases, substernal goiters may not be contiguous with the cervical thyroid gland.

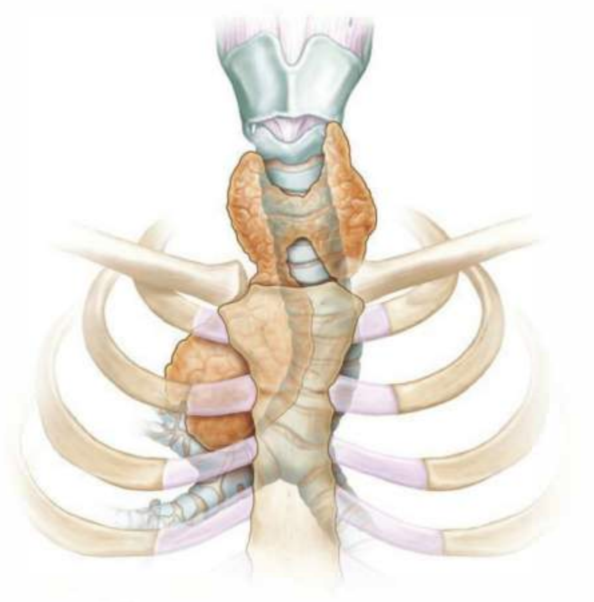

FIG 1 ● Anatomy of substernal goiter. The substernal component of the thyroid gland usually originates from one lobe. Left substernal goiters are anteriorly displaced by the aortic arch. Right substernal goiters (pictured) are frequently nestled between the superior vena cava and the prevertebral muscles.

Approach

- The cervical vascular supply, anterior position, and rarity of bilateral intrathoracic extension typically facilitate complete removal of substernal goiters transcervically.[5]
- Less than 10% of substernal goiters require sternotomy or thoracotomy.
- Relative indications for sternotomy include the following:
  - Prior mediastinal surgery
  - Retroesophageal/posterior mediastinal location
  - Goiter abutting the carina
  - Intrathoracic malignancy with extrathyroidal extension
  - Intimate association with the great vessels
  - Massive substernal goiters that physically cannot be removed through the neck
- When sternotomy is indicated, a "T" incision is frequently preferred.
- Transcervical dissection and ligation of vessels occur prior to opening the chest. However, in cases with venous obstruction, sternotomy precedes vessel ligation in order to limit intrathoracic venous distension.
- The sternotomy may be partial or complete.
- Care is necessary in order to identify and manage aberrant mediastinal vascular tributaries supplying the thyroid gland.
- The intrathoracic trajectory of the RLNs can be identified and preserved under direct vision.
- Lateral thoracotomy typically provides suboptimal visualization of critical structures but may be preferred in specific cases.
- Video-assisted thoracic surgery may also be considered.

TECHNIQUES

INCISION AND EXPOSURE

- Exposure is critical, as satisfactory access facilitates appropriate visualization. Thus, a generous transverse neck incision is planned within an existing neck crease, approximating the level of the cricoid cartilage.
- The strap muscles are identified and divided along the midline raphe. In order to obtain sufficient access, the strap muscles are transected at least on the side of intrathoracic extension (FIG 2).

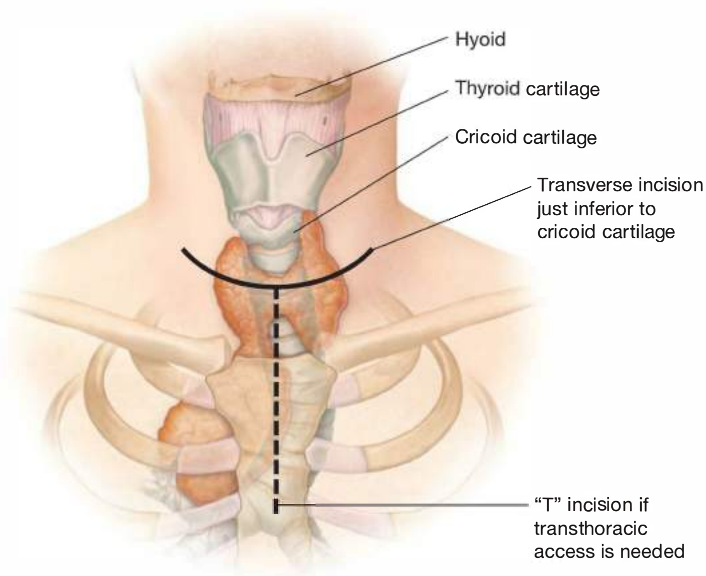

FIG 2 ● Incision and exposure. The patient is positioned supine with gentle neck extension. A generous transverse neck incision is planned within an existing neck crease, approximating the level of the cricoid cartilage. The chest should be prepped within the field. When sternotomy is indicated, a "T" incision is preferred.

MOBILIZATION OF THYROID GLAND

- As the thyroid is gently and bluntly freed from surrounding areolar tissue, meticulous attention is necessary to ensure extracapsular dissection in order to maintain a bloodless field.
- The middle thyroid vein is isolated and divided.
- The superior parathyroid gland is identified and preserved, given that the inferior glands are at higher risk for injury during dissection of the substernal extent of the thyroid gland.
- When necessary, devascularized or excised parathyroid glands may be autotransplanted into the sternocleidomastoid muscle. Perform frozen section confirmation of histology prior to reimplantation.
- The superior thyroid pedicle is isolated and divided close to the superior pole, taking care not to injure the superior laryngeal nerve or superior parathyroid gland.

IDENTIFICATION OF RECURRENT LARYNGEAL NERVE

- The RLN is identified. The size and bulk of the thyroid gland may make this dissection difficult, and the nerve may be displaced from its standard anatomic position. In general, its entry into the larynx at the cricothyroid joint is the most consistent and reliable location for identification.
- The RLN is traced and exposed inferiorly. In cases in which the substernal goiter is posteriorly positioned, the nerve is likely to be displaced anteriorly, putting it at higher risk for injury.
- In some cases, the thyroid gland will need to be displaced in order to facilitate nerve dissection, which involves retrograde dissection of the RLN from the cricothyroid joint inferiorly while displacing the thyroid gland anteromedially ("toboggan approach") (**FIG 3**).
- The RLN may branch prior to its entry into the larynx, and such anatomic variations should be expected. Anterior divisions of the nerve are more likely to be motor branches.

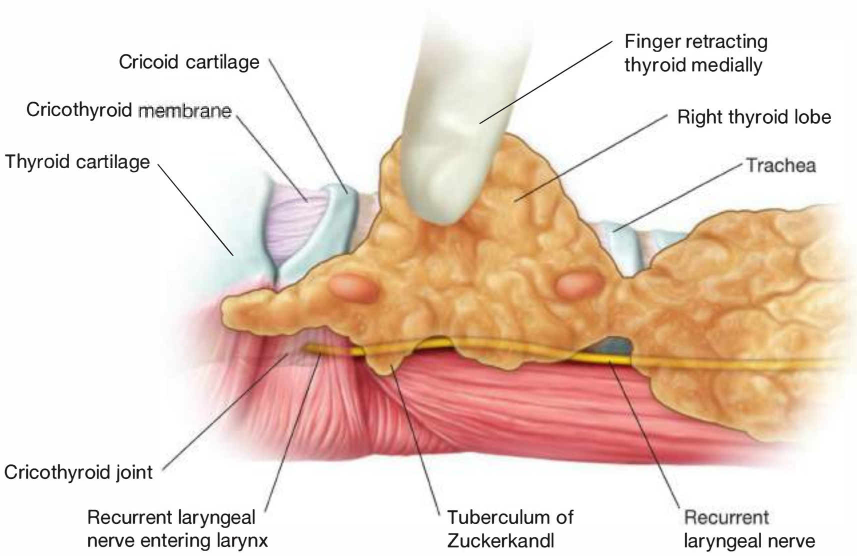

FIG 3 ● Identification of RLN. The RLN's entry into the larynx at the cricothyroid joint is the most consistent and reliable location for identification. The RLN is traced and exposed inferiorly. In some cases, the thyroid gland will need to be displaced in order to facilitate nerve dissection, which involves retrograde dissection of the RLN from the cricothyroid joint inferiorly while displacing the thyroid gland anteromedially ("toboggan approach").

LIGATION OF THE INFERIOR PEDICLE AND MOBILIZATION

- The inferior thyroid vessels are isolated and divided meticulously. Damage to these vessels during mobilization can cause intrathoracic hemorrhage not amenable to transcervical hemostasis.
- Gentle, blunt substernal dissection should commence laterally, under the sternocleidomastoid muscle, and progress medially. It may be useful to divide the sternal head of this muscle to improve access. Small venous tributaries are frequently encountered and divided.
- Hemoclips, LigaSure™, or other hemostatic adjunctive devices may be employed at the surgeon's discretion (**FIGS 4** and **5**).

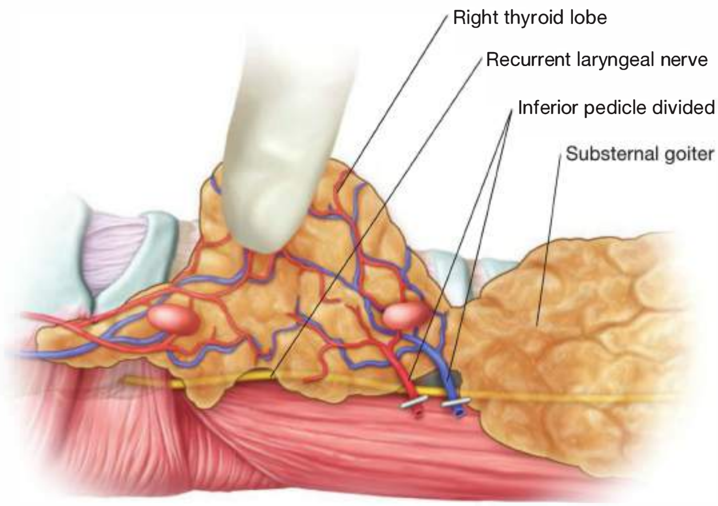

FIG 4 ● Ligation of the inferior pedicle. The inferior thyroid vessels are isolated and divided meticulously. Damage to these vessels during mobilization can cause intrathoracic hemorrhage not amenable to transcervical hemostasis. It may be difficult to visualize and preserve the ipsilateral inferior parathyroid gland.

FIG 5 ● Mobilization of substernal goiter. Gentle, blunt substernal finger dissection should commence laterally, under the sternocleidomastoid muscle, and progress medially.

CONTRALATERAL DISSECTION

- The procedure is repeated on the other thyroid lobe.
- Typically, the lobe with substernal extension is removed first in order to ensure that the RLN is preserved prior to contralateral dissection. If the nerve monitor is being used, it is appropriate to test the dissected nerve's integrity prior to contralateral surgery.
- Care should be taken when freeing the gland off of the cricothyroid joint and Berry's ligament, as small vessels can cause bleeding that obscures visualization of the RLN.

TECHNIQUES

CLOSURE

- Closed suction drain placement is frequently indicated due to the large potential space created by expansive substernal goiters.
- Wound closure is performed in the standard manner, taking care to reapproximate divided muscles (sternocleidomastoid and straps). The midline raphe between the strap muscles should be loosely approximated to facilitate egress of blood and transudate and to mitigate airway compression in the case of an expansile hematoma.
- The method of skin closure is at the discretion of the surgeon (**FIG 6**).
- Smooth extubation and anesthetic emergence is important in order to limit sudden increases in intrathoracic pressure. If airway concerns are present, delayed extubation can be considered.

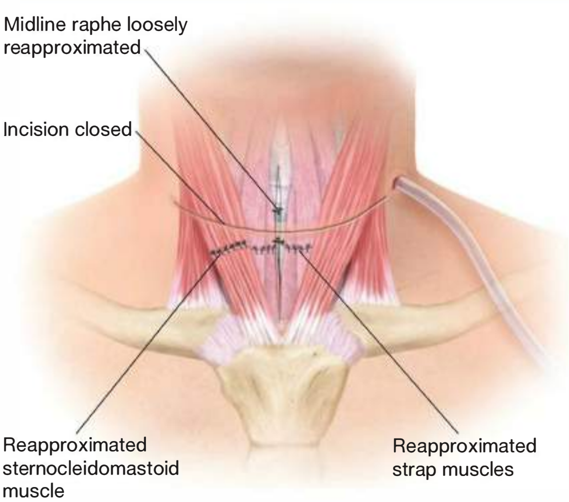

FIG 6 ● Closure. Take care to reapproximate divided muscles (sternocleidomastoid and straps). The midline raphe between the strap muscles should be loosely approximated to facilitate egress of blood and transudate. Closed suction drain placement is frequently indicated.

PEARLS AND PITFALLS

Indications	■ Given that most goiter operations are elective, prudent and deliberate preoperative planning and counseling are essential.
Approach	■ Sternotomy is rarely necessary for removal of a substernal thyroid gland.
Positioning	■ The patient should be placed supine with gentle neck extension and draped in a manner that facilitates movement of the head and neck.
Airway	■ Although most patients can be readily intubated, airway compression or deviation must be considered. Because the endotracheal tube has a tendency to become displaced during surgical manipulation, confirm that the cuff is well below the vocal folds.
Exposure	■ Satisfactory access is critical for safety and visualization. Use a generous transverse neck incision and consider dividing strap muscles at least on the side of intrathoracic extension.
Plane of dissection	■ As the thyroid is mobilized, meticulous attention is necessary to ensure extracapsular dissection in order to maintain a bloodless field.
Management of parathyroid glands	■ The inferior glands are at higher risk for injury or devascularization during dissection of the substernal extent of the thyroid gland. Thus, make sure to identify and preserve the superior parathyroid glands.

POSTOPERATIVE CARE

- Check postoperative serum calcium levels. The use of intraoperative and/or postoperative parathyroid hormone levels is optional. Decisions regarding calcium supplementation and further laboratory studies should be based on individual circumstances, laboratory findings, and clinician preferences.
- Patients should be informed to call 911 if they develop any sudden difficulty breathing or neck swelling.
- Patients should be encouraged to ambulate early and perform pulmonary toilet, although they should restrict from strenuous physical activity and heavy lifting for a few weeks.

COMPLICATIONS

- Surgical site infection—In general, strict adherence to aseptic technique and maintenance of the sterile field assures that surgical site infections are uncommon in patients without underlying risk factors. Perioperative antibiotics should be administered in accordance with established guidelines.[6]
- Seroma—Some degree of seroma formation within the operative bed is inevitable. Intervention rarely becomes necessary.
- Intraoperative hemorrhage—Meticulous technique including limiting shearing/tearing vessels and maintaining an

intact thyroid capsule are critical. Rarely, uncontrolled intrathoracic hemorrhage will require emergent sternotomy and/or aggressive resuscitation.

- Hematoma—Approximately 1% to 3% of cases will develop a postoperative hematoma that requires intervention. All cases of expansile hematomas require consideration of airway compression and prompt attention.
- Nerve injury—The RLNs are susceptible to injury both within the neck and chest. Rates of injury are slightly higher in cases of substernal goiter than in standard thyroidectomies.
- Hypoparathyroidism—Inferior parathyroid glands are more difficult to identify and preserve with substernal goiters, making identification and meticulous preservation of superior glands critical.
- Hemothorax/pneumothorax—Intrathoracic complications are quite rare. Routine postoperative chest x-ray should be considered.
- Tracheomalacia—Despite frequent tracheal deviation and/or compression, clinically significant tracheomalacia is rare. The adult airway is quite resilient, and even long-standing compression will not often be problematic.

Chapter 38

Subtotal Thyroidectomy for Graves' Disease

Edwin L. Kaplan Raymon H. Grogan

DEFINITION

- Subtotal thyroidectomy means the removal of most of both lobes of the thyroid, but some thyroid tissue is intentionally left on one or both sides of the neck.
  - Total thyroidectomy alone or with appropriate neck dissections is the procedure of choice for most thyroid cancers and is discussed in Part 5, Chapter 36.
  - Thyroid lobectomy is used for some unilateral benign colloid nodules or goiters and for many indeterminate thyroid lesions; that is, when the fine needle aspirate demonstrates a possible follicular neoplasm or a follicular lesion of undetermined significance (FLUS) that requires operation (see Part 5, Chapter 35).
  - Subtotal thyroidectomy is frequently used in the treatment of *benign* thyroid diseases such as nontoxic or toxic multinodular goiters, especially when the disease is bilateral and commonly in the treatment of Graves' disease, although near-total or total thyroidectomy may be more appropriate in some patients.
  - The purpose of subtotal thyroidectomy is to reduce the incidence of postoperative complications of total thyroidectomy—permanent hypoparathyroidism and recurrent laryngeal nerve injury—and to leave functional thyroid tissue in the neck of some patients. Although the rate of complications of total thyroidectomy is low in the hands of expert thyroid surgeons, most surgeons would agree and most studies have demonstrated a lower incidence of complications when subtotal thyroidectomy is performed.
  - This section will briefly discuss the diagnosis and preoperative assessment of patients with benign thyroid conditions and will illustrate the preoperative management and surgical technique when performing *a subtotal thyroidectomy for Graves' disease.*

PATIENT HISTORY AND PHYSICAL FINDINGS

- In order to differentiate these benign thyroid conditions, a careful history and physical examination are first necessary.
- History: Of greatest importance is a previous history of low-dose (or high-dose) radiation to the neck, which is associated with an increased risk of thyroid cancer. Also important are the metabolic status of the patient and whether or not there are symptoms of respiratory impairment, pressure on the trachea, or difficulty swallowing from an enlarged thyroid or from thyroid nodules.
  - Major symptoms of hypothyroidism
    - Severe fatigue, weight gain, dry skin, irregular menstrual periods, constipation, depression, hair loss, brittle nails, feeling cold, slowness of speech, and puffiness. In its most severe form, hypothyroid coma may rarely occur.
  - Major symptoms of hyperthyroidism (thyrotoxicosis)
    - Weight loss despite a normal or an increased appetite, rapid or irregular heartbeat, nervousness, anxiety, irritability, tremor, sweating, changes in menstrual pattern, increased sensitivity to heat, more frequent bowel movements, fatigue, muscle weakness, difficulty sleeping, and fine brittle hair. In its most severe form, thyroid storm might occur.
  - Respiratory and compressive changes and difficulty swallowing
    - Nodules of the thyroid or an enlarged thyroid (goiter) may cause pain and tenderness in the neck as well as trouble breathing. As the thyroid enlarges, the trachea can be compressed and narrowed and eventually respiratory impairment may occur resulting in coughing, shortness of breath, and stridorous breathing. Rarely, an enlarged goiter can result in recurrent laryngeal nerve impairment with hoarseness. Pressure from a goiter or from thyroid nodules can also result in trouble swallowing.
  - Physical findings
    - The physician should assess the size of the thyroid gland and the size, consistency, number, and position of any thyroid nodules; whether or not the trachea is deviated; and if any enlarged and abnormal lymph nodes are present in the central or lateral neck. Finally, the physician should assess whether there are any signs of thyrotoxicosis in general or evidence of manifestations of Graves' disease such as exophthalmos, pretibial myxedema, and a diffuse goiter with a bruit.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Thyroid function tests
  - Almost all patients with hypothyroidism have an elevated thyrotropin (TSH) level with low free thyroxine (FT4) and triiodothyroxine (T3) values.
  - Almost all thyrotoxic patients have a suppressed TSH with elevated FT4 and T3 values.
- Tests for autoimmunity
  - In Hashimoto's disease and Graves' disease, antibodies to thyroid peroxidase (anti-TPO antibodies) are found in up to 90% of patients, whereas antithyroglobulin (anti-TG) antibodies are found in approximately 50%. Elevated anti-TSH receptor antibodies (TSab) are also commonly detected in patients with Graves' disease and these thyroid-stimulating immunoglobulins (TSI) are the cause of the thyrotoxicosis of Graves' disease.
- Imaging and nuclear uptake scanning
  - The thyroid uptake of radioiodine or technetium isotopes is usually increased in toxic multinodular goiter, toxic adenoma, and Graves' disease.
  - Nuclear scans may help to differentiate each of these diseases.
    - With toxic multinodular goiter, an enlarged thyroid gland is noted with one or more "hot" areas usually among other "cold" areas.
    - Toxic adenoma. A single hot area is clearly seen which corresponds to the thyroid nodule. The remaining thyroid

tissue is suppressed and barely visualized on the scan.
    - Graves' disease. Both lobes of the thyroid demonstrate increased uptake of isotope on the scan.
- Other imaging studies
    - Ultrasound examinations are commonly used to evaluate the thyroid for nodules and to identify abnormal lymph nodes and have replaced a nuclear scan unless a hot nodule is suspected.
    - Computerized tomography (CT) scan and magnetic resonance imaging (MRI) exams are helpful to evaluate the presence or absence of tracheal compression; abnormal lymph nodes; or the presence, size, and anatomic location of a substernal goiter. These are often reserved for goiters that extend below the clavicle or if significant tracheal narrowing is of concern.
    - The most important test to evaluate a thyroid nodule is a fine needle aspiration (FNA) with cytologic examination. This exam should be used liberally. Usually, it is performed under ultrasound guidance in order to be certain that the nodule in question has correctly been sampled.

DIFFERENTIAL DIAGNOSIS

- A short list of common benign thyroid conditions:
    - Thyroid abnormalities associated with normal thyroid function or hypothyroidism
        - Single colloid nodule or cyst
        - Single microfollicular or macrofollicular adenoma
        - Multinodular goiter
        - Hashimoto's thyroiditis
    - Thyroid abnormalities associated with thyrotoxicosis
        - Toxic adenoma
        - Toxic multinodular goiter
        - Graves' disease
            - Graves' disease is an autoimmune disease characterized by a goiter, thyrotoxicosis, and exophthalmic eye disease. Less commonly, pretibial myxedema is also present. It is closely related to Hashimoto's thyroiditis, which usually presents with hypothyroidism.
            - It was described first in the English language by Caleb Perry (1755–1822) but commonly bears the name of the Irish physician, Robert Graves. On the European continent, it is called Basedow's disease.
            - As an autoimmune thyroid disease, it exhibits both antibodies and cell-mediated immunity directed to thyroid peroxidase (TPO) and thyroglobulin (TG) as well as stimulating antibodies against the TSH receptor (called TSab, but formerly called long-acting thyroid stimulator [LATS]). Antibodies against eye muscle and fibroblasts are also found in the serum of same patients with severe Graves' ophthalmopathy.
            - Incidence of Graves' disease
                - Found in women 5 to 8 times more commonly than in men
                - Thirty cases per 108,000 population annually in Ohmstead County, Minnesota
                - Increases in incidence during each decade from adolescence to 60 years of age
                - Six percent of all Americans have autoimmune thyroid disease.

SURGICAL MANAGEMENT

- A thyroidectomy is usually indicated for the following reasons:
    - To treat thyroid malignancies and some benign thyroid nodules
    - To establish a definitive diagnosis when diagnosis by FNA is equivocal, nondiagnostic, or indeterminate
    - To alleviate pressure symptoms or respiratory difficulties associated with a malignant or a benign process
    - To remove a substernal goiter
    - To remove an unsightly goiter
    - As definitive therapy for individuals with thyrotoxicosis—selected patients with hot nodules, toxic multinodular goiter, and Graves' disease
- Preparation for surgery
    - Most patients undergoing a thyroid operation are euthyroid and require no specific preoperative preparation related to their thyroid gland. Determination of serum calcium and parathyroid hormone (PTH) levels may be helpful. Endoscopic or indirect laryngoscopy might be helpful for all patients preoperatively but definitely should be done in those who are hoarse or who have had a change in voice and in others who have had a prior thyroid, parathyroid, carotid, lateral neck, anterior cervical disc, or chest operation in order to detect the possibility of a recurrent laryngeal nerve injury.
- Hypothyroidism
    - Modest hypothyroidism is of little concern when treating a surgical patient; however, severe hypothyroidism can be a significant risk factor. Severe hypothyroidism can be diagnosed clinically by myxedema as well as by slowness of affect, speech, and reflexes. Circulating thyroxine and triiodothyronine values are low. The serum TSH level is high in all cases of hypothyroidism that are not caused by pituitary insufficiency. In the presence of *severe* hypothyroidism, both the morbidity and the mortality of surgery are increased as a result of the effects of both the anesthesia and the operation. Such patients have a higher incidence of perioperative hypotension, cardiovascular problems, gastrointestinal hypomotility, prolonged anesthetic recovery, and neuropsychiatric disturbances. They metabolize drugs slowly and are very sensitive to all medications. Therefore, when severe myxedema is present, it is preferable to defer elective surgery until a euthyroid state is achieved.
- Hyperthyroidism
    - Toxic multinodular goiter and a toxic adenoma are usually treated to a euthyroid state with an antithyroid medication such as methimazole (Tapazole) or propylthiouracil (PTU), and the possible use of a beta-adrenergic blocker such as propranolol. Radioiodine therapy may sometimes be used as definitive therapy.
    - Operative therapy for a toxic multinodular goiter is usually a subtotal or total thyroidectomy. For a toxic adenoma, enucleation of the nodule or a thyroid lobectomy is curative because a hot nodule is almost always benign. This can be confirmed preoperatively by FNA evaluation. Furthermore, because most of the thyroid tissue remains after enucleation, the majority of patients become euthyroid postoperatively without the need for thyroid hormone replacement.
- Treatment of patients with Graves' disease
    - In the United States, most patients with thyrotoxicosis have Graves' disease. Furthermore, in the United States,

over 90% of all patients with Graves' disease are treated with radioiodine therapy.
- Operative indications for Graves' disease may include very young patients, others with very large goiters, some pregnant women, and those with suspicious thyroid nodules or severe ophthalmopathy.
- For greatest safety, patients with Graves' disease should be treated preoperatively with PTU or methimazole and iodine drops to restore a euthyroid state and to prevent *thyroid storm*. Thyroid storm is the name for the most severe manifestations of thyrotoxicosis including a very rapid heart rate or cardiac arrhythmias, fever, disorientation, hypotension, coma, and even death. In the past, mortality of thyroid storm was very high, but now, with the use of beta-blockers, antithyroid medications, iodine, oxygen, glucose, possibly adrenocortical steroids, and intensive care measures, the death rate has been greatly reduced. Both anesthesia and operation on a poorly prepared thyrotoxic patient are the leading precipitating factors for this event. Furthermore, operation on an unprepared Graves' gland can be more difficult because severe bleeding may occur because the thyroid is often soft and very vascular. With proper preoperative preparation, however, operation on the thyroid gland in Graves' disease can be performed safely.

- Preparation of Graves' patient for operation
  - In *mild* cases of thyrotoxicosis with Graves' disease, iodine therapy alone has been used for preoperative preparation, although we do not recommend this approach routinely. Lugol's solution or a saturated solution of potassium iodide (SSKI), two or three drops twice daily, is given for 8 to 10 days preoperatively. This medication is taken in milk or orange juice to make it more palatable. Iodine therapy suppresses thyroid hormone release only in Graves' disease and should not be given to patients with toxic nodular goiter or toxic adenoma.
  - Most patients with Graves' disease are treated initially with antithyroid drugs, PTU or more commonly, methimazole (Tapazole) until they approach a euthyroid state. Then iodine is added to the regimen for 8 to 10 days before surgery. The iodine decreases the vascularity and increases the firmness of the gland. Sometimes, thyroxine is added to this regimen to prevent hypothyroidism and to decrease the size of the gland. Beta-adrenergic blockers such as propranolol (Inderal) are used commonly with the antithyroid drugs to decrease the pulse rate and eliminate the tremor. Other preoperative protocols using propranolol alone or with Lugol's solution are sometimes necessary, especially when allergic reactions to antithyroid medications have occurred. However, we do not use these routinely because they appear to be less safe.

OPERATION

- Following general anesthesia, the patient is placed in a supine position with the neck extended. A low collar incision is made, usually in a skin crease, and carried down through the subcutaneous tissue and platysma muscle. Currently, small incisions are the rule unless a large goiter is present.
- Superior and inferior subplatysmal flaps are developed, and the strap muscles are divided vertically in the midline and retracted laterally. Often, a large pyramidal lobe is present (**FIG 1**, **left**).

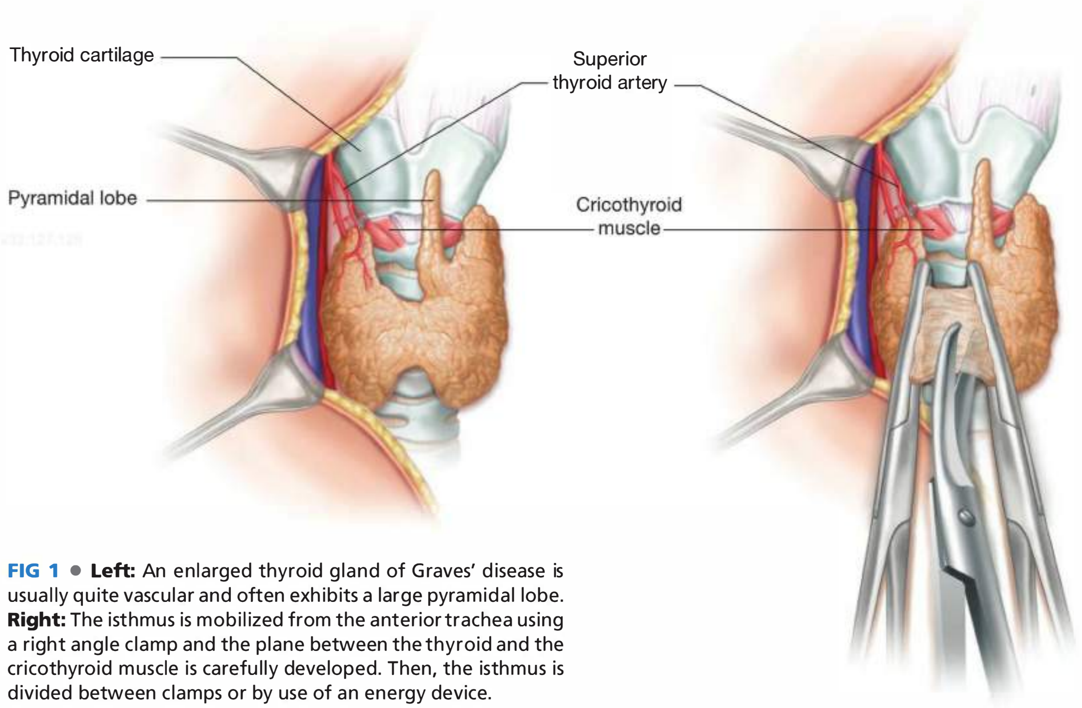

FIG 1 ● **Left:** An enlarged thyroid gland of Graves' disease is usually quite vascular and often exhibits a large pyramidal lobe. **Right:** The isthmus is mobilized from the anterior trachea using a right angle clamp and the plane between the thyroid and the cricothyroid muscle is carefully developed. Then, the isthmus is divided between clamps or by use of an energy device.

- The thyroid isthmus is clamped and divided early in the course of operation for most patients with Graves' disease (**FIG 1**, **right**). Alternatively, an energy device can be used to transect the isthmus.
- The isthmus on each side is then sharply dissected from the front of the trachea in order to improve mobilization of the gland. The isthmus on each side is oversewn for hemostasis (**FIG 2**). The medial side of the thyroid lobe to be operated on first is then carefully dissected in a superficial plane toward the upper pole, developing a plane between the thyroid lobe and the cricothyroid muscle. Care is taken to preserve and not damage the external branch of the superior laryngeal nerve and the cricothyroid muscle.
- The thyroid lobe to be operated on first is mobilized by dividing the areolar tissue and any small vessels along its lateral surface.
- The upper pole vessels are then individually ligated along the front surface of the upper pole and not more cephalad in the neck. The right angle is kept "pointing out laterally" to prevent damage to the external branch of the superior laryngeal nerve (**FIG 2**). This nerve can often be visualized if the area is carefully evaluated.
- The thyroid lobe is then retracted medially again and the middle thyroid vein is identified, ligated, and divided (**FIG 3**). This vein is usually in a plane superficial to the inferior thyroid artery and to the recurrent laryngeal nerve, but all structures should be carefully evaluated before ligation.
- The inferior thyroid artery, a branch of the thyrocervical trunk which runs medially and enters the field deep to the carotid artery, as well as the recurrent laryngeal nerve are now carefully identified (**FIG 4**). Whenever

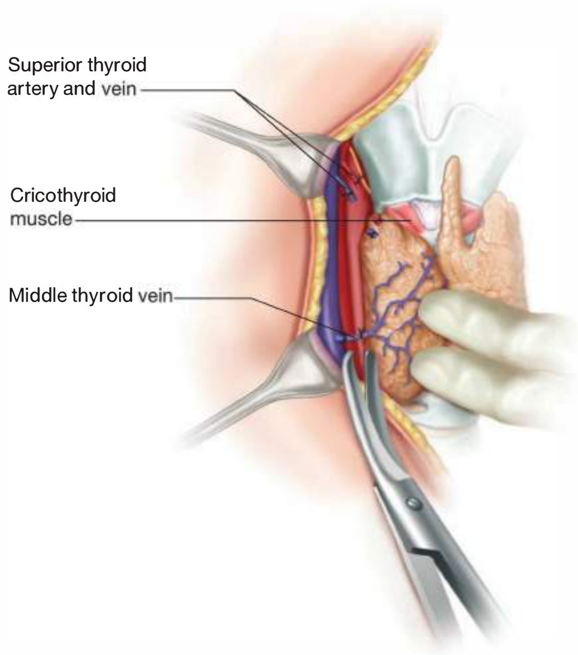

FIG 3 ● The thyroid lobe is retracted medially and care is taken to clearly identify the middle thyroid vein and to ligate and divide it. Be certain that the vein is separate from other structures before dividing it in order to avoid injury to the recurrent laryngeal nerve.

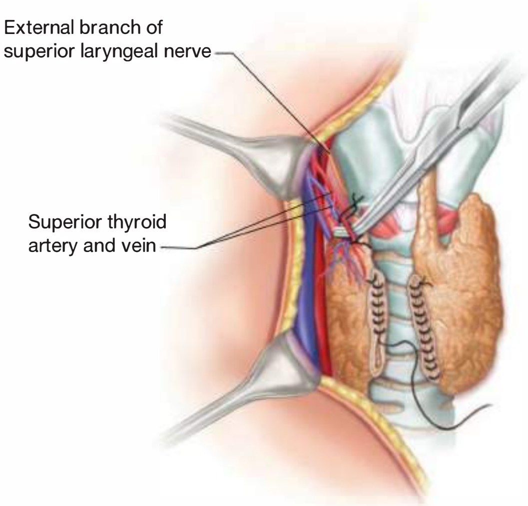

FIG 2 ● If the isthmus was clamped, it is oversewn by a running horizontal mattress suture behind the hemostat followed by a "baseball stitch" for hemostasis. The upper pole vessels are individually ligated on the anterior surface of the upper thyroid pole and divided. The points of the right angle should face away from the trachea and care is taken to identify the external branch of the superior laryngeal nerve when possible and not to injure it.

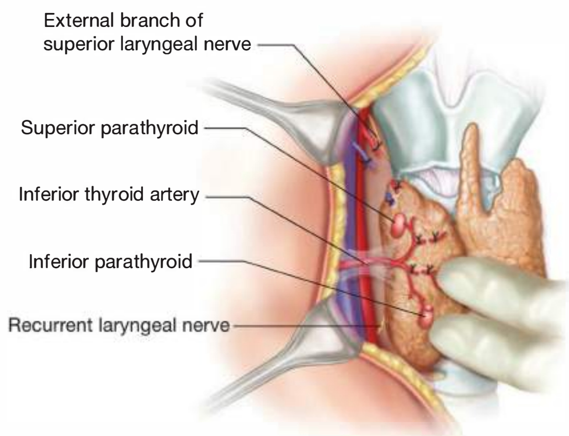

FIG 4 ● With further blunt dissection, the inferior thyroid artery, which runs transversely toward the thyroid lobe, is identified and the recurrent nerve is visualized. The inferior thyroid artery is not ligated as a single trunk but rather individual branches of it are ligated and divided on the surface of the lobe, and the lower parathyroid gland is moved off the thyroid lobe with its blood supply intact.

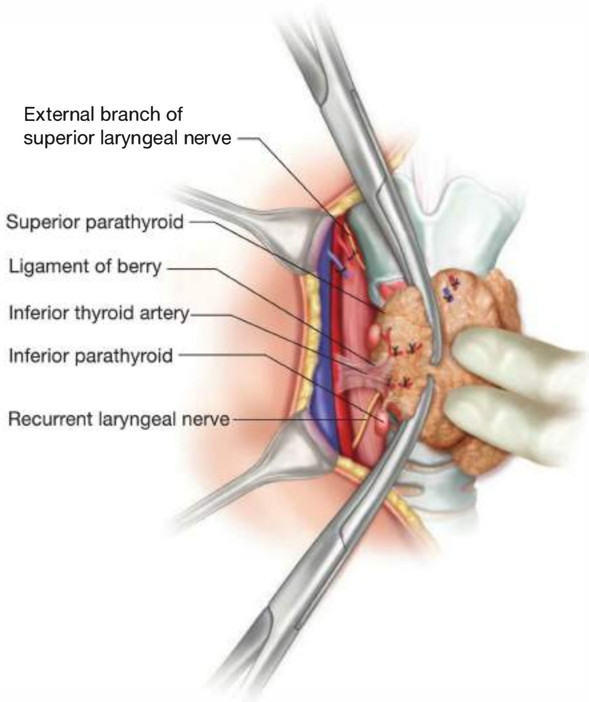

FIG 5 ● The recurrent laryngeal nerve should be visualized and followed up toward the ligament of Berry. The nerve should be treated gently and tissues "unroofed" from its anterior surface. Clamps are then applied (or an energy device used) only after the recurrent laryngeal nerve and parathyroids are seen to be safely preserved.

possible, the inferior thyroid artery is not ligated as a single trunk because this might devascularize the parathyroid glands. Rather, the small branches of the artery are individually ligated and divided along the surface of the thyroid lobe. The inferior parathyroid gland, which often is present high along the lower thyroid lobe, is mobilized with its blood supply and moved more posteriorly and laterally off the thyroid lobe.

- The carotid artery is now retracted laterally and the recurrent laryngeal nerve is more carefully identified, usually in the lower neck, and followed in an inferior to superior direction by "unroofing" the tissues from the front of the nerve (**FIG 5**). Remember that on the right side, the recurrent laryngeal nerve takes an oblique course from lateral to medial and from deep to superficial. On the left side, the nerve usually runs straight upward and is usually found in the lower neck much more medially than on the right side within or near the tracheoesophageal groove.
- If a subtotal lobectomy is to be done, before any clamps are placed on the thyroid lobe, the surgeon must be certain that the recurrent nerve has been identified and followed in a cephalad direction to near the ligament of Berry and that the nerve and parathyroid glands are clearly posterior and away from the sites to be clamped. Then hemostats are applied to the tissue and most of the lobe is resected (**FIG 5**). The remaining small thyroid remnant is oversewn for hemostasis. This resection can also be accomplished by using an energy device if one is far enough from the nerve so the heat does not damage it. Do not perform a subtotal thyroid lobectomy without visualizing the recurrent laryngeal nerve, for this is unsafe.
- At the end of the procedure for Graves' disease (**FIG 6**), a small, well-vascularized remnant of thyroid tissue can be left on each side, a procedure called bilateral subtotal lobectomies. In other instances, to achieve the same

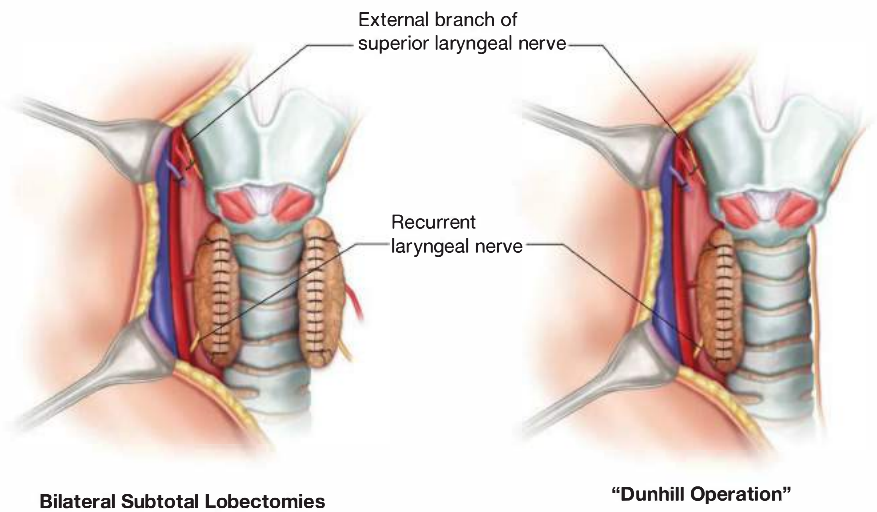

FIG 6 ● At the end of an operation for Graves' disease, each recurrent laryngeal nerve has been identified and preserved, and the parathyroid glands have been spared. Either small thyroid remnants are left bilaterally **(left)** or a total lobectomy and contralateral subtotal lobectomy **(right)** are performed, often called a "Dunhill operation."

result, a lobectomy can be performed on one side with a subtotal lobectomy on the other side, often called a Dunhill operation from the Australian surgeon who popularized this technique. Whichever operation is performed, it is important to leave small thyroid remnants especially in young patients in order to prevent a recurrence of disease. When severe ophthalmopathy is present, a total thyroidectomy may be most appropriate and many surgeons recommend total thyroidectomy instead of subtotal thyroidectomy more commonly for patients with graves' disease. However, always remember that Graves' disease is a benign disorder and our aim is to do an operation that does not cause a nerve injury or hypoparathyroidism.

- Many surgeons find a recurrent laryngeal nerve monitor to be helpful; although in current practice, its use is not mandatory.
- Finally, as stated, instead of suturing the thyroid, an energy device may be used. However, be careful when using these instruments, especially near the recurrent laryngeal nerve for the heat generated may damage it.

PEARLS AND PITFALLS

Preoperative considerations	■ When operating on the thyroid, some surgeons raise the head of the bed. Although this may seem attractive because it decreases venous bleeding, it is more dangerous because it increases the chance of an air embolism if a major vein is opened during the dissection. ■ The operation for Graves' disease is often more difficult than for colloid nodular disease because of an increase in vascularity and "stickiness" in some cases. Treatment with iodine preoperatively has been shown to decrease the blood flow to the thyroid. ■ Although it may be best to check the vocal cords preoperatively in all patients, the surgeon must be sure that both vocal cords are moving well in any patient who has had a previous neck or chest operation or in others who are hoarse.
Recurrent laryngeal nerve	■ Always visually identify the recurrent laryngeal nerve, carefully "unroof" it, and gently follow its course. Although temporary nerve injuries may occur when this practice is followed, rarely will the injury be permanent. ■ Remember that nonrecurrent recurrent laryngeal nerves may occur especially on the right side of the neck. Each is associated with a vascular anomaly. ■ Use of a recurrent laryngeal nerve monitor may be helpful especially in a reoperative thyroidectomy. However, this technique has not been shown to reduce nerve injuries and sometimes can be misleading to the casual user. ■ If the nerve monitor demonstrates the loss of recurrent laryngeal nerve function on the first side of the neck, one should strongly consider halting the operation or limiting the contralateral resection in order to prevent the possibility of a bilateral nerve injury if one proceeds.
Parathyroid	■ Carefully search for and try to save each parathyroid gland with a good blood supply. ■ Do not ligate the inferior thyroid artery as a single trunk. Rather, ligate small branches on the surface of the thyroid lobe in order to preserve the delicate blood supply to the parathyroid glands. ■ Autotransplant each parathyroid gland that looks devascularized, if it does not bleed well on biopsy or if it is accidently removed.
Postoperative care	■ Observe patients carefully postoperatively. Delayed bleeding with a hematoma can occur. ■ A postoperative neck hematoma is an emergency which requires rapid return to the operating room or opening of the wound at the bedside if respiratory symptoms are present. ■ In the postoperative care of a patient with Graves' disease, one cannot reliably use the TSH value alone to assess thyroid function, for the TSH value may stay suppressed even for weeks postoperatively if the patient was still thyrotoxic at the time of operation. The FT4 is usually a better indicator of function in the early postoperative course.

POSTOPERATIVE CARE

- In the recovery room, the patient should be observed for difficulty breathing and for swelling of the neck, which might indicate postoperative bleeding or hematoma. Return the patient to the operating room as an emergency if an expanding hematoma is recognized. Some surgeons advise endoscopic evaluation of the vocal cords in each patient; however, this should definitely be done if respiratory impairment is present.
- A serum calcium and PTH value is helpful. Some obtain a PTH in the recovery room; however, the authors generally wait until the morning of the first operative day to routinely obtain these results. Patients with Graves' disease may be more prone to manifesting hypocalcemia than others, partly due to bone hunger.
- Severe symptomatic hypocalcemia may require intravenous calcium therapy followed by oral calcium and vitamin D therapy. However, most patients are treated with oral calcium, which is given liberally and do very well. Thyroid

Table 1: Ablative Treatment of Graves' Disease with Thyrotoxicosis

Method	Dose or Extent of Surgery	Onset of Response	Complications	Remarks
Surgery	Subtotal excision of gland	Immediate	Mortality <1% Permanent hypothyroidism 20%–30% or greater[a] Recurrent hyperthyroidism <15%[a] Vocal cord paralysis approximately 1% Hypoparathyroidism approximately 1%	Applicable in young patients, pregnant women, large goiter, or nodular gland
Radioiodine 5–10 mCi		Several weeks to months	Permanent hypothyroidism, at least 50%–70%, often with delayed onset; multiple treatments sometimes necessary in large goiters	Avoid in children or pregnant women

[a]*Depends on size of thyroid remnant which is left in neck. As more tissue is removed, the incidence of hypothyroidism is increased but recurrence rate is diminished.*

replacement is given to many patients soon after surgery unless they are still thyrotoxic with a tachycardia. Although TSH is usually the best indicator of thyroid function, the FT4 is often a better indication in Graves' patients postoperatively because their TSH value may be suppressed for a considerable period of time.

OUTCOMES

- Although radioiodine therapy is the usual treatment, thyroidectomy is a very successful treatment for the thyrotoxicosis of Graves' disease in selected patients (Table 1). A major benefit is the rapid return to a euthyroid state, which is much quicker than following radioiodine therapy. It can be used in very young patients and during pregnancy if necessary. In each of these instances, radioiodine therapy is contraindicated. It removes the goiter and any thyroid nodules which are present. Finally, in patients with severe ophthalmopathy, many studies have shown improvement of eye changes or stabilization in others following thyroidectomy, whereas following radioiodine, the eye changes in some patients become worse.
- Postoperative thyroid function is directly related to the size of the thyroid remnants which are left in the neck. The larger the size of the remnant thyroid, the greater the rate of recurrence of thyrotoxicosis. Most patients and endocrinologists want a cure for the thyrotoxicosis and thus small thyroid remnants are preferable. In young patients, the chance of recurrence is greater and very small remnants should be used. In patients with severe ophthalmopathy, total thyroidectomy should be performed and may be most beneficial. Finally, subtotal or near-total thyroidectomy results in a lower incidence of complications than total thyroidectomy in most surgeons' practice and thus remains the surgical procedure of choice, especially in young children.

COMPLICATIONS

- Thyroid storm
- Postoperative hemorrhage (with respiratory distress)
- Injury to the external branch of the superior laryngeal nerve
- Unilateral or bilateral recurrent laryngeal nerve injury
- Temporary or permanent hypoparathyroidism

Chapter 39

Minimally Invasive Video-Assisted Thyroidectomy

Paolo Miccoli Gabriele Materazzi

DEFINITION

- Minimally invasive video-assisted thyroidectomy (MIVAT) is an endoscopic procedure characterized by the use of external retraction, avoiding any gas inflation, in order to create an operative space in the neck.
- This approach to the thyroid has been used at our Department of Surgery for the last 15 years on more than 3,500 patients with results that can successfully rival those of standard open surgery.
- This is not an appropriate operation for any patient with thyroid disease; patients must be strictly selected. Only 10% to 30% of the cases[1] are appropriate for a MIVAT procedure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The inclusion criteria and the main contraindications are summarized in the following text. The most significant limit is represented by the size of both the nodule(s) and/or the gland as measured by means of an accurate ultrasonographic study obtained preoperatively. In countries where goiter is endemic, the gland volume can be relevantly independent from the nodule volume, and this aspect might be responsible for the necessity of converting the procedure.
- Ultrasonography can also be useful to exclude the presence of thyroiditis, which might make the dissection troublesome. In case ultrasonography only gives the suspicion of thyroiditis, autoantibodies should be measured in the serum. If thyroiditis is diagnosed preoperatively, this is a consideration to MIVAT.
- One of the most controversial aspects regarding the appropriateness of MIVAT is in the treatment of malignant thyroid disease. "Low-risk" papillary carcinoma constitutes an ideal indication for MIVAT,[2,3] but it is important to take into account the possibility of lymph node involvement in the neck. Great caution should be taken when there is the possibility of either metastatic lymph nodes or extracapsular invasion of the gland, both of which represent a contraindication to the minimally invasive endoscopic procedure.
- Indications
  - Multinodular goiter (thyroid volume less than 25 mL and nodules smaller than 3 cm)
  - Low-risk papillary carcinoma
  - Graves' disease
  - Microfollicular/Hürthle cell adenoma
  - *RET* gene mutation carriers (familial medullary thyroid carcinoma)
- Contraindications
  - Absolute
    - Previous neck surgery
    - Acute thyroiditis
    - Metastatic carcinoma (levels II to VI)
    - Locally advanced carcinoma
    - Sporadic medullary carcinoma
  - Relative
    - Previous neck irradiation
    - Short neck in an obese patient
    - Chronic thyroiditis

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients should undergo (1) neck ultrasound in order to evaluate thyroid gland total volume (this should be less than 25 mL) and diameter of nodule/s (these should be less than 3 cm); (2) fine needle aspiration cytology of suspicious nodules; (3) blood tests in order to exclude thyrotoxicosis and acute thyroiditis before surgery; (4) basal serum calcitonin dosage is strongly suggested in order to exclude medullary carcinoma, which is a contraindication to MIVAT; (5) routine preoperative laryngoscopy is strongly recommended in all patients in order to identify asymptomatic vocal cord palsy.

TECHNIQUES

POSITIONING OF THE PATIENT AND DRAPING

- Patient is positioned in supine position without neck extension (FIG 1). Hyperextension must be avoided because it would reduce the operative space. Conventional neck preparation and draping is obtained. The skin is protected by means of a sterile film (Tegaderm®).

FIG 1 • Position of the patient on the operative table: Neck is not extended and skin is covered by sterile drapes.

POSITIONING OF THE SURGICAL TEAM

- Operation is performed by four surgeons: The first surgeon is on the right side of the table, the first assistant is on the left side of the table. The second assistant, who is holding the retractors, is at the head of the table. The third assistant, who is holding the endoscope, is on the left side of the table.The scrub nurse is behind the surgeon on the right side of the table (**FIG 2**).

FIG 2 ● Operating room setup: Team

- The surgeon is on the right side of the table.
- The first assistant is on the left side of the table (opposite the surgeon).
- The second assistant is at the head of the table.
- The third assistant is on the left side of the table.
- The scrub nurse is behind the surgeon on the right side of the table.

INSTRUMENTATION

- Forward-oblique telescope 30 degrees, diameter 5 mm, length 30 cm; suction dissector with cutoff hole, with stylet, blunt, length 21 cm; ear forceps, very thin, serrated, working length 12.5 cm; conventional tissue retractor army navy type; small tissue retractor, double-ended, length 12 cm; clip applier for vascular clips; straight scissors, length 12.5 cm, Harmonic Scalpel CS14; electrocautery (monopolar) (**FIG 3**).

FIG 3 ● Instrumentation for MIVAT.

INCISION AND PREPARATION OF THE OPERATIVE SPACE

- A 1.5-cm horizontal skin incision is performed 2 cm above the sternal notch in the central cervical area (**FIG 4**). Subcutaneous fat and platysma are carefully dissected so as to avoid any minimum bleeding.
- Two small retractors are used to expose the midline, which has to be incised for 2 to 3 cm in an absolutely bloodless plane (**FIG 5**).
- The blunt dissection of the thyroid lobe from the strap muscles is performed through the skin incision by gentle retraction and using tiny spatulas. When the thyroid lobe is almost completely dissected from the strap muscles,

FIG 4 ● A 1.5-cm horizontal skin incision is performed 2 cm above the sternal notch in the central cervical area.

larger and deeper retractors (army navy type) can be inserted and they will maintain the operative space during all the endoscopic part of the procedure (FIG 6).

- Then, a 30-degree, 5-mm or 7-mm endoscope is introduced through the skin incision: From this moment on, the procedure is entirely endoscopic until the extraction of the lobe of the gland. Preparation of the thyrotracheal groove is completed under endoscopic vision by using small (2 mm in diameter) instruments such as spatulas, forceps, spatula-sucker, and scissors.

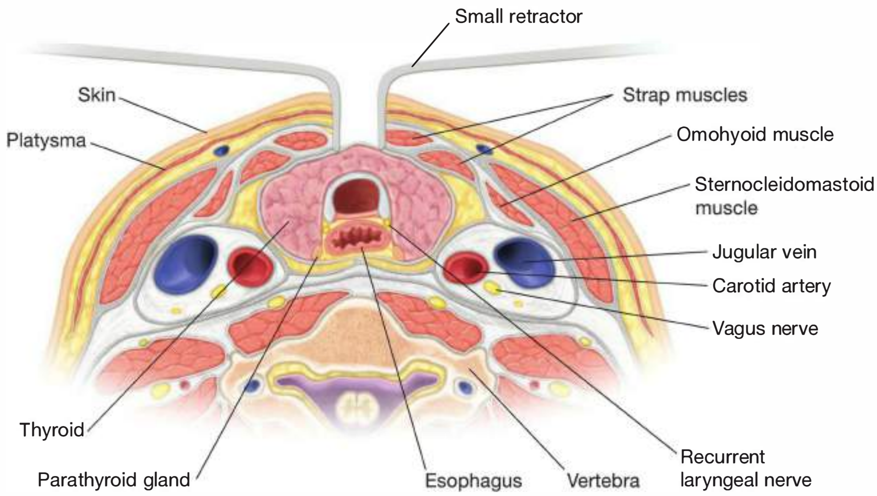

FIG 5 ● Two small retractors are used to expose the midline, which has to be incised for 2 to 3 cm on an absolutely bloodless plane.

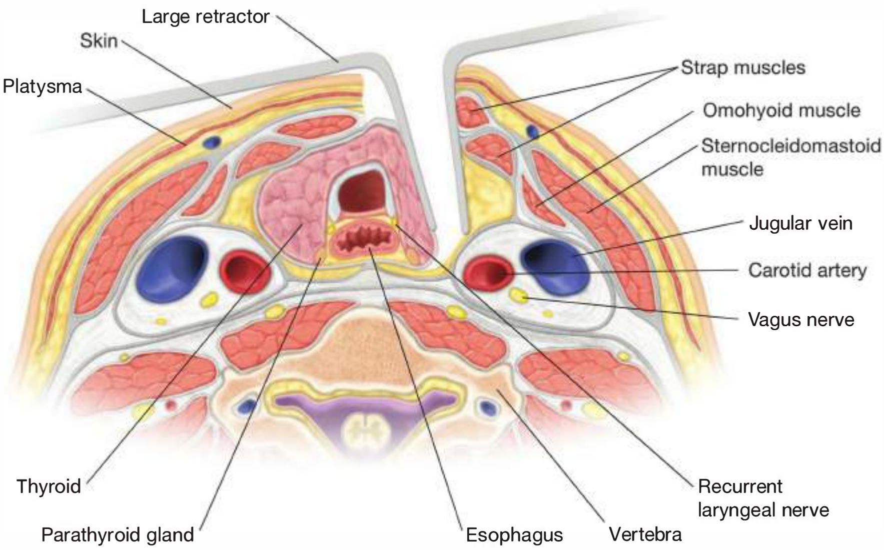

FIG 6 ● Access to the operative space during MIVAT: when the thyroid lobe is almost completely dissected from the strap muscles, larger and deeper retractors (army navy type) can be inserted and they will maintain the operative space during all the endoscopic part of the procedure.

SECTION OF THE MAIN THYROID VESSELS

- The first vessel to be ligated is the middle vein, when present, or the small veins between jugular vein and thyroid capsule. This step allows a better preparation of the thyrotracheal groove where the recurrent nerve will be later searched.
- During this step, the endoscope has to be held inside the camera with the 30-degree tip looking downward and in an orthogonal axis with the thyroid lobe and trachea.
- A further step is represented by the exposure of the upper pedicle, which must be carefully prepared, until an optimal visualization of the different branches is achieved. During this step, the endoscope should be rotated to 180 degrees with the 30-degree tip looking upward (**FIG 7**) and held in a parallel direction with the

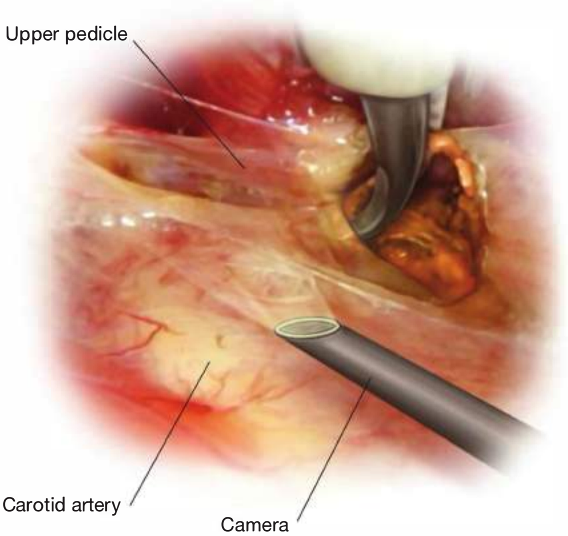

FIG 7 ● Upper pole section: During this step, the endoscope should be rotated to 180 degrees with the 30-degree tip looking upward and held in a parallel direction with the thyroid lobe and trachea in order to better visualize the upper portion of the operative space where the superior thyroid vein and artery are running.

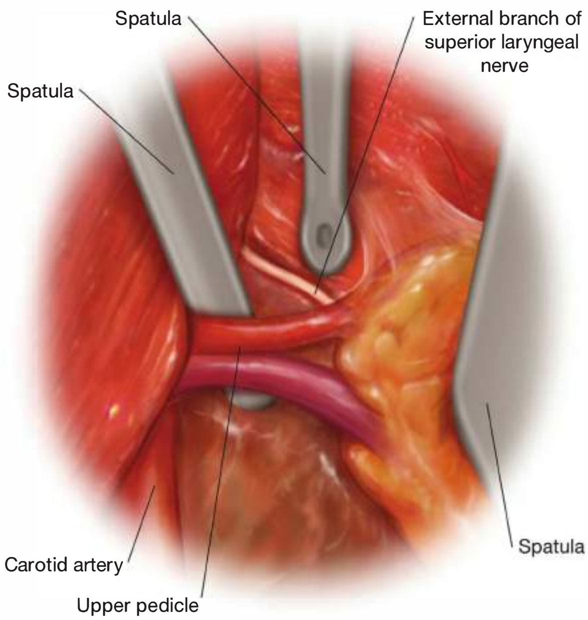

FIG 8 ● Identification of the external branch of the superior laryngeal nerve: The vessels (right side) are prepared by retracting downward and medially the thyroid lobe by means of the retractor and the spatula. A further spatula can be used to pull the vessels laterally. This will allow the external branch of the superior laryngeal nerve (SLN) to be easily identified during most procedures.

thyroid lobe and trachea in order to better visualize the upper portion of the operative space where the superior thyroid vein and artery are running.

- The upper pedicle is then prepared by retracting downward and medially the thyroid lobe by means of the retractor and the spatula. A further spatula can be used to pull the vessels laterally. This will allow the external branch of the superior laryngeal nerve to be easily identified during most procedures (**FIG 8**). Its injury can be avoided by keeping the inactive blade of Harmonic® in the posterior position so as to not transmit the heat to this delicate structure. At this point in time, section of the upper pedicle can be obtained by harmonic scalpel en bloc or selectively, depending on the diameter of the single vessels and/or the anatomic situation (**FIG 9**).

FIG 9 ● Section of the upper pedicle (left side) by harmonic scalpel. The inactive blade must be on the larynx in order to avoid any injury on laryngeal muscles and superior laryngeal nerve.

INFERIOR LARYNGEAL NERVE AND PARATHYROID GLANDS IDENTIFICATION AND DISSECTION

- After retracting medially and lifting up the thyroid lobe, the fascia can be opened by a gentle spatula retraction. During this step, the endoscope should be repositioned in an orthogonal axis with the thyroid lobe and trachea, looking downward with its 30-degree angle (**FIG 10**). The recurrent laryngeal nerve appears generally at this point in time, lying in the thyrotracheal groove, posterior to the Zuckerkandl tuberculum (posterior lobe), which is an important landmark in this step. This way, the recurrent nerve and the parathyroid glands are dissected and freed from the thyroid (**FIG 11A,B**).
- Dissection of the entire nerve from the mediastinum to its entrance into the larynx is not mandatory and might result in a time waste during the endoscopic phase. It is correct and very safe to identify the laryngeal nerve, to free it from the thyroid capsule as much as possible, but it is important to stress that the complete dissection of the nerve can be more easily obtained during the subsequent step, under direct vision, when the thyroid lobe has already been extracted.
- Both parathyroid glands are generally easily visualized during the endoscopic step; thanks to the camera magnification. Their vascular supply is preserved by selective division of the branches of the inferior thyroid artery. During dissection, when dealing with large vessels or small vessels close to the nerve, hemostasis can be achieved by 3-mm titanium vascular clips.

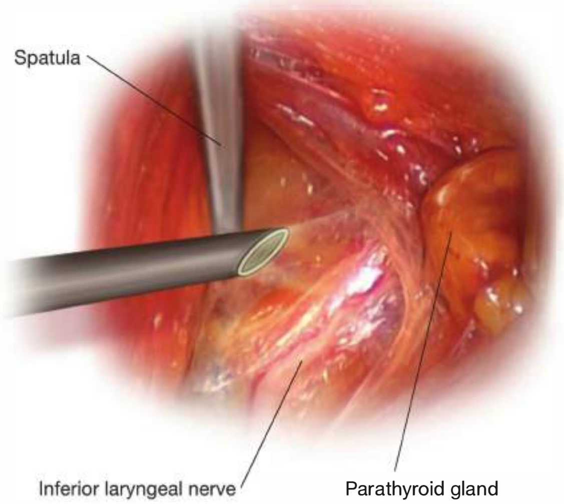

FIG 10 ● Inferior laryngeal nerve and parathyroids dissection: During this step, the endoscope should be repositioned in an orthogonal axis with the thyroid lobe and trachea, looking downward with its 30-degree angle.

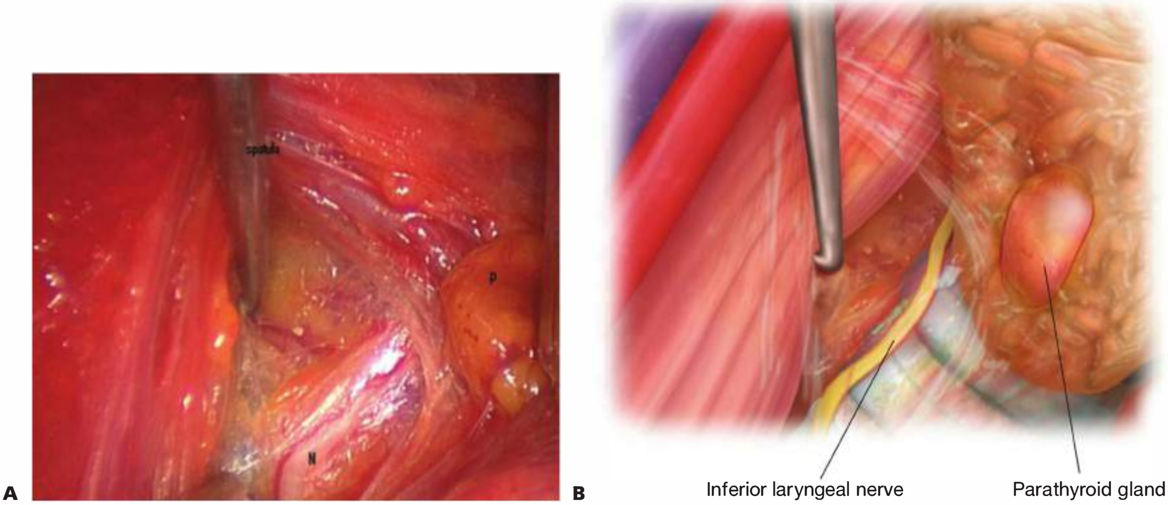

FIG 11 ● **A.** Endoscopic vision: dissection of the inferior laryngeal nerve. The recurrent laryngeal nerve *(n)* appears lying in the thyrotracheal groove. Parathyroid gland is also well visible *(p)*. **B.** Illustration of this step.

EXTRACTION OF THE LOBE AND RESECTION

- At this point in time, the lobe is completely freed. The endoscope and the retractors can be removed and the upper portion of the gland rotated and pulled out using conventional forceps. A gentle traction over the lobe allows the complete exteriorization of the gland (FIG 12). The operation is now conducted as an open surgery under direct vision. The lobe is freed from the trachea by ligating the small vessels and dissecting the Berry ligament. It is very important to check once again the laryngeal nerve at this point in time, so to avoid its injury before the final step. The isthmus is then dissected from the trachea and divided. After completely exposing the trachea, the lobe is finally removed.

FIG 12 ● Thyroid lobe extraction. A gentle traction over the lobe allows the complete exteriorization of the gland.

CLOSURE

- Drainage is not necessary. The midline is then approached by a single stitch; platysma is closed by a subcuticular suture and a cyanoacrylate sealant is used for the skin (FIGS 13 and 14).

FIG 13 ● Skin is reapproximated and closed by means of glue.

FIG 14 ● MIVAT: final result.

PEARLS AND PITFALLS

Indications	■ Perform preoperative ultrasound in order to evaluate thyroid volume (less than 25 mL) and nodule diameter (less than 3 cm). ■ Exclude thyrotoxicosis and acute thyroiditis ■ Exclude locally advanced or metastatic carcinoma
Incision	■ Create a central cervical incision two fingers above the sternal notch in order to easily allow for eventual conversion to cervicotomy. ■ Use a thin film of sterile drape on the electrocautery blade, leaving just the tip able to coagulate, in order to avoid damage to the skin or the superficial planes. ■ Avoid any bleeding from the anterior jugular veins.
Section of upper pedicle	■ The correct position of the retractors (both the first one on the strap muscles and the second one on the upper part of the thyroid lobe) is very important during this step, in order to obtain the best visualization of the vessels. ■ The endoscope should be rotated 180 degrees with the 30-degree tip looking upward.
Recurrent laryngeal nerve dissection	■ Avoid electrocautery (bipolar or monopolar) until both laryngeal nerves have been exposed. The Harmonic® device is used for almost all the vascular structures; but if the vessel is running particularly close to the inferior laryngeal nerve, then hemostasis is achieved by means of small vascular clips.
Closure	■ Close the midline with one single stitch, leaving some space in between the strap muscles, allowing quick blood evacuation in case of compressive hematoma.

POSTOPERATIVE CARE

- After surgery, patients undergoing MIVAT require strict observation during the first 5 to 10 hours on the ward. Dysphonia, airway obstruction, and neck swelling must be carefully checked. No drain is left, so careful surveillance for postoperative hematomas is required during the immediate postoperative period. Postoperative bleeding risk is very low and dramatically decreases after 5 hours.
- In case of postoperative hematoma, if compressive symptoms and airway obstruction are present, reintervention and immediate hematoma evacuation is required.
- Patients can start oral intake on the evening of the operative day and will be discharged the day after. On the first and second postoperative days, serum calcium must be checked in order to control hypoparathyroidism by substitutive therapy, as described in Table 1.
- Wound care is not really necessary after MIVAT because of the glue covering the skin, and postoperative pain will be controlled by means of both intravenous (IV) or oral analgesics.
- Voice impairments and subjective or objective dysphonia requires an immediate postoperative vocal cord check by an otolaryngologist. In the case of a normal postoperative course, a vocal cord check can be delayed until after 3 months.

Table 1: Management of Postoperative Hypocalcemia

Management of Hypocalcemia following Thyroidectomy on the First Postoperative Day	
Acute symptomatic	Calcium gluconate IV
Asymptomatic calcium ≤7.5 mg/dL[a]	Calcium (3 g) + vitamin D (0.5 μg) per os daily
Asymptomatic calcium 7.5–7.9 mg/dL	Calcium (1.5 g) per os daily

[a]Normal range: 8 to 10 mg/dL.

COMPLICATIONS

- Transient hypoparathyroidism and definitive hypoparathyroidism
- Transient monolateral inferior laryngeal nerve palsy and definitive monolateral inferior laryngeal nerve palsy
- Transient bilateral inferior laryngeal nerve palsy and definitive bilateral inferior laryngeal nerve palsy
- Hematoma (subcutaneous-conservative treatment; below strap muscles-reoperation)
  - Seroma
  - Wound infection

Chapter **40**

Lymph Node Dissection in Thyroid Cancer

Gerard M. Doherty

DEFINITION

- Most thyroid cancer develops from the follicular cells of the thyroid gland (differentiated thyroid cancer includes papillary and follicular subtypes).
- Rare thyroid cancers develop from the C cells of the thyroid gland (medullary thyroid cancer).
- Thyroid cancer of any subtype can be associated with lymph node metastases in the neck.
- Clinical circumstances can indicate the need for cervical lymphadenectomy either as a therapeutic intervention for known metastases or as a prophylactic procedure for the diagnosis or therapy of occult metastases.
- The lymph node compartments of the neck are divided into "levels" to allow communication of the affected and dissected areas (**FIG 1**).
  - Level 6 is also known as the central neck and includes the lymph nodes medial to the carotid sheath on each side and bounded by the hyoid bone superiorly and the sternum inferiorly.
  - Levels 1 through 5 are also known as the lateral neck and include all of the node compartments lateral to the carotid sheath on each side.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Thyroid cancer lymph node metastases can be palpable or, more often, nonpalpable but identifiable by imaging. Very small foci of thyroid cancer in lymph nodes may only be evident at microscopic pathology examination.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients with thyroid cancer should each have a staging ultrasound examination prior to operation.[1] This allows mapping of the lymph node status of each compartment in the neck (**FIG 2**).
- The level 6 lymph nodes are the most difficult to evaluate by ultrasound when the thyroid gland is still present, as these structures are in the same compartment.
- Patients with large tumors or gross adenopathy may be best studied by computed tomography (CT) scan with contrast or magnetic resonance scanning, as these modalities allow better examination of the areas low in the neck that may be obscured by gross disease on ultrasound (**FIG 3**).

SURGICAL MANAGEMENT

- Dissection of the level 6 lymph nodes is generally performed in conjunction with total thyroidectomy.
- The level 6 lymph nodes are removed by clearing the soft tissue that surrounds the thyroid gland. No additional incision or mobilization is necessary.
- Clearing these level 6 nodes involves additional manipulation of the soft tissue and vascular supply that surrounds the parathyroid glands. With these glands at additional risk of being damaged during operation, the performance of parathyroid autograft is particularly important to avoid permanent hypoparathyroidism[2] (**FIG 4**).

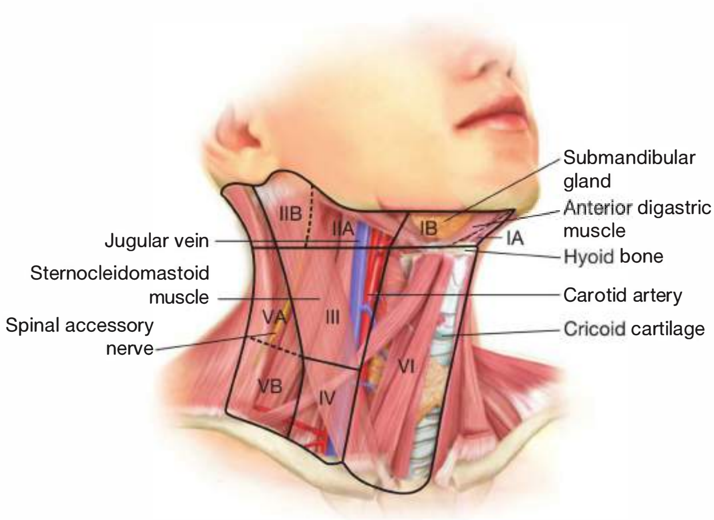

FIG 1 • Lymph node levels in the neck.

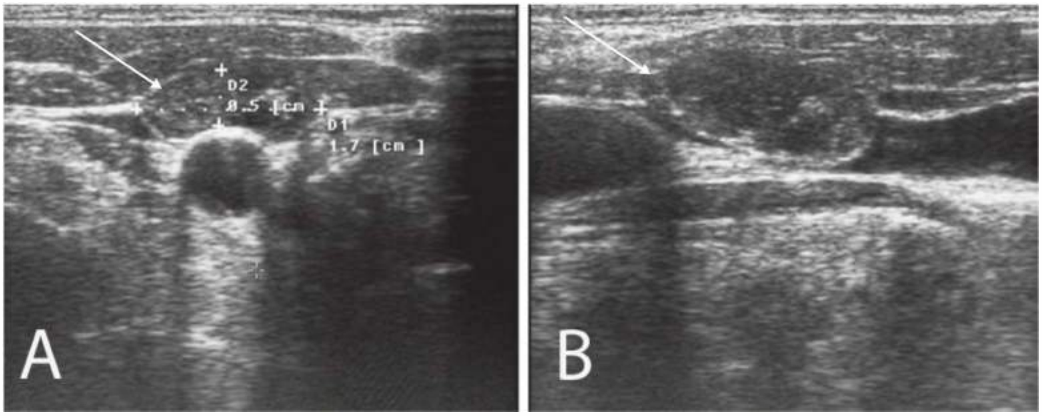

FIG 2 ● Ultrasound demonstration of metastatic lymph nodes in thyroid cancer. **Panel A** shows a transverse view *(arrow)*, and **panel B** shows the longitudinal view *(arrow)*.

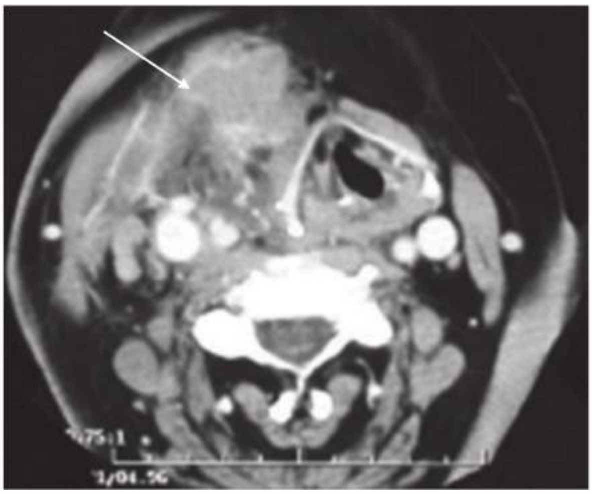

FIG 3 ● CT scan of recurrent nodal disease in the lateral neck impinging upon the central compartment *(arrow)*. CT is useful in this instance as ultrasound cannot completely define the anatomy.

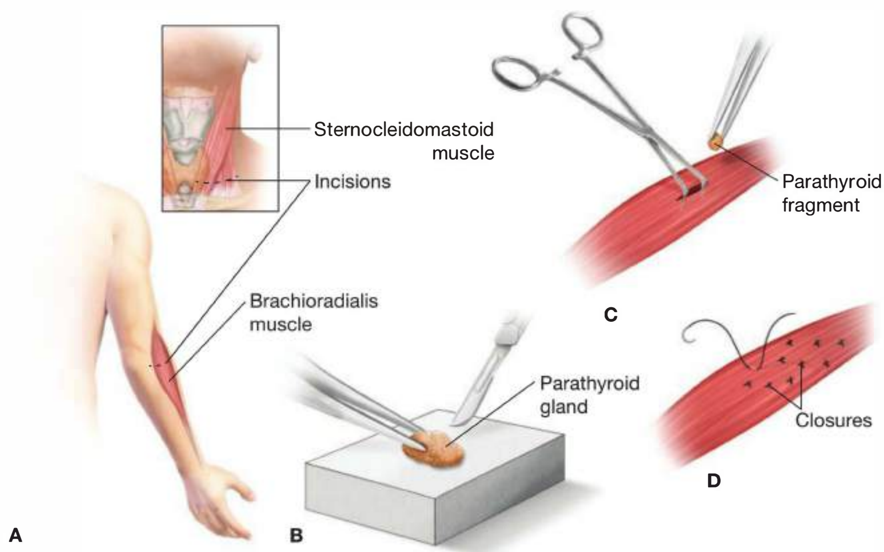

FIG 4 ● Schematic of parathyroid autograft. If a parathyroid gland has been devascularized during dissection, then the best management is parathyroid autograft. **A.** Parathyroid glands can be grafted into any muscle; common choices include the neck muscles for normal glands and the brachioradialis muscle for abnormal glands. **B.** The gland should be minced into small pieces (1- to 2-mm in each dimension). **C,D.** The fragments are placed into individual muscle pockets. The pockets are secured with a stitch. The grafts typically require 10 to 12 weeks before measurable function.

Preoperative Planning

- Review of the preoperative ultrasound findings is critical to the proper inclusion of all suspicious lymph nodes.
- Especially in reoperations, ultrasound in the operating room after the induction of anesthesia and positioning can be helpful to localize small lymph nodes.
- A nerve stimulating and monitoring system can be helpful and is commonly used to identify and to test function of motor nerves during dissection. Testing of the vagus nerve is probably best accomplished by using a specialized nerve stimulator that includes electromyography (EMG) monitoring pads on the endotracheal tube to detect vocalis muscle contraction. Testing of motor nerves for which the enervated muscle is visible can be done with a simple nerve stimulator.

Positioning

- The patient should be supine and the head may be raised above the heart to decrease venous congestion in the neck (FIG 5).
- Airway management is of particular concern. Preoperative anesthesiology consultation should alleviate positioning concerns while ensuring proper airway safety during the procedure.
- A towel roll or thyroid air pillow can be placed beneath the shoulder blades to facilitate neck extension.
- Arms should be tucked.

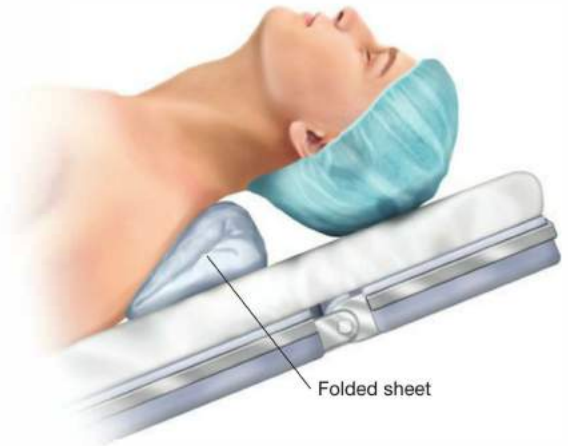

FIG 5 ● Position of the neck should emphasize extension, but support. Overextension of the neck or lack of support for the head and neck can cause avoidable posterior neck stiffness postoperatively.

TECHNIQUES

INCISION

- If a thyroidectomy is performed during the same anesthetic, the incision is extended laterally toward the posterior aspect of the neck; if not, then the dissection can generally be completed through a transverse incision at the level of the lower edge of the cricoid cartilage from the edge of the trachea to the anterior border of the trapezius muscle. The goal is to provide exposure of the anterolateral neck and posterior triangles.

RAISING SKIN AND PLATYSMA MUSCLE FLAPS

- Flaps are made superiorly, inferiorly, and posteriorly (FIG 6). The flaps should be in a plane superficial to the external jugular vein and should extend broadly over the compartments to be dissected. The facial vein can be divided and retracted superiorly. This has some benefit to retract and protect the marginal mandibular branch of the facial nerve. Erb's point can be identified as the area where the greater auricular nerve comes around the posterior edge of the sternocleidomastoid (SCM) muscle. This site is important to identify in order to protect the superficial sensory nerves that converge at that site.

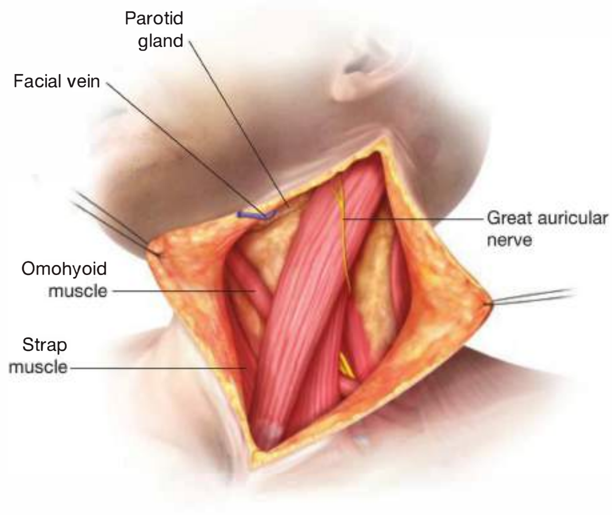

FIG 6 ● The subplatysmal flaps should be generous to avoid struggling at the margins of dissection later in the case.

MOBILIZING THE STERNOCLEIDOMASTOID MUSCLE

- The fascia over the middle of the SCM muscle is incised longitudinally with careful preservation of the greater auricular nerve.
- The fascia is then stripped from the muscle over a broad area, unwrapping the muscle and following the fascial plane around the front edge of the muscle to its deep surface. The plane is continued deep to the muscle back to its posterior edge.
- The sensory nerves at Erb's point (greater auricular, lesser occipital, transverse cervical, and supraclavicular) are all preserved.
- The SCM muscle is encircled with a Penrose drain for traction to provide exposure (**FIG 7**).
- The omohyoid muscle is divided to improve exposure of the underlying nodal packet.

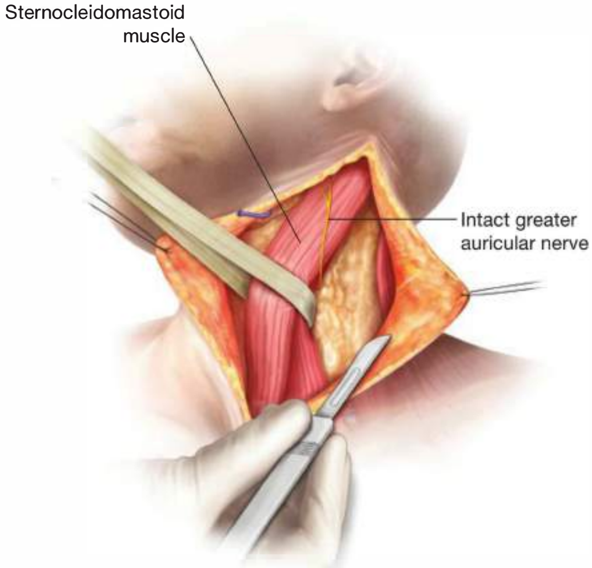

FIG 7 ● Once the SCM muscle has been mobilized, the fascia over the node packet can be incised laterally. This will allow separation of the fatty soft tissue from the anterior edge of the trapezius muscle. Great care is needed to identify the spinal accessory nerve without injury.

DISSECTION OF SOFT TISSUE SPECIMEN

- Dissection of the nodal packet can be initiated in a number of places (**FIG 8**). The posterior triangle is a common choice. The superficial fascia along the anterior edge of the trapezius muscle is carefully incised along the muscle edge to avoid inadvertent division of the spinal accessory motor nerve.
- The nodal packet attachments to the trapezius are taken down initially with blunt dissection, especially prior to identification of the spinal accessory nerve. Unless there is direct involvement of the nerve by tumor, the nerve should be preserved.
- The specimen is dissected from lateral to medial with attention to the underlying structures.
  - The supraclavicular sensory nerves fan out from Erb's point and divide the level 5 specimen into superficial and deep components. Removal of all nodes with preservation of the major branches of these nerves requires recognition of this and careful dissection.
- Once the dissection reaches the area deep to the SCM muscle, the jugular nodes (levels 2 to 4) are dissected either starting from the top (level 2) or the bottom (level 4) of the jugular chain, removing these nodes en bloc with the posterior triangle specimen.
- The jugular vein is generally preserved unless there is involvement of the vein by direct invasion or tumor thrombus. If the vein cannot be preserved, it is included in the specimen. There is no morbidity of including this in a unilateral dissection.
- The specimen is removed en bloc, marked, and prepared for pathologic examination.

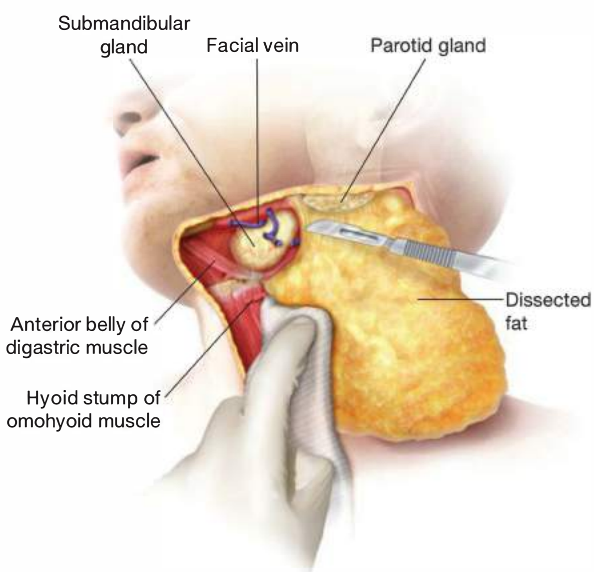

FIG 8 ● The dissection progresses with mobilization of the soft tissues away from the jugular vein (SCM not shown).

INSPECTION AND CLOSURE

- Once the specimen has been removed, the field is carefully inspected for residual soft tissue that can be removed (FIG 9). Nerves are tested for confirmation of function findings and hemostasis is ensured. Special inspection at the base of the jugular vein should ensure that there is no evidence of chyle leak.
  - A small drain is often placed to remove serum or chyle that could accumulate. If the operation has been straightforward and the disease burden low, then this may be omitted.
- The wound is closed in two layers, the platysma muscle layer with interrupted absorbable suture and the skin by whatever cosmetically advantageous method the surgeon chooses.

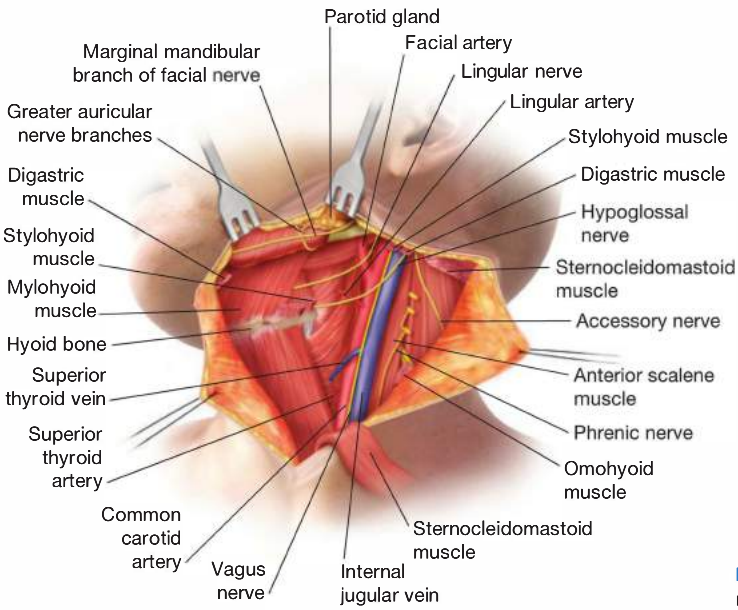

FIG 9 ● Anatomy of the neck after the node-bearing soft tissues have been removed.

PEARLS AND PITFALLS

Indications	■ Prophylactic lateral neck dissection is not generally indicated for thyroid cancer.
Raising of flaps	■ The flaps plane must be accurately placed deep to platysma and superficial to external jugular vessels.
Mobilizing SCM muscle	■ Avoid injury to the sensory nerves at Erb's point.
Dissecting specimen	■ Identify the spinal accessory nerve early to avoid injury.
Ensuring hemostasis	■ Small venous branches in the soft tissue deep to the clavicle, at the inferior margin of the dissection, can cause bothersome bleeding.
Avoiding chyle leak	■ Pay careful attention to clear fluid welling up near the inferior-most visible portion of the jugular vein, on either side but especially the left.

POSTOPERATIVE CARE

- Drains should be inspected for lymphatic leak and patients instructed on drain care.
- Drains should be removed once output decreases to 30 mL or less per day.

OUTCOMES

- Functional outcomes are excellent if nerves are preserved.
- A minority of patients requires physical therapy to regain full range of shoulder motion.

COMPLICATIONS

- Nerve injury: spinal accessory nerve; vagus or recurrent laryngeal nerve injury (if central neck dissection is included in the procedure); brachial plexus
- Vascular injury: internal jugular vein; carotid artery causing neck hematoma, which can progress to airway compromise
- Thoracic duct injury leading to lymphatic leak, possibly requiring operative intervention for thoracic duct ligation
- Regional disease recurrence

Chapter 41

Open Neck Exploration for Primary Hyperparathyroidism

Christopher R. McHenry

DEFINITION

- An open neck exploration for hyperparathyroidism (HPT) is defined as exposure of an abnormal parathyroid gland or glands using standard operative techniques through a single incision without endoscopic or videoscopic assistance. This includes bilateral neck exploration for patients with multiglandular disease and unilateral focused parathyroidectomy with intraoperative parathyroid hormone (PTH) monitoring for a single adenoma localized preoperatively.

DIFFERENTIAL DIAGNOSIS

- Primary HPT and malignancy account for 80% of all causes of hypercalcemia.
- Primary HPT accounts for 50% to 60% of all cases of hypercalcemia diagnosed in an ambulatory setting and approximately 30% of cases diagnosed in a hospital setting.
- There are many less common causes for hypercalcemia (Table 1).
- In patients with primary HPT, 85% to 90% will have a single adenoma, 5% to 10% hyperplasia, 3% to 4% double adenoma, and less than 1% carcinoma.

Table 1: Causes of Hypercalcemia

Hyperparathyroidism
Primary and tertiary
Malignancy
Osteolytic bone metastases
Tumor production of PTH-related polypeptide
Squamous cell carcinoma of the lung
Renal cell carcinoma
Bladder cancer
Hematologic malignancies
Leukemia
Lymphoma
Multiple myeloma
Granulomatous disease
Tuberculosis
Sarcoidosis
Fungal infection
Medications
Calcium
Vitamin A or D intoxication
Lithium
Thiazides
Milk-alkali syndrome
Miscellaneous
Hyperthyroidism
Paget's disease
Immobilization
Familial hypocalciuric hypercalcemia

PTH, parathyroid hormone.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Primary HPT occurs in 1 out of every 500 women and 1 out of every 2,000 men. It most commonly occurs in women between the ages of 50 and 60 years.
- Most patients with primary HPT are diagnosed as a result of the incidental hypercalcemia detected on blood work that is obtained for an unrelated medical problem. Patients often have nonspecific symptoms such as fatigue, weakness, constipation, and depression.
- Patients with primary HPT may present with plethora of clinical manifestations (Table 2). Nephrolithiasis is the most common metabolic complication of primary HPT occurring in 15% to 20% of patients; however, only 2% to 5% of patients with kidney stones have primary HPT.
- Approximately 3% of patients may present with hyperparathyroid crisis manifested by severe hypercalcemia (serum calcium >14 mg/dL), nausea, vomiting, dehydration, and central nervous system dysfunction including coma.[1]
- Primary HPT is associated with a higher risk of cardiovascular disease and mortality that decreases after parathyroidectomy.[2]
- A prior history of head or neck radiation in childhood, radioiodine treatment, and long-term lithium therapy are associated with a greater prevalence of primary HPT.
- In 5% of patients, primary HPT is an inherited syndrome, underscoring the importance of obtaining a thorough family history. Familial HPT is inherited as an autosomal dominant

Table 2: Clinical Manifestation of Primary Hyperparathyroidism

Renal	**Psychiatric**
Nephrolithiasis	Depression
Nephrocalcinosis	Lethargy
Polyuria	Memory loss
Renal insufficiency	Confusion
	Hallucinations
	Coma
Skeletal	**Neuromuscular**
Generalized bone or joint pain	Fatigue
Osteopenia	Weakness
Osteoporosis	Malaise
Gout	
Pseudogout	
Pathologic bone fracture	
Osteitis fibrosa cystica	
Gastrointestinal	**Cardiovascular**
Constipation	Exacerbation of hypertension
Peptic ulcer disease	Cardiac calcification
Pancreatitis	Left ventricular hypertrophy
Nausea	Decreased QT interval
Vomiting	Conduction abnormalities
Abdominal pain	Heart block

Table 3: Familial Hyperparathyroidism
A. Familial isolated hyperparathyroidism
B. MEN I
Primary hyperparathyroidism
Gastroenteropancreatic tumors
Pituitary adenoma
Adrenocortical and thyroid tumors
Lipomas
Meningiomas
Facial angiofibromas
Bronchial, gastric, and thymic carcinoid tumors
C. MEN IIA
Medullary thyroid cancer
Pheochromocytoma
Primary hyperparathyroidism
Lichen planus amyloidosis
Hirschsprung disease
D. Hyperparathyroidism–jaw tumor syndrome
Ossifying fibromas of the mandible or maxilla
Renal cysts, hamartomas, and Wilms tumor
Uterine adenosarcoma, adenofibroma, leiomyoma, adenomyosis, and endometrial hyperplasia

syndrome with primary HPT occurring as an isolated entity or as part of multiple endocrine neoplasia (MEN) I, MEN IIA, or the hyperparathyroidism–jaw tumor syndrome (Table 3). Patients with hyperparathyroidism–jaw tumor syndrome have more severe hypercalcemia and a 10% to 15% incidence of parathyroid cancer.

- In most patients with primary HPT, the physical examination is normal. Less than 5% of patients with primary HPT will have a palpable parathyroid tumor. Patients with hyperparathyroid crisis are more likely to have a palpable neck mass.
- A palpable neck mass in patients with primary HPT should raise suspicion for parathyroid cancer or an associated thyroid nodule.
- Rare patients may have band keratopathy, a condition characterized by calcium phosphate deposition in the cornea, which can be identified by slit lamp examination.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A diagnosis of primary HPT is made by an elevated serum calcium level and an elevated or inappropriately normal intact serum PTH level.
- Up to 20% of patients have normocalcemic primary HPT with a serum calcium level in the normal range. Most patients with normocalcemic primary HPT are diagnosed as a result of evaluation for kidney stones, osteoporosis, or osteopenia. Vitamin D deficiency, excess phosphate intake, low calcium set point, and hypo- or hypermagnesemia may be contributory factors to normocalcemic HPT.
- Patients with primary HPT may have low or low normal serum phosphate and high serum chloride, alkaline phosphatase, and uric acid levels. Alkaline phosphatase is elevated in patients with bone disease.
- Patients may also have a mild metabolic acidosis, which occurs because of the inhibitory effect of PTH on phosphorus and bicarbonate reabsorption in the kidney.
- Prior to the introduction of sensitive immunoradiometric and chemiluminescence assays for measurement of intact PTH levels, a chloride to phosphorus ratio greater than 33:1 was used to make the diagnosis of primary HPT.
- Blood urea nitrogen, serum creatinine, and glomerular filtration rate should be measured and followed, because renal insufficiency is a known complication of primary HPT.
- Bone mineral density should be measured at the lumbar spine, hip, and distal radius using dual energy x-ray absorptiometry.
- A calcium:creatinine clearance ratio should be determined if familial hypocalciuric hypercalcemia (FHH) is suspected. FHH is a rare autosomal dominant disorder characterized by asymptomatic hypercalcemia, hypocalciuria, and variable PTH elevation that results from a higher renal setpoint for calcium secretion. Patients with FHH have one or more first-degree relatives with hypercalcemia, a calcium:creatinine clearance less than 0.01, and a 24-hour urine calcium less than 100 mg. Parathyroidectomy is not indicated.
- Once a diagnosis of primary HPT has been established, imaging should be performed to localize an abnormal parathyroid gland or glands. When an abnormal parathyroid gland can be localized preoperatively, a focused parathyroidectomy can be performed with intraoperative PTH measurement to confirm cure of the primary HPT. This minimizes dissection, shortens the operation, and reduces cost.
- Localization studies should only be performed once a diagnosis of HPT has been established and a decision to proceed with surgical therapy has been made. The role of localization studies is to help determine the site of the incision and where in the neck to begin the exploration.
- Office-based, high-resolution ultrasonography is the initial imaging study performed. A parathyroid adenoma appears as a homogeneous, hypoechoic, oval- or bean-shaped mass posterior to the thyroid gland (**FIG 1**). Occasionally, a parathyroid adenoma may be multilobulated. Ultrasound is also of value in identifying concomitant nodular thyroid disease.
- Technetium-99m-sestamibi with single-photon emission computed tomography (SPECT) is a combined functional and anatomic imaging study, which is obtained prior to operation. It is particularly beneficial for identifying ectopic parathyroid glands (**FIG 2**).
- Four-dimensional computed tomography and positron emission tomography/computed tomography (PET/CT) fusion imaging are other potentially valuable imaging studies to help localize abnormal parathyroid glands but are usually reserved for patients with persistent or recurrent HPT.

FIG 1 ● High-resolution ultrasound image of 1.32 × 0.77 cm homogenous, hypoechoic mass inferior to the right lobe of the thyroid gland in a sagittal view. At operation, this was confirmed to be a right inferior parathyroid adenoma.

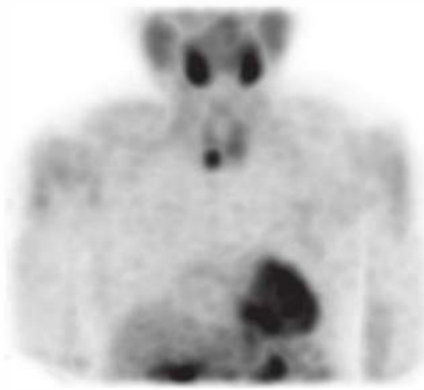

FIG 2 ● Technetium-99m-sestamibi image demonstrating abnormal radiotracer accumulation inferior to the inferior pole of the right lobe of the thyroid gland.

- Intraoperative PTH monitoring is most valuable in patients with discordant lesions on ultrasound and technetium-99m-sestamibi. It has been suggested that intraoperative PTH monitoring is unnecessary in patients with concordant lesions detected on ultrasound and technetium-99m-sestamibi imaging.

SURGICAL MANAGEMENT

- All patients with primary HPT should be presented with option of surgical therapy, because parathyroidectomy is the only curative treatment. The classical symptoms of primary HPT (nephrolithiasis, osteoporosis, osteitis fibrosa cystica, and neuromuscular dysfunction) are well-established indications for surgery.
- In patients with asymptomatic primary HPT, indications for surgical therapy have been defined by the 2008 revised consensus guidelines sponsored by the National Institutes of Health[3] (Table 4). Parathyroidectomy is recommended in all patients younger than 50 years of age because at least 25% will develop one or more complications of HPT during their lifetime, which can be irreversible. Significant hypercalcemia, renal dysfunction, reduction in bone mineral density, and inability or unwillingness to participate in subsequent medical surveillance and follow-up are other indications for parathyroidectomy in patients with asymptomatic primary HPT.

Table 4: Indications for Surgical Therapy in Patients with Asymptomatic Primary Hyperparathyroidism as Established by the 2008 Revised National Institutes of Health Consensus Guidelines

Serum calcium >1 mg/dL above the upper limit of the normal range
Glomerular filtration rate <60 mL/min
Decreased bone density: T score of −2.5 or less at lumbar spine, femoral neck, hip, or distal radius
Age <50 years
When routine follow-up and medical surveillance is problematic or not possible

- Open neck exploration for primary HPT is performed as an outpatient procedure under general anesthesia or local anesthesia with sedation. Various intraoperative adjuncts may be used including ultrasound, PTH monitoring, and radio guidance.
- Intraoperative ultrasound may be used to help determine the best site for the incision.
- Intraoperative PTH monitoring may be used to help determine that all hyperfunctioning parathyroid tissue has been excised and to confirm cure of primary HPT.
- Administration of technetium-99m-sestamibi prior to operation and use of a gamma probe intraoperatively is used by some surgeons to help localize abnormal parathyroid tissue and confirm ex vivo that a sestamibi-avid parathyroid gland has been removed and that no sestamibi-avid glands remain in the neck. Some of the limitations of this technique include that hyperplastic parathyroid glands are most often not sestamibi-avid, and thyroid nodules may also retain sestamibi, producing false-positive results.
- For a single adenoma localized preoperatively, a unilateral focused parathyroidectomy with intraoperative PTH monitoring to confirm cure of primary HPT is performed.
- Bilateral neck exploration is indicated for patients with negative preoperative imaging or when bilateral disease is detected preoperatively and for patients with a higher likelihood of multiglandular disease such as patients with MEN I, MEN IIA, or lithium-associated HPT. It may also be necessary for patients with associated thyroid disease. Bilateral neck exploration may also be preferentially used in all patients with primary HPT.
- Patients with a double adenoma are treated with resection of the two enlarged glands.
- Patients with parathyroid hyperplasia are preferentially treated with subtotal parathyroidectomy, leaving a well-vascularized parathyroid remnant that approximates the weight and size of one normal parathyroid gland. A bilateral transcervical thymectomy is also performed because of a 5% to 15% incidence of supernumerary parathyroid glands, which are most commonly found in the thymus. Alternatively, a total parathyroidectomy and parathyroid autotransplantation into the brachioradialis muscle of the nondominant forearm may be performed (see Part 5, Chapter 42).
- Patients with parathyroid cancer are treated with an en bloc resection of the tumor and the surrounding structures that are invaded. This usually involves resection of the lobe of the thyroid gland and the strap muscles.
- Patients with parathyroid cancer usually present with marked elevation in serum calcium and PTH levels and they may have a palpable neck mass. Parathyroid cancer typically has a gray-white appearance and diagnosis is confirmed by the presence of local invasion of surrounding structures (**FIG 3**).

Preoperative Planning

- Serum levels of 25-hydroxy-vitamin D and alkaline phosphatase are measured preoperatively. Patients with low 25-hydroxy-vitamin D and elevated alkaline phosphatase levels are at increased risk for symptomatic postoperative hypocalcemia.

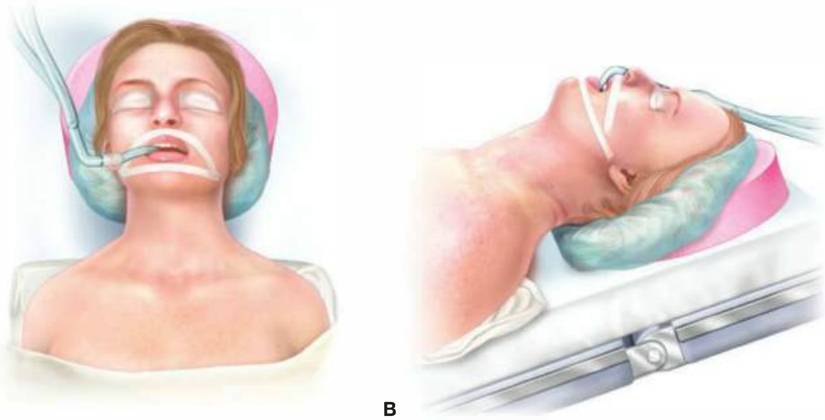
FIG 3 ● A parathyroid cancer with its typical gray-white appearance and the lobe of the thyroid gland, which was invaded by the cancer.

- A sequential compression device is preferably used for prophylaxis against deep vein thrombosis to minimize the risk of postoperative neck hematoma, which may occur with the use of subcutaneous heparin or Lovenox. Routine surgical antimicrobial prophylaxis is unnecessary.
- No special preoperative preparation is required except for patients who present with hyperparathyroid crisis. Hydration with a saline infusion, calciuresis, bisphosphonate therapy, and/or a calcimimetic agent are used to correct severe life-threatening hypercalcemia before proceeding with parathyroidectomy.[1]

TECHNIQUES

POSITIONING

- The patient is positioned on the operating table with a roll placed lengthwise beneath the shoulders, the neck extended, and the head on a soft foam headrest. The patient's arms are tucked at the side (**FIG 4**).
- The bed is placed in slight reverse Trendelenburg to reduce venous pressure. The ventilatory tubing is directed off the back of the operating table to optimize the working space for the surgeon and assistants (**FIG 4**).
- The surgical field is widely prepped with ChloraPrep and allowed to dry for 3 minutes before sterile drapes are applied.



A **B**

FIG 4 ● Anteroposterior and lateral views of patient who is positioned for parathyroid surgery. The patient's neck is extended with a soft roll placed beneath the shoulder blades and their head positioned on a soft foam pillow. The bed is placed in approximately 30 degrees of reverse Trendelenburg. The ventilator tubing is passed of the head of the bed.

INCISION

- The surface anatomy of the neck is identified before determining the site of the skin incision (**FIG 5**). For the best cosmetic result, it is often best to mark the site of the incision with the patient standing in the preoperative holding area. This will help to ensure that the incision is within a normal skin crease and is symmetrical. A curvilinear incision is made in the midline of the neck between the cricoid cartilage and the sternal notch.
- The site of the incision is based on preoperative localizing scans, the patient's natural skin creases, and other cosmetic considerations. Intraoperative ultrasound may sometimes be of help to decide the placement of the incision.

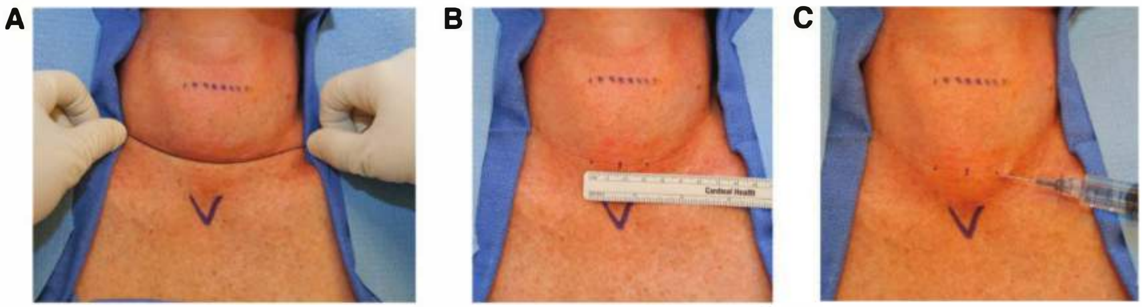


FIG 5 ● **A.** The sternal notch and cricoid cartilage are marked to help decide the most appropriate site for the incision. A 0 silk suture is used to mark the site of the incision. **B.** A 3-cm incision is marked in the midline. **C.** 0.5% Marcaine is used to anesthetize the site of the incision prior to making the incision to establish preoperative analgesia.

- A midline incision is cosmetically preferable and it allows easy access to both sides of the neck for exploration.
- Applying gentle pressure to the neck using a 0 silk suture marks the site of the incision. This is important to maintain symmetry and ensure a curvilinear incision (**FIG 5**).
- The midpoint of the incision is marked on the skin using the midpoint of the sternal notch as a landmark.
- A 2- to 4-cm incision in the midline of the neck is used for parathyroidectomy (**FIG 5**). Patients with a short, thick neck and/or morbid obesity may require a longer incision to improve exposure.
- 0.5% bupivacaine is used to anesthetize the site of the incision prior to making the incision to establish preemptive analgesia (**FIG 5**). This helps enhance patient comfort postoperatively.
- A no. 15 blade scalpel is used to incise the skin. The electrocautery is used to divide the subcutaneous tissue and the platysma muscle.

CREATION OF A WORKING SPACE

- Skin flaps are raised in a subplatysmal plane using skin hooks and small Richardson retractors to elevate the skin (**FIG 6**).
- The anterior jugular veins are identified and the plane of dissection is established immediately anterior to the veins (**FIG 6**).
- The superior skin flap is raised to the prominence of the thyroid cartilage and the inferior skin flap is raised to the sternal notch.
- The sternal heads of the sternocleidomastoid muscle are exposed laterally.

FIG 6 ● **(A)** Superior skin flaps raised in a subplatysmal plane using the anterior jugular veins (**B** and **C**) to create the plane of dissection.

EXPOSURE OF THE THYROID GLAND

- The sternohyoid muscles are separated in the midline along the median raphe with the electrocautery from the sternal notch inferiorly to the thyroid cartilage superiorly (**FIG 7**). The median raphe is an avascular plane consisting of the investing fascia of the thyroid gland.
- Separation of the sternohyoid muscles exposes the thyroid gland.
- The sternothyroid muscle is then dissected and elevated from the surface of the thyroid lobe (**FIG 8**). This is accomplished by blunt and sharp dissection of the intervening loose areolar tissue.

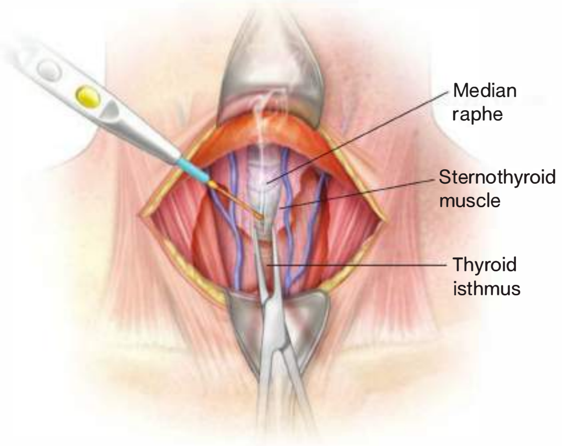

FIG 7 ● The sternothyroid muscles are separated along the median raphe to expose the underlying thyroid gland.

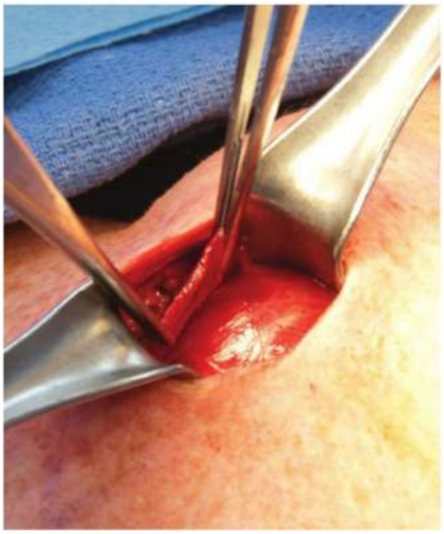

FIG 8 ● The sternothyroid muscle is gently retracted with forceps and is freed from the underlying thyroid lobe.

MOBILIZATION OF THE THYROID LOBE AND EXPOSURE OF AN ABNORMAL PARATHYROID GLAND

- The sternothyroid and the sternohyoid muscles are retracted laterally.
- The lobe of the thyroid gland is elevated anteriorly and medially. An Allis clamp applied to the thyroid lobe facilitates retraction and optimizes exposure in a small working space.
- The middle thyroid vein is identified. It may be divided if necessary for improved exposure.
- It is important to maintain a bloodless field. Blood staining of the tissues can make it more difficult to identify normal and abnormal parathyroid tissue.
- The initial search for an abnormal parathyroid gland is based on preoperative localization studies. Exploration of the normal anatomic location for a superior or inferior parathyroid gland is completed first.
- Abnormal parathyroid glands are larger, more firm, and darker in color than normal parathyroid glands (**FIG 9**).
- In adults, a normal parathyroid gland is yellow-tan in color and oval-, spherical- or bean-shaped. It is usually 5 mm in maximum dimension and, on average, weighs 35 to 50 mg (**FIG 10**). In general, there is no need to biopsy a normal-appearing parathyroid gland.
- The normal location for a superior parathyroid gland is posterior and superior to the recurrent laryngeal nerve. It is approximately 1 cm cephalad to the junction of the inferior thyroid artery and the recurrent laryngeal nerve where the recurrent laryngeal nerve enters the

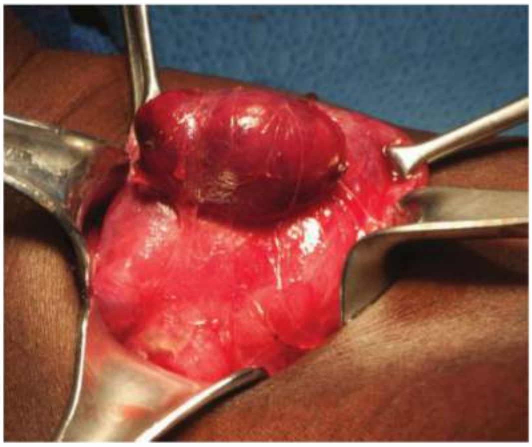

FIG 9 ● Anteromedial rotation of the lobe of the thyroid gland to expose a large abnormal parathyroid gland that is firm and dark in color.

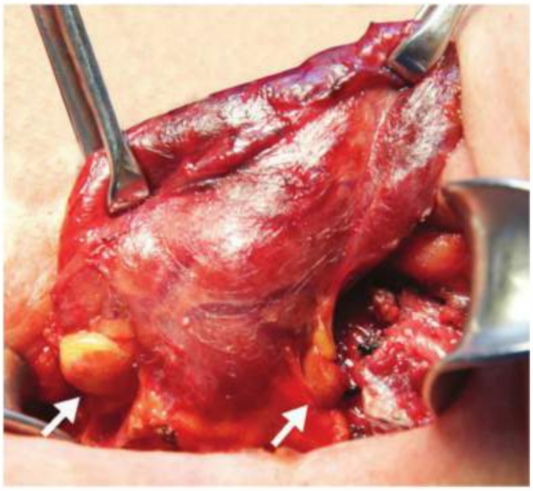

FIG 10 ● Two normal parathyroid glands are seen in their normal anatomic position *(arrows)*. Both have a typical yellow-tan color and are oval in shape. The superior parathyroid gland is surrounded by the adipose tissue.

larynx posterior to the inferior pharyngeal constrictor muscle (FIG 11).

- The normal location for an inferior parathyroid gland is approximately 1 cm caudal to the junction of the inferior thyroid artery and the recurrent laryngeal nerve on the posterior lateral aspect of the inferior pole of the thyroid lobe. It is usually anterior to the recurrent laryngeal nerve (FIG 11).
- Approximately 16% of patients with primary HPT will have ectopic parathyroid glands.[4] The inferior parathyroid gland is more likely to be in an ectopic location related to its more extensive embryologic migration.
- When a parathyroid gland is not found in its normal anatomic location, a search for an ectopic gland should be completed.
- The most common location for an ectopic inferior parathyroid gland is in the thymus. Other ectopic locations are the thyrothymic ligament, the anterior superior mediastinum, intrathyroidal, the carotid sheath, and undescended in a submandibular location (see Part 5, Chapter 42 and Part 5, Chapter 45).
- The most common location for an ectopic superior parathyroid gland is the tracheoesophageal groove. Other ectopic locations are retroesophageal, retropharyngeal, posterior mediastinal, and intrathyroidal.
- A transcervical thymectomy is performed to resect an intrathymic parathyroid adenoma. This is accomplished by exposing the cervical tongue of the thymus beneath the sternothyroid muscle. The thymus is anterior to the inferior thyroid veins and is often immediately adjacent to the inferior pole of the thyroid lobe. The recurrent laryngeal nerve is routinely exposed and dissected into the chest to avoid injury. The connective tissue anterior to the thymus is divided. The thymic veins, which drain into the innominate veins, are divided with an electrothermal bipolar vessel-sealing system. Gentle traction is applied

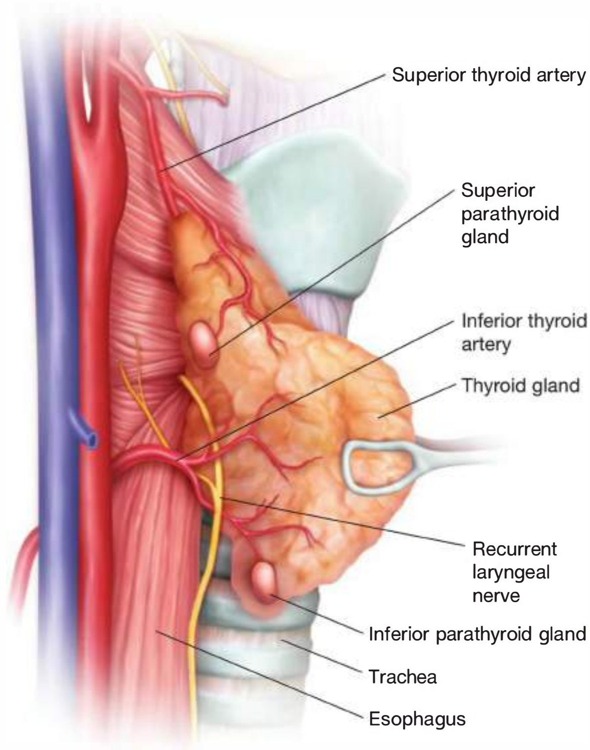

FIG 11 ● Anteromedial rotation of the lobe of the thyroid gland to expose the normal superior and inferior parathyroid glands seen with the right lobe of the thyroid gland retracted anteriorly and medially.

to the cervical tongue of the thymus with a right-angle clamp, progressively elevating more and more of the retrosternal thymic tissue into the operative field.

- An intrathyroidal parathyroid adenoma (FIG 12), found in approximately 1% of patients with primary HPT, can usually be enucleated and does not require resection of the lobe of the thyroid gland.

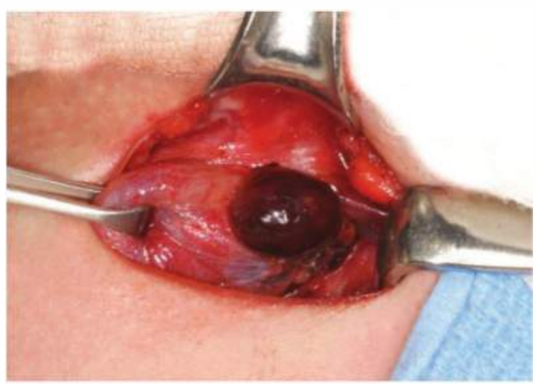

FIG 12 ● Enucleation of an intrathyroidal parathyroid adenoma.

- Division of the superior pole vessels may be helpful when a superior parathyroid gland is not found in its normal anatomic location and it is necessary to search ectopic sites.
- For patients who undergo bilateral neck exploration for multiglandular disease, parathyroid gland location is most often symmetrical.

RESECTION OF AN ABNORMAL PARATHYROID GLAND

- Initially, the enlarged parathyroid gland is dissected anteriorly, laterally, and posteriorly. The medial dissection is left until the end (**FIG 13**).
- An enlarged parathyroid gland is gently mobilized by separating it from the surrounding areolar tissue using blunt dissection with a fine curved hemostat until all that remains is the vascular pedicle.
- Care should be taken to avoid violation of the capsule of the abnormal parathyroid gland, which can lead to parathyroid cell deposition into the soft tissue or parathyromatosis, which is a cause for recurrent HPT.
- The surgeon should always be aware of the recurrent laryngeal nerve, but it is not necessary to routinely expose it nor is nerve monitoring necessary during parathyroidectomy. This is left up to surgeon discretion.
- Care should be taken to stay close to the enlarged parathyroid gland when it is being dissected to avoid injury to the recurrent laryngeal nerve.
- Exposure of the recurrent laryngeal nerve is more often necessary when searching for and removing an enlarged superior parathyroid gland. The superior parathyroid gland is usually posterior to the recurrent laryngeal nerve and the nerve may need to be dissected to resect the gland.
- After mobilization of a parathyroid adenoma has been completed and prior to ligating the vascular pedicle, 3 mL of blood is obtained from the internal jugular vein, a peripheral vein or an arterial line for intraoperative PTH monitoring (**FIG 14**). The vascular pedicle is then ligated and divided and the enlarged parathyroid gland is weighed and submitted to pathology for paraffin evaluation. An additional 3 mL of blood is obtained 5 and 10 minutes after resection of an abnormal parathyroid gland for intraoperative PTH measurement.
- A more than 50% decline in PTH compared to the preexcision or preoperative PTH value is predictive of cure, although a more than 50% decline compared to the preoperative value is preferred before deciding that no additional exploration is necessary. Because of some variability in the half-life of intact PTH, which is normally between 3 and 5 minutes, it may be necessary to obtain an additional intact PTH level before making a decision to proceed with additional exploration. Intact PTH levels that fail to decline by more than 50% suggest that there is persistent hyperfunctioning parathyroid tissue.
- Frozen section exam of an excised parathyroid adenoma is unnecessary if intraoperative PTH monitoring is used. Frozen section exam may be of value to distinguish normal or hyperplastic parathyroid tissue from nodal or thyroid tissue. It may also be useful in patients who undergo thyroidectomy for a nodule with an inconclusive fine needle aspiration biopsy or an incidentally discovered thyroid nodule that has not been previously biopsied.

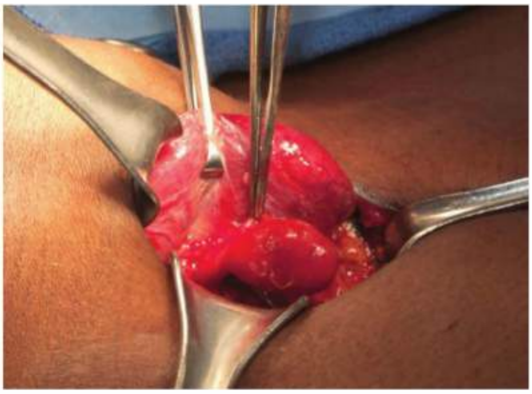

FIG 13 ● A large, superior parathyroid adenoma that has been completely mobilized and all that remains is the medial vascular pedicle.

FIG 14 ● Blood is obtained from the internal jugular vein for intraoperative PTH monitoring. The thyroid lobe is retracted with an Allis clamp. The strap muscles are retracted laterally and the common carotid artery is identified. The internal jugular vein is anterior and lateral to the common carotid artery.

SURGICAL SITE CLOSURE

- The surgical site is closed while awaiting the results of the intraoperative PTH measurements, which have a minimum 20-minute turnaround time. The wound is examined for hemostasis. Venipuncture sites in the internal jugular vein close with some brief, gentle pressure.
- The sternohyoid muscles are reapproximated in the midline with a running absorbable suture, leaving a 3-cm opening at the inferior aspect of the incision (**FIG 15**). This is done to prevent blood from collecting in an enclosed space if bleeding should occur postoperatively. It allows the blood to drain into the subcutaneous space, delaying the onset of respiratory compromise, which occurs from impairment of the venous return from the larynx and laryngeal edema.
- The subcutaneous tissue is reapproximated with absorbable suture. The skin is closed with absorbable suture placed in a subcuticular fashion and Mastisol and Steri-Strips or Dermabond is applied (**FIG 16**).

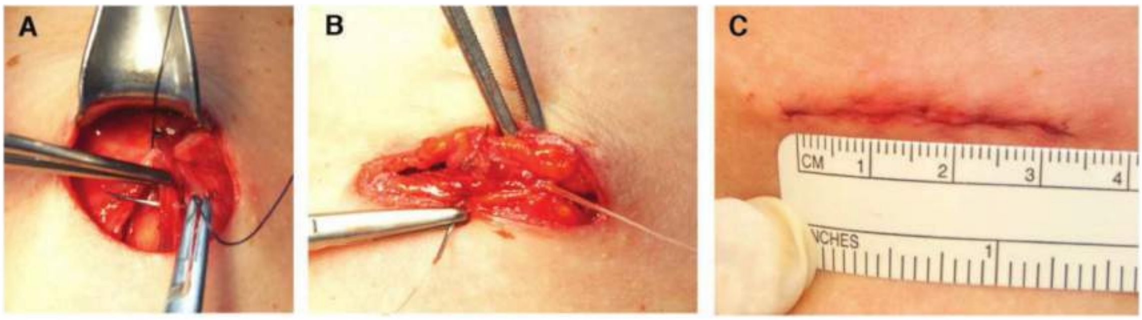

FIG 15 ● **A.** The sternohyoid muscles are reapproximated in the midline with a running absorbable suture. **B.** The subcutaneous tissue is reapproximated in the midline with interrupted absorbable suture. **C.** The skin is closed with an absorbable suture placed in a subcuticular fashion.

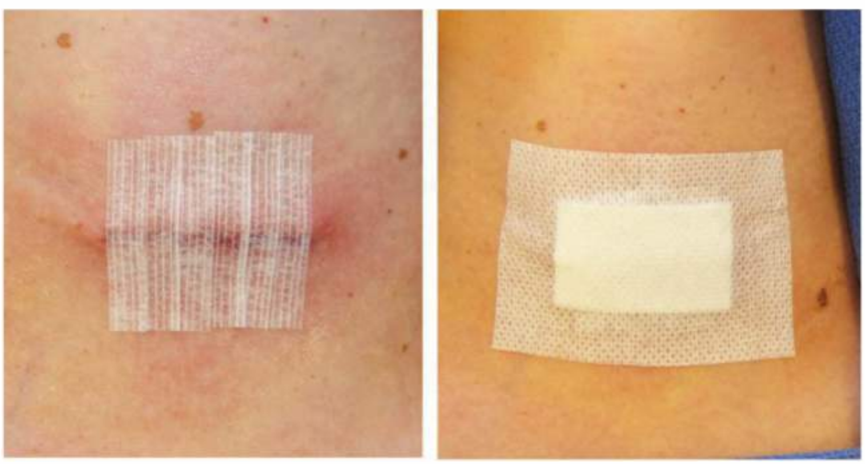

FIG 16 ● Mastisol, Steri-Strips, and a dressing are applied. Alternatively, Dermabond may be used.

PEARLS AND PITFALLS

Incision	■ For the best cosmetic result, mark the site of the incision with the patient standing in the preoperative holding area. This will help to ensure that the incision is within a normal skin crease and is symmetrical.
Raising skin flaps	■ Use the anterior jugular veins to help develop the skin flaps. For the most part, the plane just anterior to the veins is avascular.
Mobilization of the thyroid lobe	■ Use an Allis clamp to apply traction and elevate the thyroid lobe anteromedially. This will allow you to optimize exposure and use a smaller incision.
Parathyroid dissection	■ An enlarged parathyroid gland is surrounded by areolar tissue anteriorly, laterally, and posteriorly. The vascular pedicle is medial in location. The gland is mobilized primarily by blunt dissection, staying close to the gland to avoid the recurrent laryngeal nerve. The vascular pedicle is ligated last. The capsule of the parathyroid gland should not be violated. This can lead to parathyroid cell implantation in the soft tissues (parathyromatosis) and recurrent HPT.
Ectopic parathyroid glands	■ A gland that is described as inferior on a localizing scan may actually be a superior gland that has descended posteriorly from its normal anatomic location. The most common location for a supernumerary or an ectopic inferior parathyroid gland is in the thymus and is resected by performing a transcervical thymectomy. The most common location for an ectopic superior parathyroid gland is in the tracheoesophageal groove. An intrathyroidal parathyroid adenoma can usually be enucleated and normally does not require thyroid lobectomy.
Multiglandular disease	■ Parathyroid glands are most often symmetrical in location.

POSTOPERATIVE CARE

- Patients are discharged home after routine recovery in the postambulatory care unit. They are instructed to keep their dressing on for 48 hours and keep the Steri-Strips on until they return for their first follow-up visit in 2 weeks.
- Patients are instructed about the potential for neck hematoma and symptoms of hypocalcemia. They are told to come directly to the emergency department if they experience neck swelling that is out of the ordinary or they have difficulty breathing. They are asked to call if they develop symptoms of hypocalcemia and are told to begin oral calcium 500 to 1,000 mg three times daily.
- A serum calcium level is obtained at their first follow-up visit and in 6 months to confirm curative parathyroidectomy. Patients are followed yearly thereafter with a serum calcium level to assess for recurrent disease.

OUTCOMES

- The cure rate for primary HPT with parathyroidectomy performed by an experienced surgeon is 95% to 99%.
- Parathyroidectomy for primary HPT results in improvement in health quality-of-life measures including energy level, muscle strength, fine motor skills, and neurocognitive deficits.[5–7]
- Parathyroidectomy for primary HPT results in improvement of bone density.[8]
- After parathyroidectomy, there is complete resolution of the skeletal abnormalities associated with osteitis fibrosa cystica and the reduced concentrating ability of the renal tubules. In 90% of patients, kidney stone formation resolves.
- Parathyroidectomy may halt progressive and irreversible renal insufficiency and hypertension, although hypertension is unlikely to remit.
- The increased cardiovascular mortality associated with primary HPT is reversed with parathyroidectomy.[2]
- Recurrent HPT, defined as hypercalcemia with an elevated or inappropriately normal serum PTH level that develops 6 months following curative parathyroidectomy, occurs in 1% to 3% of patients.
- Approximately 25% of patients have postparathyroidectomy secondary HPT manifested by a normal serum calcium level with an elevated serum PTH level following curative parathyroidectomy. The pathogenesis is not completely understood. Low vitamin D levels, impaired kidney function, and bone remineralization has been suggested as contributory factors. This entity is important to recognize because it can be confused with recurrent disease, but it is rarely of clinical significance.

COMPLICATIONS

- The potential complications from parathyroidectomy include bleeding with neck hematoma that can lead to acute respiratory compromise, hypocalcemia, permanent hypoparathyroidism, recurrent laryngeal nerve injury, transient thyrotoxicosis, and persistent HPT.
- Recurrent laryngeal nerve injury and significant bleeding and neck hematoma are rare following parathyroidectomy, occurring in less than 1% of patients. They occur less often than in patients who undergo thyroidectomy because there is less tissue dissection—most of which is blunt—and no major vessels are ligated and divided.
- Symptomatic hypocalcemia is uncommon after resection of a single adenoma. Patients with elevated preoperative alkaline phosphatase levels are at higher risk for symptomatic hypocalcemia from "bone hunger" following parathyroidectomy. Patients who undergo subtotal or total parathyroidectomy are at higher risk for developing symptomatic postparathyroidectomy hypocalcemia and permanent hypoparathyroidism.
- Permanent hypoparathyroidism may occur in patients following subtotal parathyroidectomy when the remnant fails and total parathyroidectomy when the autotransplant fails.

- Persistent HPT may occur as a result of an ectopic adenoma, a supernumerary parathyroid gland, unrecognized multiglandular disease in patients with false-positive intraoperative PTH results (>50% decline), and an adenoma in a normal anatomic position unrecognized as a result of surgeon inexperience.
- Transient thyrotoxicosis may occur in one-third of patients following parathyroidectomy. It is thought to be the result of thyroid gland manipulation and it is self-limited. Beta-blocker therapy may be used for patients who are symptomatic.
- Recurrent HPT occurs in 1% to 3% of patients and should raise concern for MEN I or MEN IIA.

Chapter 42

Subtotal Parathyroidectomy or Total with Autologous Graft

Brian D. Saunders

DEFINITION

- Parathyroidectomy is a functional surgical procedure performed to remove all or nearly all of a patient's hyperactive parathyroid tissue. Primary hyperparathyroidism is the most common pathologic entity requiring parathyroidectomy. Although roughly 85% to 90% of primary hyperparathyroidism involves a single overactive parathyroid gland, there are somatic, as well as inherited, conditions that result in multiglandular parathyroid pathology.[1] Further, secondary and occasionally tertiary hyperparathyroidism may require surgical resection of more than one parathyroid gland. Subtotal parathyroidectomy is the removal of all but a small portion of one parathyroid gland from the neck. This usually equates to removing three and a half parathyroid glands. The remnant portion of parathyroid tissue is left on its native blood supply and in its normal anatomic position. An alternative to a subtotal resection of parathyroid tissue is a total or complete removal of parathyroid tissue (e.g., all four glands) and the immediate transplantation of autologous parathyroid tissue into a heterotopic position.

DIFFERENTIAL DIAGNOSIS

- The necessity for a multiglandular resection of parathyroid tissue may be recognized preoperatively or intraoperatively. There are a number of etiologies for hyperparathyroidism that are always multiglandular in nature and, as such, would warrant preoperative planning for either a subtotal parathyroidectomy or a total parathyroidectomy with parathyroid autotransplantation. These include multiple endocrine neoplasia (MEN) type I– and type IIa–related primary hyperparathyroidism and secondary hyperparathyroidism related to renal failure. Other pathophysiologic conditions leading to hyperparathyroidism may involve the overactivity of more than one gland. Intraoperative recognition of multiple enlarged glands, or recognition through intraoperative parathormone monitoring data, may lead the surgeon to subtotally resect the parathyroids or perform a total parathyroidectomy with immediate transplant. These include sporadic primary hyperparathyroidism due to multiglandular hyperplasia, lithium-related primary hyperparathyroidism, tertiary hyperparathyroidism, and CDC73-related causes of hyperparathyroidism.[2] This latter category is a familial hyperparathyroidism caused by germline mutations in the CDC73 gene (also known as HRPT2 or parafibromin) and includes familial, isolated hyperparathyroidism and hyperparathyroidism–jaw tumor syndrome.[3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Hyperparathyroidism is a biochemical diagnosis. The evaluation of a patient for hyperparathyroidism may begin with an incidental note of an elevated calcium level on a laboratory report or with interrogating a patient's calcium level based on the patient's presenting signs or symptoms. Patients with recurrent nephrolithiasis (especially calcium-based kidney stones) or osteoporotic (e.g., fragility or nontraumatic) bone fractures should be evaluated for hypercalcemia and hyperparathyroidism. Other, less specific, symptoms that may warrant a biochemical investigation for hyperparathyroidism include fatigue; musculoskeletal aches and pains; neurocognitive decline; mood lability; abdominal pain; and recurrent, otherwise unexplained, pancreatitis.
- A detailed family history should be sought to evaluate the possibility of an inherited cause of hyperparathyroidism. The patient should be queried about family members with pituitary tumors, other cases of parathyroid disease, medullary thyroid cancer, pheochromocytomas, enteropancreatic neuroendocrine tumors (especially gastrin-producing tumors), and ossifying fibromas of the mandible.
- Patients with suspected inherited causes of hyperparathyroidism should be counseled to seek genetic counseling and testing as this may impact operative planning, future disease surveillance, and the health of relatives.
- Renal-related secondary hyperparathyroidism is a constant and expected biochemical finding in all patients with chronic kidney dysfunction. The degree of hyperparathormonemia is routinely followed by treating nephrologists, especially in patients who have progressed to some form of renal replacement therapy (peritoneal or hemodialysis). National management guidelines exist for the target parathyroid hormone (PTH) level for each stage of chronic kidney disease.[4]
- Physical examination findings for patients with hyperparathyroidism are uncommon. Certainly, the neck of each patient proposed for a parathyroidectomy should be thoroughly examined. The identification of a palpable mass would warrant further imaging investigation. It is distinctly unusual to palpate a parathyroid adenoma. A palpable mass with severe hyperparathyroidism should raise the specter of the unusual entity of parathyroid carcinoma. Often, though, a palpable central neck mass in a patient with hyperparathyroidism is an incidentally discovered thyroid nodule.
- For patients planned to undergo a total parathyroidectomy with immediate autologous parathyroid transplantation, a detailed inspection of the forearms should be undertaken. It is important to note the handedness of the patient, as the parathyroid autograft is usually placed in the nondominant forearm. In patients with preexisting or impending renal failure, note should be made of arteriovenous fistula position. Great care should be taken to avoid injuring a functional fistula or disturbing the bed of a soon-to-be constructed fistula.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Hyperparathyroidism (whether primary, secondary, or tertiary) is a biochemical diagnosis. This must be made to the satisfaction of the surgeon prior to contemplating any procedure. The surgeon should consider imaging studies only after a diagnosis has been secured and the need for an operation has been established.
- Known multiglandular parathyroid disease processes that will require preoperative planning for a subtotal parathyroidectomy or a total parathyroidectomy with autologous graft do not require parathyroid imaging as both sides of the neck will need to be explored and all four of the parathyroid glands identified.
- High-resolution ultrasonography of the neck (whether performed by the surgeon or a radiologist) is an excellent modality to attempt to localize enlarged parathyroid glands. Parathyroid adenomas appear as hypoechoic, ovoid masses that are separable from the thyroid gland. Upper parathyroid adenomas that lie in the tracheoesophageal groove will often be mobile with graded compression of the ultrasound probe (**FIG 1A,B**). Parathyroid adenomas adjacent to the thyroid can usually be well seen, although ectopic parathyroid adenomas (e.g., posterior to the clavicular heads) may be difficult to visualize due to limitations of the ultrasound waves in travelling through bone. Ultrasonography will also aid in the identification of concurrent thyroid pathology, which may then be dealt with at the time of the parathyroid operation.
- Nuclear medicine parathyroid scans using technetium sestamibi as a tracer can accurately identify overactive parathyroid glands about 85% of the time.[5] When performed with a concurrent single-photon emission computed tomography (SPECT)/computed tomography (CT) scan, this overlay of functional and structural imaging provides an excellent anatomic map of disease localization invaluable to the operating surgeon (**FIG 2A,B**). One caveat is that small parathyroid adenomas in close association with the thyroid gland may be difficult to visualize with this imaging technique.
- Neck CT scan or magnetic resonance imaging (MRI) is occasionally used to image parathyroid glands. Newer CT scan imaging protocols are becoming more widespread, such as 4D CT scans. This takes advantage of the timing of the intravenous (IV) contrast bolus, the vascularity of the parathyroid tumors, and the delayed washout of hyperactive parathyroid lesions.
- More invasive modalities of parathyroid localization include selective venous sampling for PTH measurement. This technique requires experienced interventional radiologists and is best reserved for the reoperative setting.
- Imaging prior to reoperative parathyroid surgery is essential to minimize exploration in a scarred operative field and to minimize iatrogenic morbidity. It is ideal to have two concordant imaging studies prior to all reoperative parathyroid surgery (see Part 5, Chapter 45).

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to any parathyroid operation, all diagnostic biochemical data should be reviewed to confirm to the surgeon's satisfaction that a diagnosis of surgically correctable hyperparathyroidism is present in the patient.
- If an autologous parathyroid transplant is planned, confirmation with the patient as to which upper extremity will be the recipient site should be sought.
- The wound classification for parathyroid surgery is clean. It is rare for parenteral antibiotics to be indicated prior to parathyroid surgery. Individual patient characteristics (e.g., cardiac valvular lesions, implanted prosthetic hardware), however, should always be considered.
- Local or general anesthesia may be used.

Positioning

- The patient is positioned supine on the operating room (OR) table with the arms tucked either at the sides or lying on the abdomen. A sheet, fastened with towel clips, is used to secure the arms next to the patient and to allow for removal of the arm boards from the OR table (**FIG 3**).
- If a parathyroid transplant is planned to the patient's forearm, this arm can be extended from the patient and reprepped and draped at the time of that portion of the procedure (after the parathyroid tissue has been removed from the neck).
- A towel roll or other small bump is placed behind the patient's shoulder to aid in extension of the neck.
- The bed is positioned with the head up, the feet down, and in some slight Trendelenburg. This is known as the semi-Fowler's position or the beach chair position.
- Some surgeons will rotate the OR table 90 degrees to have the head of the patient away from the anesthesia providers and thus more accessible to the surgical team.

FIG 3 ● The patient is positioned on the OR table with the arms tucked, a roll behind the shoulders, and the head elevated.

PLACEMENT OF INCISION

- A transverse incision is made in the line of a skin crease roughly 1 cm caudal to the cricoid cartilage or two fingerbreadths cephalad to the suprasternal notch. The incision may be between 3 and 5 cm in length and is centered on the midline of the neck (**FIG 4**). Some surgeons will infiltrate the region of the incision with a local anesthetic combined with epinephrine. Placement of the incision within a natural skin line or crease of the neck is more important for postoperative cosmesis than the length of the incision (**FIG 5**).

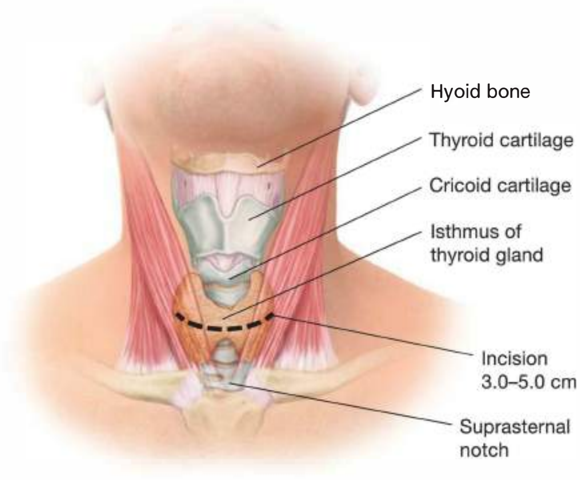

FIG 4 ● Surface anatomy and relationships for parathyroid incision placement.

FIG 5 ● Diagram of planned parathyroidectomy incision, with clavicular heads and sternal notch marked for reference.

CREATION OF FLAPS

- Dissection is deepened through the subcutaneous tissues and through the platysma muscle with electrocautery. Subplatysmal flaps are created superiorly, inferiorly, and laterally with a combination of electrocautery and blunt dissection (**FIG 6**).
- Care must be taken to avoid injury to the paired anterior jugular veins. Should a rent be made in one of these veins, it is best to ligate the vein rather than attempt to cauterize the vein.
- The superior flap should extend to the level of the thyroid cartilage and the inferior flap down to the sternal notch.

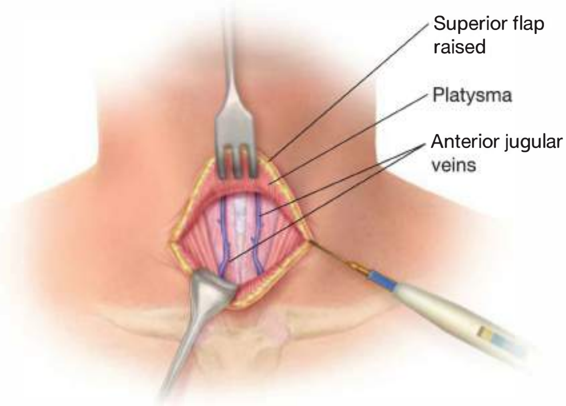

FIG 6 ● Myocutaneous flaps are raised superiorly, inferiorly, and laterally to facilitate skin retraction and to expose the various sites to be explored.

ENTRY INTO THE DEEP CENTRAL NECK SPACE

- The avascular, midline raphe between the sternohyoid and sternothyroid muscles on each side is entered with electrocautery. This midline is best identified by digital palpation of the midline of the underlying trachea. These strap muscles should be separated to expose the underlying thyroid isthmus (**FIG 7**).
- The layers of the strap muscles are separated into two by dividing the connective tissue in the layer between the sternohyoid and the sternothyroid muscles. The lateral extent of this dissection is the lateral borders of these muscles and the carotid sheath. This exposes the internal jugular vein, a site from which to draw a baseline blood sample for intraoperative PTH monitoring[6] (**FIG 8**).
- An alternate site for PTH sampling is a peripheral venipuncture (often in the lower extremity) performed by the anesthesiologist. If an arterial catheter is present for anesthetic monitoring, it is acceptable to use an arterial blood sample for PTH monitoring.

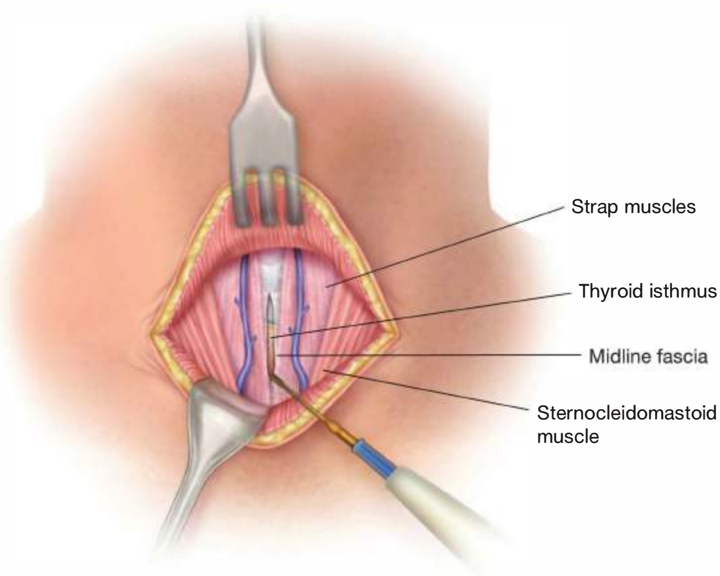

FIG 7 ● The strap muscles (sternohyoid and sternothyroid) are separated in the midline with electrocautery to expose the underlying thyroid isthmus.

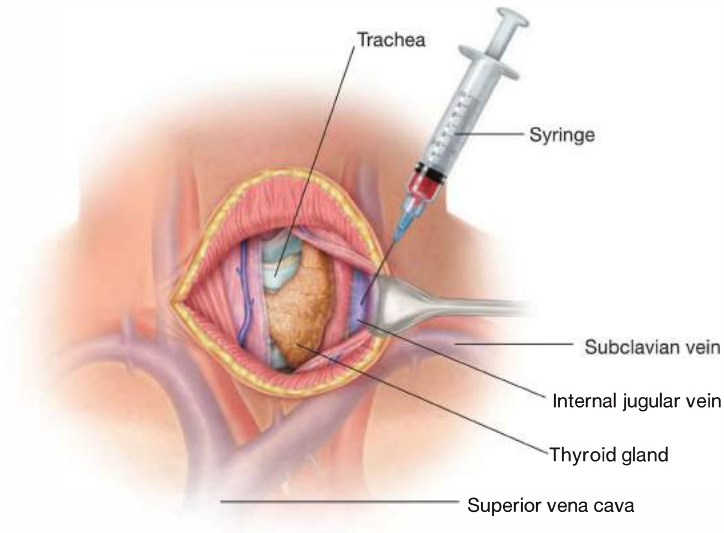

FIG 8 ● Blood is drawn from the internal jugular vein to test for PTH levels.

- The space between the sternothyroid muscle and the thyroid lobe is developed with a combination of blunt dissection and electrocautery. The operation must necessarily begin on one side of the neck, but an identical procedure will be done on the contralateral side of the neck to identify all four parathyroid glands. This space lateral to the thyroid lobe and medial to the carotid artery is developed back to the level of the prevertebral fascia. The crossing middle thyroid vein may need to be divided. This may be accomplished with metallic clips, suture, or through any of the available powered surgical devices (**FIG 9**). Caution must be taken to avoid searching for parathyroid tissue too soon, as it is possible for the tumor to be more posterior than one has opened, or remaining with either the thyroid or the carotid sheath.
- The recurrent laryngeal nerve may be identified at this point, coursing superiorly in the tracheoesophageal groove (**FIG 10**).

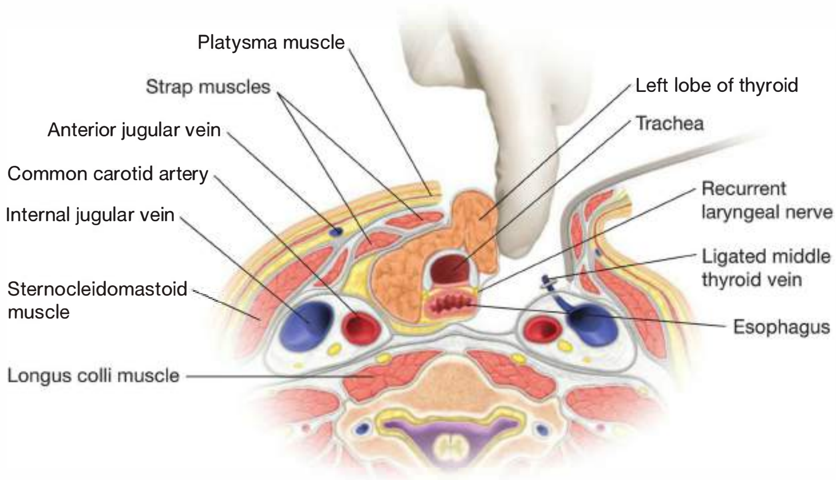

FIG 9 ● Initial dissection for a parathyroidectomy includes separating the strap muscles off the underlying thyroid lobe. The plane just medial to the carotid sheath is followed posteriorly to the level of the spine. The only transversely crossing structure is the middle thyroid vein, which can be ligated. All soft tissue, along with the thyroid lobe, is kept under the surgeon's finger.

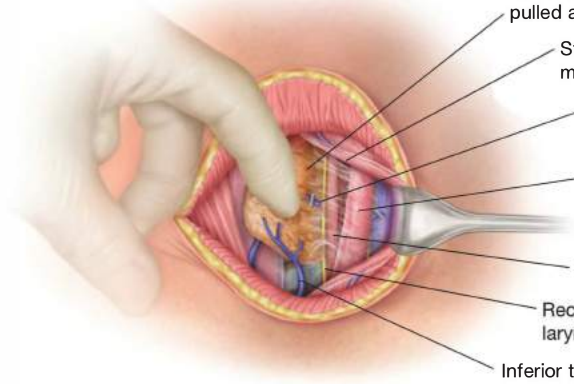

FIG 10 ● The recurrent laryngeal nerve courses superiorly in the tracheoesophageal groove and can often be identified most easily at the level of the inferior pole of the thyroid gland.

IDENTIFICATION OF SUPERIOR PARATHYROID GLANDS

- The superior parathyroid glands lie posterior to the upper pole of the thyroid lobe. To explore this space, the thyroid lobe is rolled anteromedially using one's finger or a Kittner dissector. The superior parathyroid glands are posterior to the recurrent laryngeal nerve as it passes underneath the tubercle of Zuckerkandl and just posterolateral to the ligament of Berry (**FIG 11**). Their position is more constant than that of the inferior parathyroid glands. There is often symmetry between sides of the neck, and if one cannot locate a superior parathyroid gland on one side, it is often advisable to locate it on the contralateral side.

FIG 11 ● Right superior parathyroid adenoma lying posterior to the right thyroid lobe (rolled anteriorly with Kittner dissector). The right strap musculature is seen retracted laterally.

- Due to limited space for enlargement, superior parathyroid adenomas often grow caudad and ultimately lie in a pseudoectopic position in the tracheoesophageal groove, low in the neck. The blood supply, however, remains in the eutopic position near the upper pole of the thyroid lobe. Caution must be taken elevating these low-lying superior parathyroid adenomas out of the tracheoesophageal groove as they often lie with the recurrent laryngeal nerve draped over them.
- Ectopic positions for the superior parathyroid glands include low in the tracheoesophageal groove, retroesophageal, retrotracheal, within the carotid sheath, and within the thyroid gland.
- Exploration of the carotid sheath begins with retraction of the sternothyroid muscle laterally to expose the carotid artery. Gentle blunt dissection anterior to the carotid artery allows separation of the carotid artery from the internal jugular vein just lateral to it. Posterior in the carotid sheath is the vagus nerve. Exposure of the carotid sheath for about 5 to 6 cm in a cephalocaudal direction allows one to search for a soft, brown nodule consistent with a parathyroid adenoma (**FIG 12**). Care must be taken not to mistake nodules posterior to the carotid sheath for parathyroid adenomas as these may in fact be ganglia of the sympathetic chain.
- Once identified, the parathyroid tumor should be dissected back to its single vascular pedicle. Great care should be taken to avoid entry into the parathyroid capsule and the potential for spilling and seeding parathyroid tumor cells in the central neck space (known as parathyromatosis).
- Any uncertainty in the visual identification of parathyroid tissue should prompt a biopsy sent for frozen section analysis. A small fragment of tumor can be taken with a pair of scissors. Gentle pressure can control any slight ooze from the biopsied gland.
- Once the superior gland has been identified, it should remain in place until the inferior gland has been identified.
- This same procedure will be used to identify the superior parathyroid glands on each side of the neck.

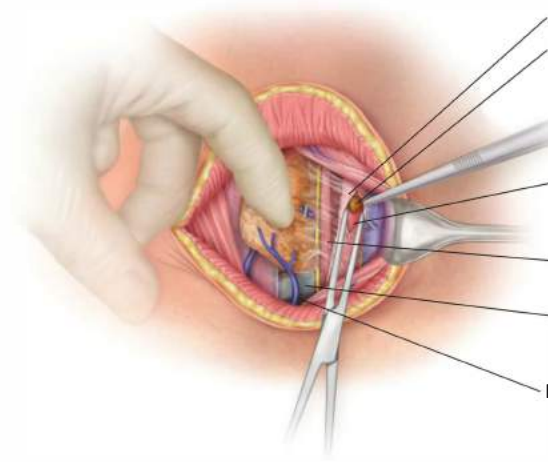

FIG 12 ● Exploration of the carotid sheath for a missing or ectopic superior parathyroid gland. The soft tissue covering the carotid artery is opened, and this space can be explored from the retropharyngeal region into the posterior superior mediastinum.

IDENTIFICATION OF INFERIOR PARATHYROID GLANDS

- The inferior parathyroid glands have a slightly more variable location than the superior parathyroid glands related to the greater distance of migration during embryologic development. The typical location for these glands is just caudal and slightly posterior to the inferior tip of the lower pole of the thyroid lobe. The inferior parathyroid glands often lie in a plane equal to the trachea. They are uniformly anterior to the recurrent laryngeal nerve (**FIG 13**).

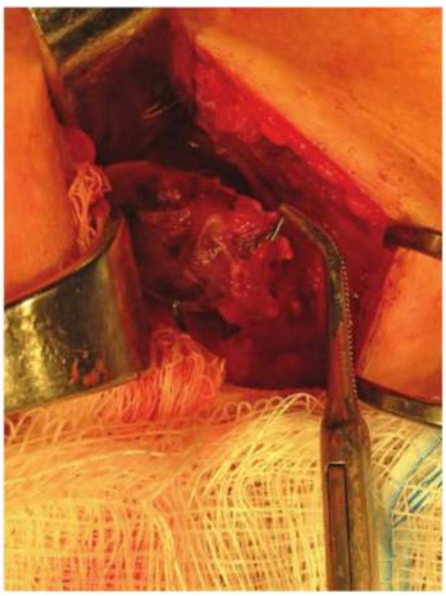

FIG 13 ● Left inferior parathyroid adenoma retracted away from the inferior pole of the thyroid gland.

- As the inferior parathyroid gland enlarges, it may descend with gravity into the fatty tissue caudal to the thyroid lobe and into the anterior superior mediastinum. Gentle dissection in this region can allow for identification of a parathyroid adenoma without causing bleeding.
- The inferior parathyroid glands may lie in the connective tissue ligament that attaches the lower pole of the thyroid to the cervical horn of the thymus (the so-called thyrothymic ligament).
- Ectopic positions for the inferior parathyroid glands include the thyrothymic ligament, the cervical portions of the thymus, the intrathoracic thymus, undescended within the neck, and with the thyroid gland itself. Each of these spaces needs to be examined for a missing parathyroid gland. There is often symmetry of location of the inferior parathyroid glands, and inability to find one inferior parathyroid gland should prompt attempts at identification of the contralateral inferior parathyroid gland as a guide.
- A transcervical thymectomy may be done to identify missing or ectopically located inferior parathyroid glands. This procedure is begun by dissecting the fatty tissue in the anterior superior mediastinum just posterior to the clavicular head and just lateral to the trachea. A search is undertaken for the canary yellow color of the remnant thymus. Gentle traction in a cephalad direction will allow one to extract the thymus from the mediastinum. An encasing membrane will often need to be opened to fully allow the thymus to be removed. The cervical thymic remnant will thin out to a small attachment often containing a blood vessel that should be clipped or suture ligated (**FIG 14**).
- Once the inferior parathyroid adenoma is identified, it should be dissected back to its vascular pedicle. Any question as to its identity should prompt a small sample to be taken with scissors for frozen section biopsy.
- An identical procedure will be followed to identify the inferior parathyroid tumor on the contralateral side.

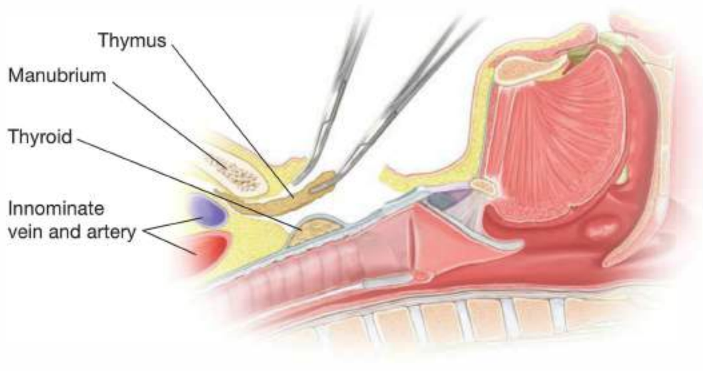

FIG 14 ● A transcervical thymectomy can be accomplished to identify ectopic inferior parathyroid glands that lie caudal to the sternal notch. The thymic tissue is grasped and gently pulled up from the mediastinum and into the cervical incision.

FROZEN SECTION PATHOLOGIC ANALYSIS

- It is often advisable to confirm the identity of the four parathyroid glands identified with frozen section.
- Frozen section is used to confirm identification as parathyroid tissue more so than to quantify cellularity of the parathyroid gland. It is nearly impossible to reliably determine parathyroid hyperplasia from a parathyroid adenoma on frozen section (**FIG 15A,B**).

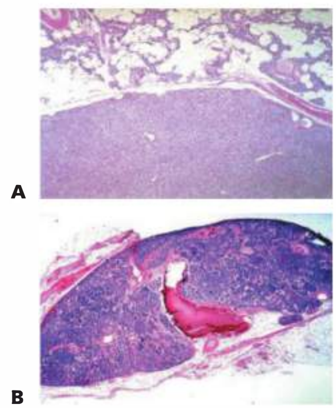

FIG 15 ● Low-power photomicrographs of **(A)** a parathyroid adenoma and **(B)** a hyperplastic parathyroid gland. The adenoma has a characteristic compressed rim of normal parathyroid tissue, with admixed adipocytes and parathyroid chief cells.

SUBTOTAL RESECTION OF PARATHYROIDS

- If a subtotal resection of the parathyroid glands is to be done, one plans to resect three and a half of the four glands. This is best done by dividing one of the glands first and continually checking on its viability as the resection of the second through fourth glands ensues to avoid an inadvertent total parathyroidectomy.
- In general, the remnant of parathyroid gland to remain on its native blood supply in the neck should be a portion of the most normal-appearing gland of the four identified.
- If possible, a remnant inferior gland should be left, as this remnant will sit more anterior, and anterior to the recurrent laryngeal nerve, making it easier to reoperate upon if necessary.
- A sufficient parathyroid remnant is about 30 to 50 mg of tissue or the size of a normal parathyroid gland.
- The parathyroid remnant is created by placing a metallic clip or clips across the gland and sharply dividing the distal segment of the gland away from the remnant (**FIG 16**).
- The remnant may also be tagged with a Prolene suture to aid in future identification if a reoperation becomes necessary. Great care should be taken when placing this marking stitch to avoid injury to the end arteriole feeding the parathyroid gland.
- The second through fourth glands are removed by dividing the vascular pedicle of the gland. The vascular pedicle can be clipped or tied as per surgeon preference.

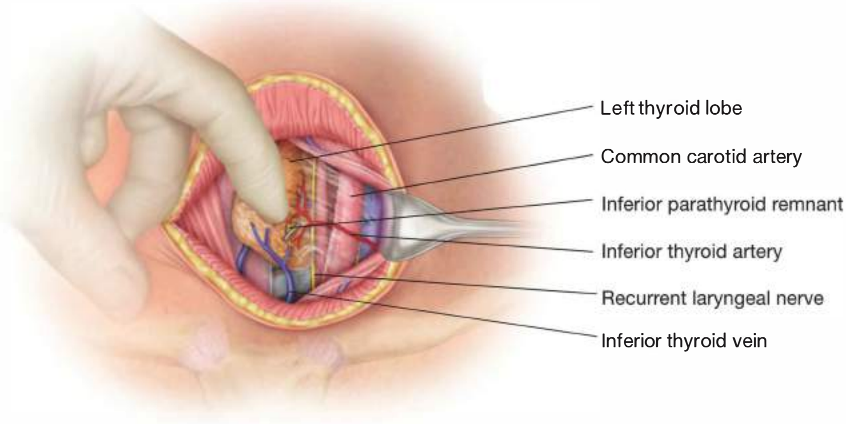

FIG 16 ● A remnant of a left lower parathyroid gland is left on its native blood supply. A metallic surgical clip is placed to divide the gland and to mark in the case that a future reoperative parathyroid surgery becomes necessary. Great care must be taken to ensure that the clip is not placed across the blood supply to the parathyroid remnant.

TOTAL PARATHYROIDECTOMY

- A total parathyroidectomy involves the removal of all parathyroid tissue (usually four glands) from the neck.
- Each gland is fully dissected back to its vascular pedicle, which is clipped or ligated and then divided.
- The parathyroid tissue to be transplanted is identified and kept moist. Great care should be taken to avoid this tissue from mistakenly being handed off the sterile field (**FIG 17**).

FIG 17 ● Ex vivo right superior parathyroid adenoma.

INTRAOPERATIVE PARATHYROID HORMONE MONITORING

- If intraoperative PTH monitoring is being used, a postresection PTH value should be drawn and sent at 5, 10, or 15 minutes postresection of all parathyroid tissue. Timing is per the surgeon's protocol. Longer time points (15 minutes) are usually used if the PTH specimen is being drawn from a central vein (internal jugular). Shorter time points may be used if the specimen is from a peripheral venipuncture or a radial arterial line.[6]
- Resolution of hyperparathyroidism and long-term eucalcemia is well predicted by postresection PTH values that are at least 50% of the baseline value and into the normal range (<40 pg/mL).[7]

HEMOSTASIS

- Careful attention to hemostasis is of paramount importance throughout the entire parathyroidectomy to ease in parathyroid identification.
- Postoperative neck hematomas are a rare but potentially disastrous complication following parathyroidectomy.
- Prior to wound closure, a Valsalva maneuver is requested to decrease venous return and to identify any slight bleeding in the operative bed.
- Topical hemostatic agents may be placed in the tracheoesophageal groove and inferior to the thyroid lobes.
- Routine placement of closed suction drains is not required.

WOUND CLOSURE

- The two layers of strap musculature are closed in the midline in either one layer or two separate layers. Three to four interrupted, absorbable stitches are sufficient to reapproximate these muscles.
- The platysma muscle layer is reapproximated with interrupted, buried, absorbable sutures.
- The skin edges are brought together with a 3-0 Prolene suture in a subcuticular stitch.
- Skin glue is applied to the wound, and once dry, the Prolene suture may be removed immediately. No further dressings are required.

IMMEDIATE PARATHYROID AUTOTRANSPLANTATION

- If a total parathyroidectomy has been performed, one must reimplant autologous parathyroid tissue to avoid permanent hypoparathyroidism.
- Roughly 30 to 50 mg of parathyroid tissue should be transplanted.
- The upper extremity in which the parathyroid graft is to be placed is extended out from the patient and supported on an arm board (**FIG 18**).
- The transplant site is into the brachioradialis muscle on the dorsal aspect of the forearm (usually the nondominant forearm). Again, thought must be given to the location of a current or future hemodialysis access in those patients on chronic renal replacement therapy.
- The dorsal forearm is prepped and draped in the usual fashion.
- A 3- to 4-cm longitudinal incision is made, and dissection is deepened through the subcutaneous tissue to the fascia overlying the brachioradialis muscle (**FIG 19A,B**).
- The fragment of parathyroid tissue to be transplanted is then cut into 1-mm^3 fragments, totaling about 15 fragments (**FIG 20**).
- A small muscle pocket is made in the brachioradialis muscle with the tip of a dissecting instrument, and a single

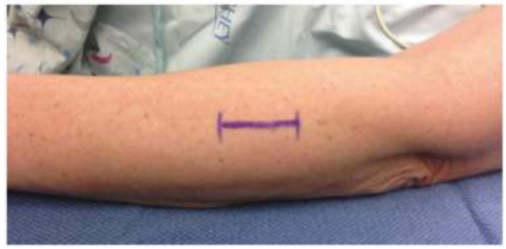

FIG 18 ● The heterotopic transplant site is marked prior to surgical prepping and draping. The transplant site is the brachioradialis muscle of the nondominant forearm.

FIG 19 ● Preparing the recipient site for parathyroid tissue. **A.** Dissection through subcutaneous tissue to the level of the brachioradialis muscle. **B.** Exposed brachioradialis muscle.

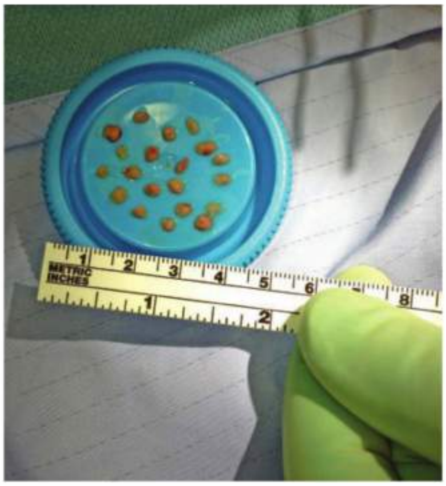

FIG 20 ● Minced parathyroid to be transplanted. Numerous 1-mm^3 fragments of parathyroid tissue await placement into individual muscle pockets.

fragment of parathyroid tissue is placed into this pocket. The edges of the pocket are loosely approximated with an absorbable suture or a metallic clip.

- This procedure is repeated until each fragment of parathyroid tissue has been placed into a separate muscle pocket (**FIG 21**).
- Great care needs to be taken to avoid any bleeding in these muscle pockets as the initial nutrient supply of the parathyroid graft requires contact with the vascularized muscle.
- The wound is then closed in layers, using interrupted, absorbable sutures to close the deep dermal layers and tissue adhesive to reapproximate the skin edges (**FIG 22**).

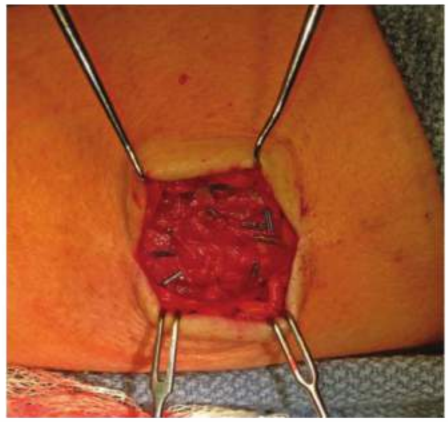

FIG 21 ● Parathyroid autotransplantation completed, with muscle pockets loosely approximated with metallic clips.

FIG 22 ● The transplant incision is closed with skin glue.

PEARLS AND PITFALLS

Indications	■ Hyperparathyroidism is a biochemical diagnosis, and this needs to be secured prior to cervical imaging or planning an operation.
Identification of parathyroids	■ Dissection in the central neck space should free the carotid sheath medially and include all the tissue down to the prevertebral fascia.
Excision of parathyroid adenomas	■ Parathyroid glands have a singular blood supply and should be dissected back to this vessel prior to ligation and division to avoid injury to critical adjacent structures such as the recurrent laryngeal nerve.
Hemostasis	■ A bloodless field greatly aids in the identification of parathyroid glands from their surrounding tissue. ■ A hematoma at the site of a parathyroid transplant greatly jeopardizes the viability of the autologous graft.
Placement of autologous graft	■ The parathyroid autotransplant may be placed in either the dorsal forearm or the presternal area.
Postoperative hypocalcemia	■ Anticipate and aggressively treat the hypocalcemia that accompanies either a subtotal parathyroidectomy or certainly a total parathyroidectomy with autologous graft.

POSTOPERATIVE CARE

- Patients undergoing subtotal parathyroidectomy or total parathyroidectomy with autologous graft should be admitted for at least 1 day to monitor postoperative calcium and PTH levels.
- Patients having undergone a forearm parathyroid transplant should have a limb alert placed, and blood pressures, IV sites, and venipunctures should be avoided in the transplant arm.
- Acetaminophen or ibuprofen is often sufficient for the pain related to the procedure. Occasionally, opioid agents are needed for a short time postoperatively.
- Endocrinology consultation can be sought as needed by the surgical team.
- Oral calcium and possibly vitamin D (in the form of calcitriol) should be started immediately and titrated if hypocalcemia occurs.
- Patients having undergone a total parathyroidectomy will have an obligate period of hypoparathyroidism until their autograft begins to function.
- Parenteral calcium should be restricted to severely low serum calcium levels and/or patients with symptomatic hypocalcemia.
- Symptoms of hypocalcemia include perioral and digital numbness or tingling, muscle aches/spasms, carpopedal spasms, facial nerve hyperactivity (Chvostek's sign), respiratory muscle insufficiency, and tetany.

OUTCOMES

- The long-term outcome as measured by eucalcemia from a subtotal parathyroidectomy and a total parathyroidectomy with immediate parathyroid autotransplantation are very similar. Both have a small rate of recurrent hyperparathyroidism (as a result of the natural history of the parathyroid disease). This recurrence may occur 10 to 20 years after the index operation.[8]
- Immediate transplantation of autologous parathyroid tissue has successful engraftment approximately 95% of the time. Most parathyroid grafts will gain function in about 8 weeks.[9]

COMPLICATIONS

- Compressive cervical hematoma
- Laryngeal nerve injuries (external branch of the superior laryngeal nerve or recurrent laryngeal nerve)
- Sympathetic chain/stellate ganglion injury
- Prolonged or permanent hypoparathyroidism
- Inability to extirpate all hyperactive tissue with resultant persistent hyperparathyroidism
- Tracheal injury
- Esophageal injury
- Lymph or chylous leak
- Wound infection
- Unsightly neck or arm scarring

Chapter 43

Minimally Invasive Parathyroidectomy

Peter Angelos Raymon H. Grogan

DEFINITION

- Although there is no uniformly agreed upon definition of a "minimally invasive parathyroidectomy" (MIP), most surgeons accept that this term refers to an operation to remove the parathyroid gland that is a focused or unilateral exploration done through a small incision.[1] Some surgeons stress that MIP should also refer to an operation done without general anesthesia in an outpatient setting. However, we believe that because the choice of anesthesia and determination of whether a patient is discharged on the day of surgery is dependent on the patient (and not always the operation), we do not limit MIP to outpatient procedures without general anesthetic. We believe that MIP is the treatment of choice for primary hyperparathyroidism (HPT) when the location of the abnormal parathyroid gland has been well localized preoperatively.[2,3]
- MIP is effective and recommended for the treatment of sporadic primary HPT but not in cases of familial HPT (e.g., multiple endocrine neoplasia type 1 or 2), secondary HPT, or tertiary HPT. In all of the latter categories, the high likelihood of multigland disease necessitates the exploration of all four glands.
- Although MIP is effective in both primary operations as well as in reoperative cases, we will focus on primary operations in the following description. The decision making for reoperative parathyroidectomy is complicated by the scarring that will be present in the neck and the potential difficulty with performing a four-gland exploration. For this reason, preoperative localization becomes much more important in reoperative cases and is beyond the scope of this chapter.

DIAGNOSIS AND INDICATIONS FOR SURGERY

- The diagnosis of HPT is made by the finding of an elevated calcium level with an elevated intact parathyroid hormone (iPTH) level. It is possible to have normocalcemic HPT if the calcium level is at the upper range of normal but the iPTH is elevated. Alternatively, patients sometimes have elevated calcium levels with the iPTH level being inappropriately in the high normal range. It is important when making the diagnosis of HPT to assess both calcium and iPTH levels so that the relative values of these tests can be compared. In a patient with normally functioning parathyroid glands, a high calcium should be associated with a low iPTH level.
- In order to confirm the diagnosis of HPT and rule out familial benign hypocalciuric hypercalcemia (FBHH), a 24-hour urine calcium should be obtained. In FBHH, the urinary calcium is expected to be very low. A normal or elevated 24-hour urine calcium level effectively rules out FBHH. An elevated 24-hour urine calcium increases the risk of kidney stones.
- The indications for surgery in HPT are well described in several National Institutes of Health (NIH) consensus conferences over the last few decades.[4] Most surgeons and endocrinologists currently agree that patients with HPT who are symptomatic or have marked elevations in serum calcium should have surgery. A history of kidney stones and the presence of osteoporosis are widely accepted as indications for surgery. It is common for patients with HPT to have additional symptoms that may be associated with the disease, including low energy, bone pain, decreased proximal extremity muscle strength, decreased ability to concentrate, and reductions in short-term memory. Although all of these symptoms may be caused by conditions other than HPT, they are very common in patients with HPT and may influence the decision to recommend surgery.
- The diagnosis of HPT in a young patient (<50 years old) also is a relative indication for parathyroidectomy because such patients will have more years to develop osteoporosis and other problems associated with HPT. In addition, for women of childbearing age, HPT also appears to increase the risks of spontaneous abortion.
- There is currently no approved medical treatment for primary HPT. For this reason, the choice for patients and physicians is between parathyroidectomy and continued observation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Once the decision is made to proceed to surgical treatment, localization studies to attempt to identify the location of the abnormal parathyroid gland are indicated. We recommend the routine use of technetium-99m (Tc-99m) sestamibi scan and ultrasound evaluation of the thyroid gland.[5]
- Sestamibi scanning has high rates of sensitivity and specificity and is effective in localizing not only parathyroid adenomas in the neck but also in ectopic locations such as undescended glands in the neck or intrathoracic glands. Unfortunately, in cases of multigland disease, sestamibi scanning is least likely to identify the location of abnormal glands. Sestamibi is taken up by both thyroid and parathyroid cells. It is more rapidly cleared from thyroid cells than from abnormal parathyroid cells. For this reason, a comparison of early and delayed scans often reveals the presence of a persistent focus of increased activity in the abnormal parathyroid gland. With the use of fused sestamibi–computed tomography (CT) scanning or three-dimensional single photon emission computed tomography (SPECT) reconstructions, it is often possible to determine

whether the focus of uptake is anterior in the neck (at or near the level of the thyroid lobe) or more posterior. Because the superior parathyroid gland is located posterior to the recurrent laryngeal, posterior parathyroid glands on scans are most likely superior glands, whereas anterior glands are more likely to be inferior glands.

- Ultrasonography is an effective noninvasive means of identifying abnormal parathyroid glands. The study can be performed in the radiology department or by surgeons in the clinic or operating room. Ultrasonography is effective in identifying enlarged parathyroid glands that are close to the thyroid gland. Abnormal parathyroid glands usually appear as hypoechoic lesions either posterior or inferior to the thyroid gland. Parathyroid glands that are located posterior to the esophagus and those in the mediastinum are less likely to be visualized on ultrasound.
- Ultrasound is very effective at identifying thyroid nodules, which may be a source of increased uptake on sestamibi scans. We believe that thyroid nodules greater than 1 cm or with suspicious characteristics should be evaluated with fine needle aspiration cytology prior to planned parathyroidectomy. This strategy limits the chances of missing a nonpalpable thyroid malignancy and thus reduces the likelihood for reoperative neck surgery.
- In cases of primary HPT when patients have negative preoperative localization studies, we recommend proceeding with surgery and planning on a four-gland exploration (see Part 5, Chapter 41). Some surgeons would obtain a four-dimensional CT scan of neck and chest prior to exploring the patient. However, we believe that additional evidence is required before this approach should be routinely adopted.

SURGICAL MANAGEMENT

- MIP can be performed either with local anesthesia and sedation or with general anesthesia, depending on surgeon and patient preference. We have found that because inferior parathyroid adenomas are located more anteriorly in the neck, these glands are more amenable to resection without using general anesthesia. Large posteriorly located superior parathyroid adenomas often are more challenging to remove without general anesthetic because of the need to rotate the thyroid lobe medially to gain access to the space posterior to the esophagus. Although it is possible to access these glands even when the patient is not asleep, surgeons should be cognizant of the challenge and choose the appropriate patient for such an approach.
- Identification of the optimal skin crease for a cosmetic incision is best done with the patient sitting up while awake. Although extending the neck in the operating room may change the location of skin creases, marking them prior to entering the operating room increases the likelihood of a good cosmetic result.
- After the patient has been either intubated or appropriately sedated, the use of superficial cervical plexus block may be used to facilitate local anesthesia if the patient has not received a general anesthetic or to improve postoperative pain control if a general anesthetic is used.
- The superficial cervical plexus block is a safe, effective technique to provide cutaneous anesthesia to the C2, C3, and C4 dermatomes. We perform a two-point (transverse and inferior), bilateral superficial blockade to allow complete local anesthesia of the midline Kocher incision, which, if done correctly, will last for several hours after the procedure. Anecdotally, this should also allow for reduced general anesthesia intraoperatively, particularly for superficial lower parathyroidectomies. We use 10 mL of 0.25% bupivacaine without epinephrine for each side of the neck.
- After induction of general anesthesia, the patient's neck is extended with a beanbag or shoulder roll. The midpoint of the posterior border of the sternocleidomastoid muscle is identified, and a 22-gauge needle is inserted subcutaneously (no more than 1 cm) at this anatomic landmark (**FIG 1**). Check to be sure the needle is not inserted into a vein by pulling back on the plunger of the syringe. First, 5 mL of anesthetic are injected straight toward the midline of the neck (transverse injection) just posterior to the muscle. The needle is then repositioned without removing it from the skin so that it is now pointing at the sternal notch. The remaining 5 mL of anesthetic is then injected inferiorly along the posterior border of the muscle (inferior injection). The other side of the neck is then injected in a similar manner.
- If done correctly, there is minimal risk associated with this technique. The main risk of this procedure occurs if the injection is done too deep. If injected too deep into the neck, branches of the brachial plexus can be anesthetized, and the patient may have a temporary paralysis of the ipsilateral upper extremity. A deep injection can also anesthetize the phrenic nerve and lead to temporary diaphragmatic paralysis. For this reason, if the injection is being done without general anesthetic while the patient is awake, it is important that bilateral blockade is not performed simultaneously on both sides of the neck. Finally, if the injection infiltrates superiorly, the greater auricular branch of the plexus will be blocked, and the patient will have numbness of the skin overlying the parotid and the earlobe. This is a common side effect that the patient should be told to be aware of in the immediate postoperative period.

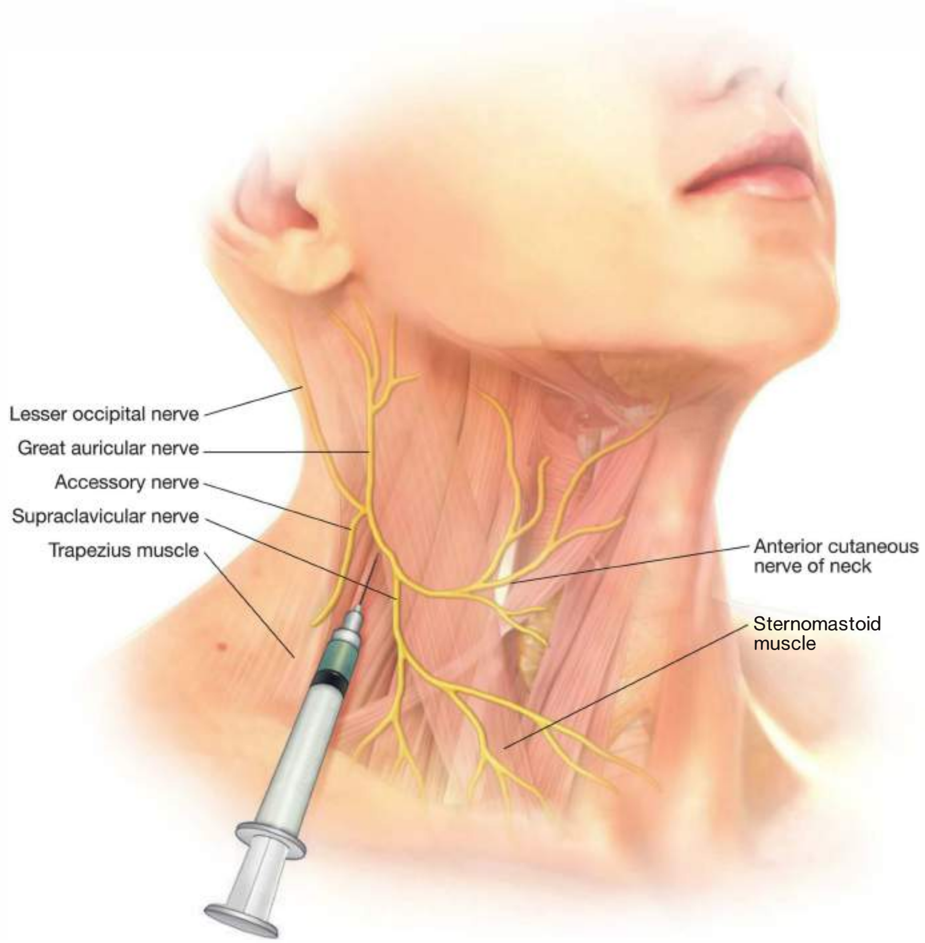

FIG 1 ● A 22-gauge needle is inserted no more than 1 cm subcutaneously at the midpoint of the posterior border of the sternocleidomastoid muscle. After assuring the needle is not in a vein, 5 mL of anesthetic is injected toward the midline of the neck (transverse injection). The needle is repositioned without removing it toward the sternal notch. The remaining 5 mL of anesthetic is then injected inferiorly along the posterior border of the muscle (inferior injection).

- Optimal positioning for parathyroidectomy is with the patient's neck gently extended but well supported. Prior to prepping the skin, we routinely perform an intraoperative ultrasound of the neck to ensure the choice of the optimal location for the skin incision (**FIG 2**). In addition, intraoperative ultrasound often allows the surgeon to confirm the location of the adenoma and focuses the subsequent surgical exploration.
- After prepping the skin, it is critical that if the patient has not received a general anesthetic, care must be taken when placing drapes to ensure that the operative field is fully separated from the space below the drapes. Patients who are receiving sedation and local anesthesia usually are also given supplemental oxygen by the anesthesiologist during the operation. This is commonly done with nasal cannula and results in relatively high oxygen concentrations below the drapes. If that oxygen comes in contact with a spark from electrocautery used during the performance of the parathyroidectomy, the risk of fire is increased. For this reason, when draping the patient, an occlusive dressing or adherent drapes are important to separate the operative field from the space below the drapes (**FIG 3**).
- A small (2 to 3 cm) incision in the midline is made in a skin crease. Although some surgeons prefer an incision shifted toward the side of the parathyroid adenoma, we prefer using a midline incision so that if it becomes necessary to explore both sides, the same incision can often be used. If it is necessary to lengthen the incision, this is usually only a minimal increase in incision size.

FIG 2 ● Ultrasound of the neck is performed prior to prepping the patient's neck. The ultrasound is particularly useful in determining the optimal location for the small neck incision. Note that the mark on the neck is of the skin crease but not the actual length of the incision.

FIG 3 ● Occlusive barrier dressing being placed. This is very important if the patient is not intubated and supplemental oxygen is used. The barrier dressing separates the space under the drapes from the operative field and reduces the risk of fire.

- Small subplatysmal flaps are created with electrocautery to allow the skin incision to be moved up or down depending on where the abnormal gland is located. The midline strap muscles are then separated in the midline so that the thyroid lobe on the involved side can be rotated medially (**FIG 4**). If, based on preoperative imaging, the abnormal parathyroid appears to be the inferior parathyroid, then the dissection is focused on the area near the inferior pole of the thyroid or in the thyrothymic tract where inferior parathyroid glands are most commonly located. If the abnormal parathyroid gland appears to be a superior gland, then dissection is focused on the more posterior tissue. The entire thyroid lobe is mobilized medially such that the space posterior to the esophagus can be adequately explored.
- Once an abnormal parathyroid gland is identified, the vascular pedicle should be carefully identified, ligated, and divided (**FIG 5**). Once adequate hemostasis is achieved, the incision is closed.

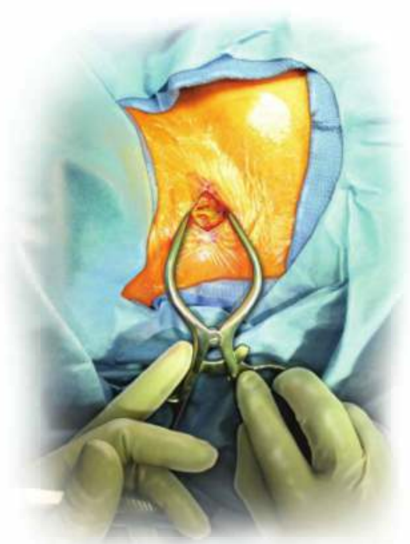

FIG 4 ● Small skin incision after the subplatysmal flaps have been created and the midline strap muscles have been separated to expose the thyroid gland below.

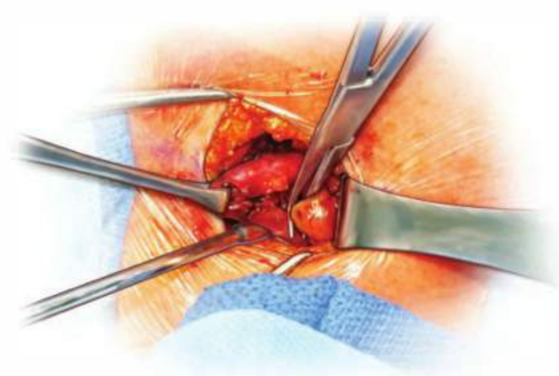

FIG 5 ● Parathyroid adenoma is identified in proximity to the thyroid gland. The parathyroid adenoma is separated from the surrounding tissue, taking care not to enter the capsule of the gland. The vascular pedicle is identified, ligated, and divided.

INTRAOPERATIVE DECISION MAKING WITH INTRAOPERATIVE PARATHYROID HORMONE

- We believe that intraoperative PTH assay is an important component of any MIP. iPTH has such a short half-life that if the abnormal parathyroid gland is removed and the other glands are normal, the PTH levels will drop by more than 50% in 5 to 10 minutes for the vast majority of patients. In most circumstances, a second peripheral intravenous catheter is placed prior to positioning the patient. Blood samples are then drawn through this intravenous catheter, taking care to ensure adequate blood is drawn to avoid a dilute sample from the intravenous fluid. We routinely draw four samples. The first is drawn after the skin preparation prior to making an incision ("preincision"). The second is drawn after finding the parathyroid adenoma prior to dividing its blood supply ("preexcision"). Postexcision levels are then drawn at 5 and 10 minutes after removing the parathyroid adenoma.
- Although many papers have been written on identifying the optimal criteria for intraoperative drop in PTH, we believe that a drop of 50% from the first baseline level at 5 or 10 minutes postexcision, as long as the value is within normal range, is strongly predictive of a successful operation.[6] If the preincision PTH level is very high and the preexcision level is even higher, it is sometimes necessary to draw levels beyond 10 minutes postexcision in order to see an adequate drop in PTH levels. We believe that with positive preoperative localization studies and a dramatic drop in PTH after excising the adenoma, the likelihood of a second abnormal parathyroid gland is exceedingly low and a four-gland exploration is not indicated.

CLOSURE

- As long as the skin incision is located in a skin crease or at least in line with skin creases, the likelihood of a cosmetically appealing scar is very high. We routinely close the skin with an absorbable suture in the platysma and subdermal level to take tension off the skin edges. The skin is closed with a 5-0 monofilament subcuticular suture with no knots. If an absorbable suture is used, Steri-Strips are applied and the suture is then cut flush with the skin. If a nonabsorbable suture is used, skin glue is placed over the incision prior to pulling the subcuticular stitch out in the operating room. Most patients have excellent cosmetic results.

POSTOPERATIVE CARE

- Assuming no other medical issues, many patients can be discharged after a successful MIP. Because a focused exploration has been undertaken, only one side of the neck has been dissected. Patients are generally given extra oral calcium for several days to prevent transient symptomatic hypocalcemia while the remaining parathyroid glands recover from having been suppressed. The extra calcium can be rapidly weaned. Patients are allowed to shower the day after surgery and the only restriction in activity is to avoid driving a car until there is no neck pain in turning and the patient is off pain medication.

OUTCOMES

- The outcomes after MIP have been shown to be excellent in several large series.[7,8] Patients recover rapidly and many have improvements in energy level with decreased bone pain in the weeks to months after surgery. The long-term risks of recurrent HPT are not different in many large series when comparing MIP with four-gland exploration.

COMPLICATIONS

- The primary risk of MIP is the small possibility of recurrent laryngeal nerve injury resulting in hoarseness. The risk of permanent hoarseness is in the 1% to 2% range in most large series of parathyroidectomies. Use of MIP in comparison to four-gland exploration does not seem to affect risk of recurrent laryngeal nerve injury. By contrast, the risk of permanent hypoparathyroidism, which is approximately 1% with a four-gland exploration, is eliminated with an MIP approach.
- Other potential complications of MIP include bleeding and infection. Both of these risks are extremely low with a parathyroidectomy and are not increased by use of MIP.

Chapter 44

Endoscopic Parathyroidectomy by Lateral Approach

Jean-François Henry

DEFINITION

- A minimally invasive parathyroidectomy (MIP) may be defined as an operation requiring a small and discrete incision for a very direct access to the parathyroid glands, resulting in a focused dissection. MIP may be divided in two groups: open MIP performed under direct vision via a small cervical incision[1] and various endoscopic MIP performed partially or totally with the help of an endoscope. Today, three different types of endoscopic parathyroidectomies can be considered to be an option for surgeons: (1) Video-assisted parathyroidectomy,[2] which is a mini-open procedure performed partially with the help of the endoscope. (2) Endoscopic techniques using an extracervical approach. These techniques have the advantage of leaving no scar in the neck area but cannot reasonably be described as minimally invasive as they require more dissection than conventional open surgery. (3) Pure endoscopic techniques using a cervical access. These operations are performed totally with the help of the endoscope and include constant gas insufflations. Two pure endoscopic techniques have been described: the endoscopic parathyroidectomy by midline approach[3] and the endoscopic parathyroidectomy by lateral approach (EPLA).[4] EPLA develops the plane between the carotid sheath laterally and the strap muscles medially. This "back-door route" does not require complete dissection of the thyroid lobe from the strap muscles. It allows direct access to the posterior aspect of the thyroid lobe and it does not require anterior and medial retraction of the thyroid lobe during the entire procedure.

DIFFERENTIAL DIAGNOSIS

- Today, the diagnosis of primary hyperparathyroidism (PHPT) can be made with near certainty by documenting an increased serum intact parathormone (iPTH) level in a patient with increased ionized or total calcium. It is therefore necessary to eliminate all other causes of hypercalcemia and iPTH elevation. As for iPTH elevation, renal dysfunction and vitamin D deficiency are well known. Among causes of hypercalcemia, thought should be given to the syndrome of benign familial hypocalciuric hypercalcemia (BFHH), where the hypercalcemia is associated with normal or slightly raised levels of iPTH coexisting with hypocalciuria.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient must be carefully selected. Not all patients presenting with HPT are candidates for an EPLA, as EPLA does not allow for a bilateral exploration.[5] Patients who are suspected to have multiglandular disease (MGD), including patients with secondary hyperparathyroidism (HPT) or patients with familial primary HPT, are not eligible for this procedure. Suspicion of parathyroid carcinoma is also an absolute contraindication. A history of neck irradiation, the presence of a large goiter and previous surgery in the thyroid vicinity are relative contraindications. EPLA can be performed in patients who have previously undergone a contralateral neck operation (Table 1).
- When considering EPLA, the adenoma must be solitary and clearly localized by preoperative imaging studies. Whether preoperative localizations techniques can rule out MGD with sufficient accuracy is questionable. Therefore, as with other minimally invasive techniques, the risk of missing MGD justifies the use of a quick intraoperative parathormone assay (QPTH).[6] The less definitive the localizations studies, the more imperative the need for QPTH.
- When patients are selected on the basis of the abovementioned criteria, no more than 50% of patients are eligible for this procedure (**FIG 1**).
- EPLA is technically more challenging than standard cervical exploration and its performance should be confined to tertiary centers. The surgeon must be experienced in conventional parathyroid surgery. Mentoring by a surgeon who has experience with endoscopic neck procedures is also recommended.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Only noninvasive tests should be considered. When these tests are negative, EPLA is not indicated and the traditional open cervicotomy is preferable. The topographic diagnosis should ideally be established by convergence of the results of two different investigations, one providing good anatomic information and the other providing functional information.
- High-resolution ultrasonography (US) and technetium-99m (Tc-99m) sestamibi scan are used most commonly in combination.[7] US can only assess the cervical region but gives good anatomic information, including useful information about the thyroid gland. The patient should be examined in the supine position with the neck in hyperextension. A pillow can be placed under the shoulders if the patient has a short neck. A high-frequency linear transducer

Table 1: Absolute and Relative Contraindications for Endoscopic Parathyroidectomy by Lateral Approach

Absolute contraindications
Suspicion of parathyroid carcinoma
Large goiter
Secondary or tertiary HPT
Familial HPT
Suspicion of MGD
No localization
Relative contraindications
Previous surgery
History of neck irradiation
Large tumor (>3 cm)
Inferior adenoma located anteriorly

HPT, hyperparathyroidism; MGD, multiglandular disease.

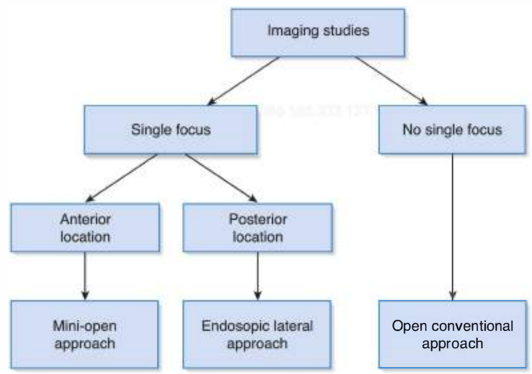

FIG 1 ● Algorithm for the surgical management of patients eligible for an endoscopic parathyroidectomy by lateral approach.

(7.5 to 10 MHz) is used to obtain optimal depth penetration of 3 to 4 cm. A bilateral and comparative scan should be performed in transverse section, then in longitudinal section. In transverse section, the examination concentrates on an area defined by the longus colli muscles posteriorly, the thyroid gland anteriorly, the trachea medially, and the carotid artery laterally. The scan is then performed in cranial and caudal directions. An additional scan can be performed with the head of the patient turned away to the side and during deglutition to optimize the lateroesophageal images. The anterosuperior mediastinum is examined by inclining the transducer deeply in a retrosternal direction. The examiner should note the precise location with respect to surrounding structures, particularly to the thyroid gland, and the depth from the skin. Finally, a color flow Doppler or a power flow Doppler will be performed to test the vascularization of the area and define the artery branches involved.

- Two protocols for sestamibi scanning can be used: the single isotope dual phase protocol and the substraction protocol. The dual protocol requires early (15 minutes postinjection) and delayed images (at 1 and 2 to 3 hours, depending on thyroid washout). In cases of multinodular thyroid disease, additional further delayed images are sometimes needed. When a subtraction protocol is used, Tc-99m sestamibi is used in conjunction with another radionuclide specific to the thyroid. Tc-99m pertechnetate and ^{123}I are the most widely used radioisotopes for thyroid scintigraphy. The main advantage of using ^{123}I is that thyroid and parathyroid images can be acquired simultaneously in a dual energy window setup. The disadvantage is the cost of the protocol related to ^{123}I. Parathyroid scintigraphy should include views of the neck and the mediastinum. Single-photon emission computed tomography (SPECT) can be helpful for more precise localization of adenomas, as it provides simultaneous three-dimensional (3-D) information on both neck and superior mediastinum.
- Instead of US and Tc-99m sestamibi scan, four-dimensional computed tomography (4D-CT)[8] or the use of computed axial tomography-methoxyisobutyl isonitrile (MIBI) image fusion,[9] when available, may be preferable.
- Consideration for EPLA depends on the results of preoperative imaging. EPLA should be strongly considered when the parathyroid adenoma is in close proximity to the recurrent laryngeal nerve, as the nerve is at risk during MIP. Therefore, EPLA is the procedure of choice in all cases where the parathyroid adenomas are deeply located in the neck.
- Three locations of parathyroid adenomas with regard to the recurrent laryngeal nerve can be described (**FIG 2**).[4] Location 1 is posterior to the two superior thirds of the thyroid lobe (**FIGS 3** and **4**). These adenomas are superior glands. Location 2 is at the level of or below the inferior pole of the thyroid lobe but in a plane posterior to it (**FIGS 5** and **6**). These adenomas may be either a superior gland that has migrated posteriorly and in a downward direction or an inferior gland that has fallen posteriorly. These glands can also migrate into the superior and posterior mediastinum. Location 3 is at the level of or below the inferior pole of the thyroid lobe but in a superficial plane (**FIGS 7** and **8**). These adenomas are always inferior glands and can be found in close contact with the tip of the inferior pole of the thyroid lobe but also along the thyrothymic ligament or into the superior pole of the thymus.

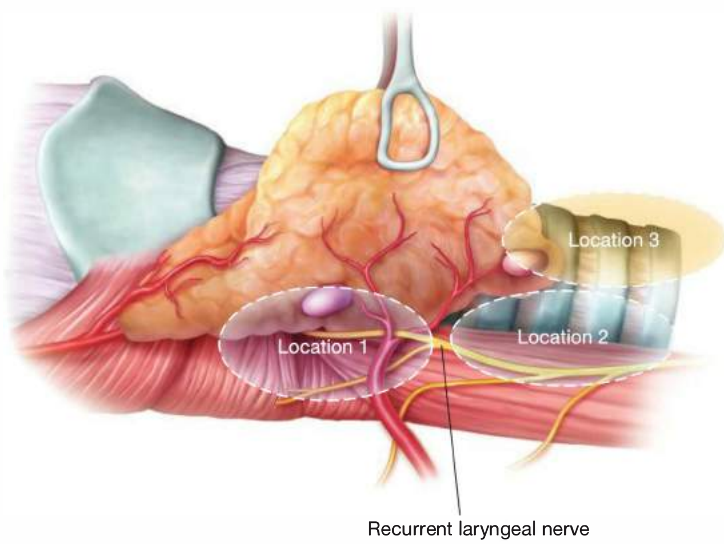

FIG 2 ● The three different locations of parathyroid adenomas with regard to the recurrent laryngeal nerve. Location 1, posterior to the two superior thirds of the thyroid lobe; location 2, at the level of or below the inferior pole of the thyroid lobe but in a plane posterior to it; location 3, at the level of or below the inferior pole of the thyroid lobe but in a superficial plane.

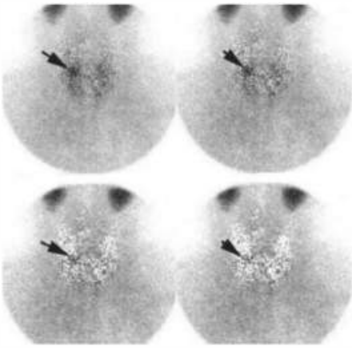

FIG 3 ● Parathyroid Tc-99m sestamibi scintigraphy; subtraction protocol. The subtraction image demonstrates a right parathyroid adenoma at the level of the middle third of the right thyroid lobe *(arrow)*.

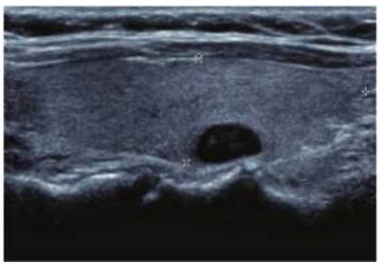

FIG 4 ● Ultrasound (same patient in **FIG 3**). Right parathyroid adenoma posterior to the middle third of the thyroid lobe: right superior parathyroid adenoma in location 1. EPLA is indicated.

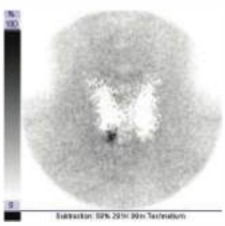

FIG 5 ● Parathyroid Tc-99m sestamibi scintigraphy; subtraction protocol. The subtraction image demonstrates a right parathyroid adenoma at the level of the inferior third of the right thyroid lobe.

FIG 6 ● Ultrasound (same patient in **FIG 5**). Right parathyroid adenoma posterior to the inferior third of the thyroid lobe: right, more probably inferior, parathyroid adenoma in location 2. EPLA is indicated.

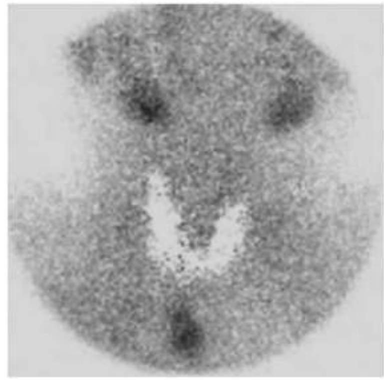

FIG 7 ● Parathyroid Tc-99m sestamibi scintigraphy; subtraction protocol. The subtraction image demonstrates a right parathyroid adenoma below the inferior pole of the thyroid lobe.

- Adenomas in locations 1 and 2 are deeply located and are in the vicinity of the recurrent laryngeal nerve. The nerve is at risk and its clear identification during the procedure is recommended. The lateral view, provided by EPLA, permits its easy identification and allows a secure dissection. On the other hand, adenomas in location 3 are at distance from the nerve, which runs more deeply. Its identification is not essential. An anterior mini-open approach without the help of the endoscope is indicated.
- In conclusion, the need to know preoperatively when the nerve is at risk reinforces the role of preoperative imaging studies. Depending on whether the patient has a deep-seated adenoma or a superficial-seated adenoma, the surgeon can choose between EPLA and an anterior mini-open approach.
- The main interest of using an endoscope is not that one can perform a parathyroidectomy through a small incision but that one can perform a safe parathyroidectomy through a small incision.

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to surgery, the patient undergoes a vocal cord check.
- The procedure is performed under general anesthesia with endotracheal intubation. Trocars are poorly tolerated by

FIG 8 ● Ultrasound (same patient in **FIG 7**). The adenoma *(2)* is in the superficial plane, below the inferior pole of the thyroid lobe *(1)*, along the thyrothymic tract: right inferior parathyroid adenoma in location 3. There is no need for the endoscope. A mini-open procedure is indicated.

FIG 9 ● Instruments of 3-mm trocars (Medtronic Xomed, MicroFrance, Saint Aubin Le Monial, France).

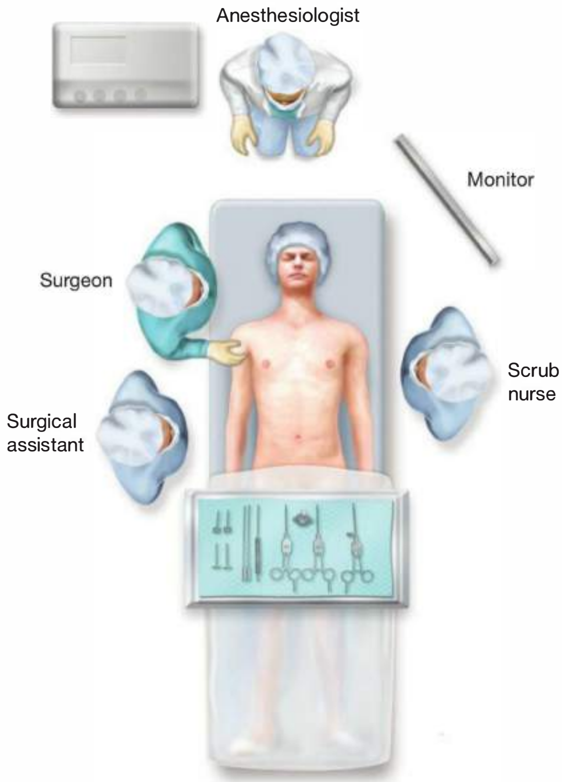

FIG 10 ● Operating room organization.

patients under local or regional anesthesia. In addition, swallowing and spontaneous breathing present impediments when dissecting in a small operative space.

- The surgical instruments required include a 10-mm trocar, which will accommodate a 0-degree fiberoptic endoscope, and two 3-mm trocars, which will receive a series of purpose-made instruments (Medtronic Xomed, MicroFrance) including blunt-tipped dissectors, graspers, scissors, a diathermy hook, and an aspiration canula. These instruments measure 25 cm in length (**FIG 9**).
- In patients presenting with small parathyroid adenomas less than 2 cm in diameter, a 5-mm trocar and a 5-mm 0-degree endoscope can be used.
- QPTH assays are performed before and at the time of incision, directly before parathyroid excision and, subsequently, 5 and 15 minutes after parathyroid excision. Parathyroidectomy is considered successful when QPTH value falls by greater than 50% with respect to the highest preexcision level and into normal range (10 to 65 pg/mL).[5]
- The surgical team consists of the operator, first assistant, and a scrub nurse. The surgeon and first assistant stand on the side of the diseased gland, with the scrub nurse facing them. The monitor is placed next to the scrub nurse and directly in front of the surgeon (**FIG 10**).

Positioning

- The patient is positioned in the supine position. The head is placed in a neutral position without hyperextension to avoid tensing the sternocleidomastoid muscle (SCM) and the strap muscles. Complete relaxation and suppleness of these muscles are essential to prevent narrowing down the operative space given that this is maintained with low-pressure gas insufflation. The patient is prepped and draped as for standard parathyroid surgery.

THE BACK-DOOR APPROACH

- An initial 12- to 15-mm transverse skin incision (optic trocar incision) is made on the anterior border of the SCM, at the level of the thyroid isthmus (**FIG 11**). It will permit the creation of a space through which the 10-mm trocar will be introduced. This incision is placed such that in the event of conversion, it can be extended medially to result in a symmetric collar incision.
- After division of the platysma, the anterior border of the SCM is identified and the investing layer of cervical fascia is incised. This allows access to the plane of dissection between the SCM laterally and the strap muscles medially, just inferior to the omohyoid muscle (**FIG 12**).
- The fascia connecting the posterior aspect of the thyroid lobe medially to the carotid sheath laterally is gently divided with scissors (**FIG 13**). A middle thyroid vein may be encountered. It is ligated without any difficulty through the incision.
- A small moist gauze is then inserted through the incision and packed deeply in an upward and downward direction into the initially created space (**FIG 14**). This blind maneuver enlarges the cavity and permits a surprisingly quick, efficient, and bloodless exposure of the operative field.

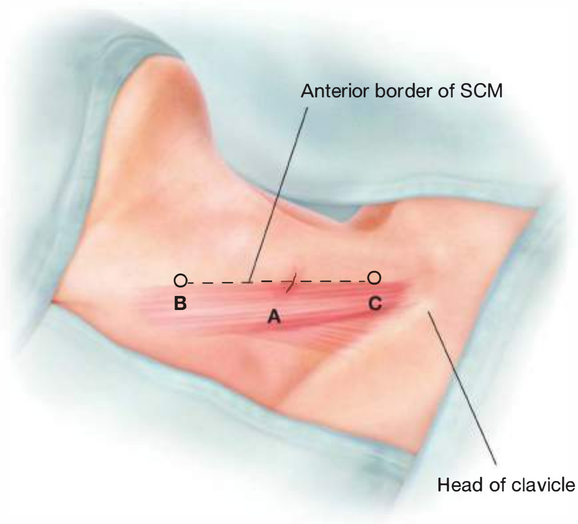

FIG 11 ● Trocar sites. All three trocars are positioned on the line of the anterior border of the SCM. Main trocar *(A)* is placed at the level of the thyroid isthmus. Trocars *B* and *C* should be 3 to 4 cm apart and will be used for the 2-mm instruments. SCM, sternocleidomastoid muscle.

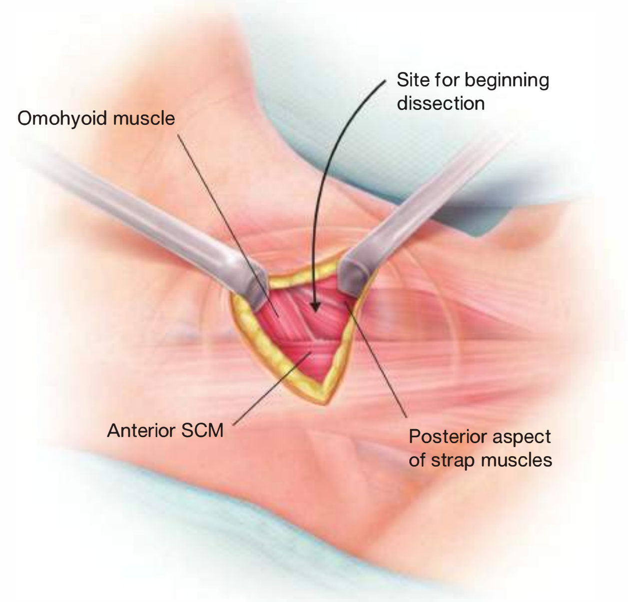

FIG 12 ● The access to the plane of dissection between the SCM laterally and the strap muscles medially is just inferior to the omohyoid muscle. SCM, sternocleidomastoid muscle.

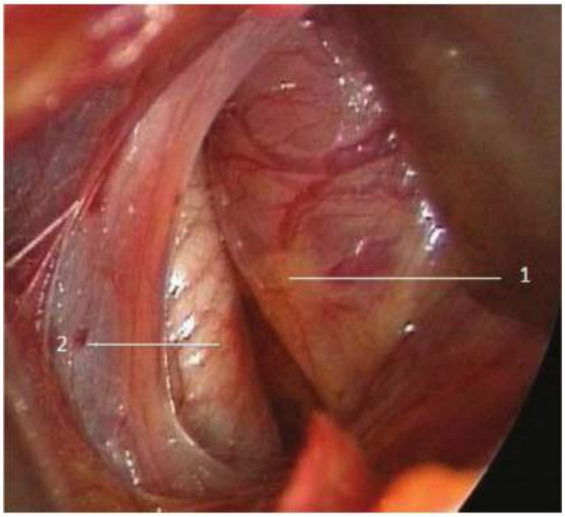

FIG 13 ● The back-door approach uses the plane between the posterior aspect of the thyroid lobe medially *(1)* to the carotid sheath laterally *(2)*.

FIG 14 ● Creating space for endoscopic exploration. A small moist gauze roll is inserted through the incision and packed deeply into the initially created space.

INSTALLATION OF THE TWO 3-MM WORKING TROCARS

- The two 3-mm trocars are placed on the line situated along the anterior border of the SCM, in their respective positions, above (5 to 6 cm) and below (3 to 4 cm) the main optic trocar incision. Safe trocar placement is achieved by tunnelling a 2.5-mm drain introducer needle inserted from within the main incision through to the skin. The direction this guide takes must follow the anterior border of the SCM. During this maneuver, one must constantly be aware of the internal jugular vein situated posteriorly, the external jugular vein situated cranially, and the anterior jugular vein situated caudally. The 3-mm trocar is placed over the tip of the introducer needle, which has pierced the skin from inside out and railroaded into the operative space (**FIG 15**). Each appropriately positioned 3-mm trocar is then loosely fixed to the skin with a nonabsorbable monofilament stitch to prevent involuntary removal.

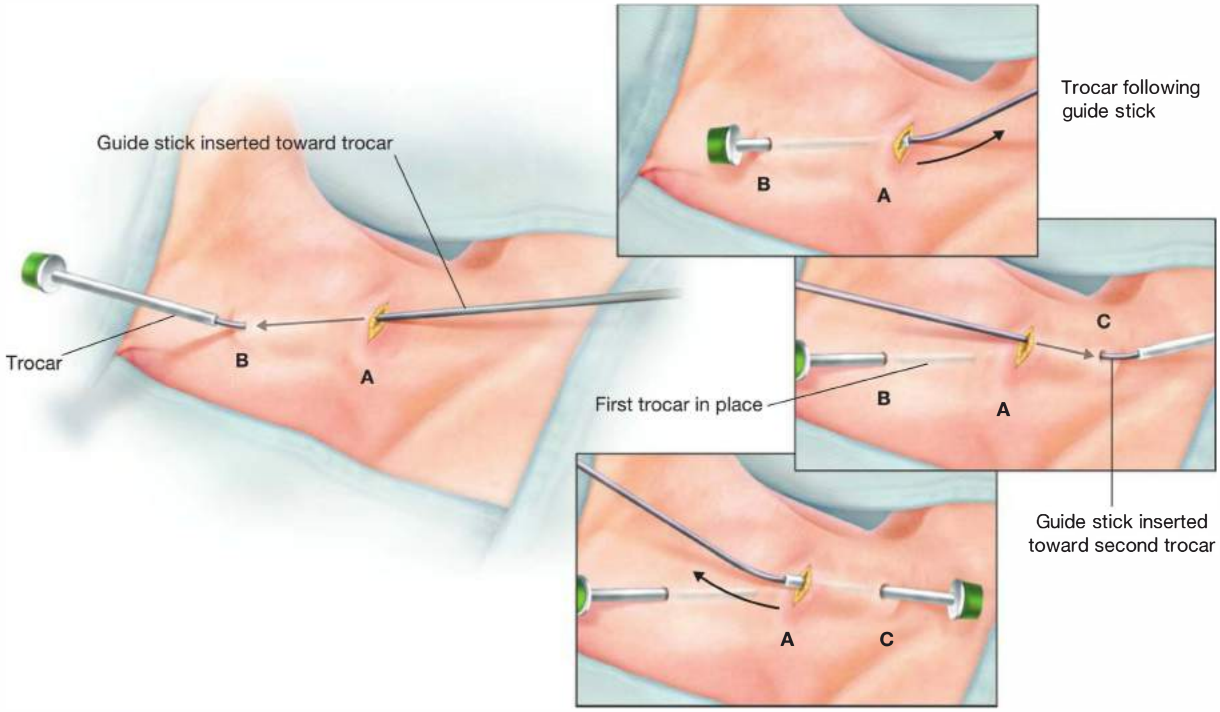

FIG 15 ● Installation of the 3-mm trocars. The transparietal path of both trocars is made through the incision *(A)*, from the inside to the outside, using a guide stick. The pathway of the guide stick must follow the anterior border of the SCM. Then, the 3-mm trocar is placed over the tip of the guide stick and railroaded into the operative space.

INSTALLATION OF THE 10-MM OPTIC TROCAR

- A purse-string stitch is placed around the main wound. It incorporates not only the skin but also the anterior border of the SCM laterally and the posterior border of the sternothyroid muscle medially. At this stage, the gauze roll is removed, the 10-mm trocar inserted and held in position with the purse-string suture.
- The purse string is subsequently threaded through an eyelet mounted on a specifically designed device encircling the trocar and secured to this (**FIG 16**). This arrangement guarantees air tightness, allows the amplification of the operative space, and prevents the trocar from slipping out of the wound.
- The three trocars are now positioned. The assistant takes care of the endoscope and the surgeon works through the other two trocars (**FIG 17**).

FIG 16 ● Installation of the main trocar. A purse-string stitch is placed around the main wound and is tied on a specifically designed device encircling the main trocar.

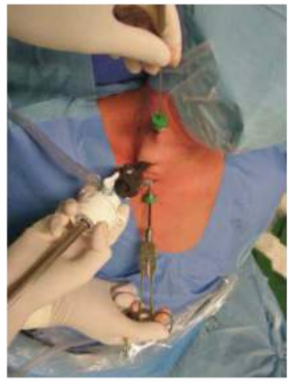

FIG 17 ● The three trocars are positioned. Insufflation (8 mmHg) is installed. The assistant holds the camera and the operator works through the other two 3-mm trocars. Endoscopic exploration can start.

ENDOSCOPIC PARATHYROID EXPLORATION

- A pneumocervicotomy is established using insufflation with carbon dioxide (CO_2) at low pressure (8 mmHg). The gas not only maintains the working operative space but also may tamponade off minor bleeders. First, the carotid must be identified. Then, the space between the carotid laterally and the posterolateral aspect of the thyroid lobe medially is developed. The dissection is performed with the help of two blunt-tipped metallic dissectors. Ligatures or clip applications are not necessary. The combination of blunt dissection and gas insufflation allows easy separation of structures, minimizing the need for sharp dissection. This facilitates identification of the key structures and landmarks that will permit a safe dissection. The inferior thyroid artery and, of course, the recurrent laryngeal nerve must be identified first. The inferior thyroid artery is a useful landmark for locating the recurrent laryngeal nerve. The easiest site to identify the nerve is at the level of the lower pole of the thyroid gland, just caudally to the trunk of the artery. On the left side, the nerve ascends at the depth of the tracheoesophageal groove. On the right side, the nerve courses more obliquely. The magnification allowed by the endoscope provides improved visualization of the vasa nervorum running along the nerve and help its identification.
- Very often one can observe that the nerve branches far below its laryngeal entry point (**FIG 18**). Also, small extralaryngeal branches extending to the adjacent trachea and esophagus are easily seen.

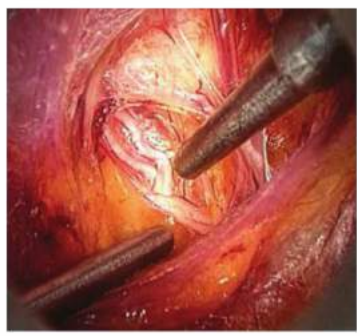

FIG 18 ● Endoscopic exploration on the right side: identification of the right recurrent laryngeal nerve. In this case, the nerve branches far below its laryngeal entry point.

IDENTIFICATION OF THE PARATHYROID ADENOMA

- Based on the results of the preoperative imaging studies, the surgeon may suspect an adenoma in location 1 or 2.
- All glands in location 1 are superior parathyroid adenomas. The search for them requires the dissection of the upper two-thirds of posterior aspect of the thyroid lobe (**FIG 19**). Small superior adenomas usually remain located in their orthotopic site, floating in a loose, fatty setting immediately adjacent to the inferior thyroid artery. Large superior adenomas tend to migrate posteriorly and downward. Therefore, if they are not found in immediate contact with the thyroid capsule, they should be sought beside or behind the esophagus.
- Glands in location 2 may be also superior parathyroid adenomas. Their migration may drag them down very low, well below the inferior thyroid artery, behind whose

FIG 19 ● Endoscopic exploration on the right side: inferior thyroid artery *(1)*, superior parathyroid adenoma *(2)* posterior to the middle third of the thyroid lobe *(3)*. The adenoma is located in location 1.

trunk they cross during their descent. Endoscopic exploration behind the inferior thyroid artery, along the esophagus, and down into the posterior mediastinum can be easily accomplished by this back-door approach. These adenomas are revealed by their vascular pedicle, which is easily dissected at the level of the inferior thyroid artery. They emerge with simple traction on it and their elongated shape is amenable to expeditious extraction.

- The search of inferior parathyroid adenomas in location 2 requires the exploration of the lower third of the posterior aspect of the thyroid lobe. Sometimes, they are identified immediately after introducing the endoscope. They tend to descend posteriorly and in a downward direction to acquire a paratracheal or a paraesophageal position. It is in these cases that they become intimate with the recurrent laryngeal nerve. Their posterior surface may adhere to the nerve. In these cases, the lateral view allows a secure dissection of the nerve.
- Although searching for the ipsilateral gland is not mandatory, it can often be identified when it is in location 1 or 2 (**FIG 20**).

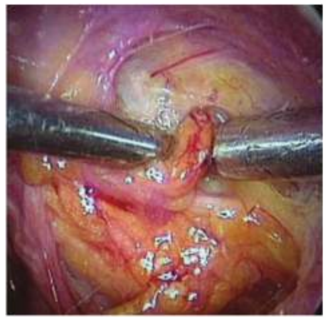

FIG 20 ● Identification of the ipsilateral inferior parathyroid gland. The gland is normal.

DISSECTION OF THE PARATHYROID ADENOMA

- The adenoma must never be grasped to avoid parathyroid fracture and potential risk of parathyromatosis. The adenoma is progressively freed from adjacent structures by blunt dissection with the help of two blunt-tipped metallic dissectors (**FIG 21**). One dissector retracts the adenoma, providing tension, while the other instrument is used to dissect the gland away from surrounding structures and loose areolar tissue until complete mobilization is achieved. When the pedicle is isolated (**FIG 22**), the terminal vascular branches are grasped, skeletonized, and electrocoagulated with the 3-mm diathermy hook (**FIG 23**).

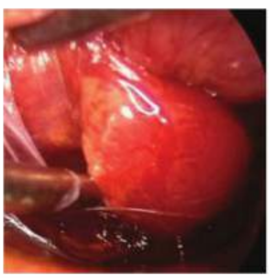

FIG 21 ● Endoscopic dissection of the superior parathyroid adenoma with the help of two blunt-tipped dissectors. The gland should not be grasped to avoid capsular disruption.

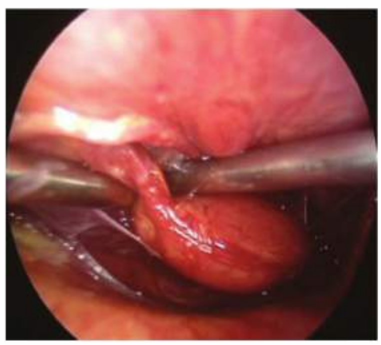

FIG 22 ● Dissection of the vascular pedicle of the superior parathyroid adenoma.

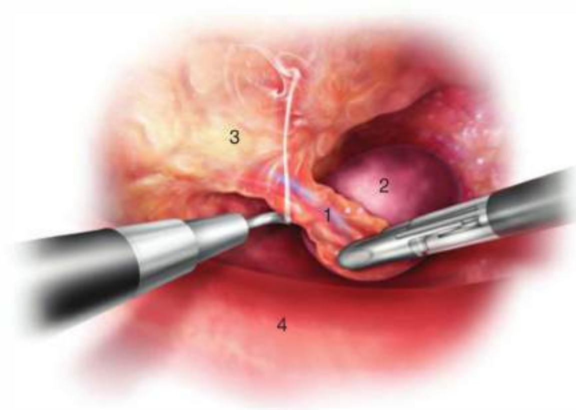

FIG 23 ● Electrocoagulation of the terminal vascular branches *(1)* of the superior parathyroid adenoma *(2)* with the 3-mm diathermy hook. *3*, thyroid lobe; *4*, carotid artery.

EXTRACTION OF THE PARATHYROID ADENOMA

- Most parathyroid adenomas can be extracted through the 10-mm trocar. In performing this step, after removing the 10-mm endoscope, a grasper and a 5-mm lens are simultaneously introduced into the 10-mm trocar. The pedicle of the adenoma is grasped and the adenoma is drawn into the trocar (**FIG 24**), the trocar containing the specimen is then removed.
- Larger adenomas that cannot be drawn into the 10-mm trocar are extracted directly through the trocar site under direct vision. There is no need to place them in a sterile plastic bag during this maneuver. After checking hemostasis, the two 3-mm trocars are removed.

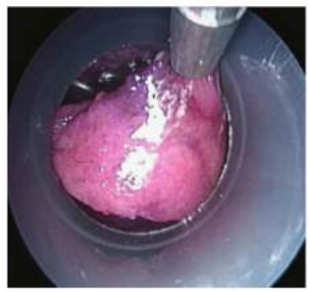

FIG 24 ● Extraction of the parathyroid adenoma. The pedicle of the adenoma is grasped and the adenoma is drawn into the trocar.

CLOSURE

- A surgical drain is not necessary. The platysma is sutured. The skin incision and the two 3-mm trocars sites are closed with fibrin glue (**FIG 25**). No dressing is required.

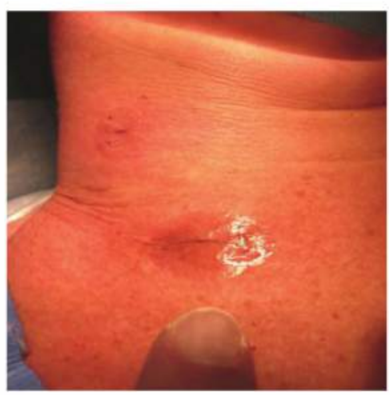

FIG 25 ● Fibrin glue is used to close the skin.

PEARLS AND PITFALLS

Indications	■ Only patients with sporadic primary HPT, in whom a single adenoma has been clearly localized by preoperative imaging studies, are potential candidates for EPLA. ■ Based on the results of preoperative imaging studies, EPLA should be reserved for patients presenting with parathyroid adenomas deeply located in the neck.
QPTH assay	■ The availability of the QPTH assay is of utmost importance. This test is especially useful when localization studies are less certain.
Installation of trocars	■ Place all three trocars on the line of the anterior border of the SCM and fix them to the skin to prevent involuntary removal. ■ Optic trocar incision should be created such that in the event of conversion, it can be extended medially to result in a traditional cervicotomy. ■ The transparietal path of the working trocars should be made through the optic trocar incision, from the inside to the outside.
Working space	■ Place the head in a neutral position to avoid tensing the SCM and the strap muscles. ■ In order to enlarge the working area, before introducing the optic trocar, stuff a small moist gauze, upward and downward, deeply into the initially created space, and then remove it.
Endoscopic exploration	■ Bear in mind that because the working space is very small, the endoscope is very close to the anatomic structures, which will therefore appear highly magnified. There is a definite risk of removing a normal gland that appears enlarged under endoscopic vision.
Endoscopic dissection	■ Never grasp the adenoma to avoid parathyroid fracture. The dissection can be performed entirely with the two blunt-tipped palpators.

POSTOPERATIVE CARE

- The patient may remain in the operating room or, in case of long processing for the QPTH assay, may be transferred to the postanesthesia care unit after extubation. In this latter case, if the results of QPTH are not consistent with successful removal of parathyroid adenoma, the patient must be returned to the operating room. In both cases, conversion to bilateral neck exploration is performed if the QPTH value does not fall by greater than 50% and into normal range (10 to 65 pg/mL).
- Patients have determination of serum parathyroid hormone (PTH) 4 hours after excision of the adenoma, then on day 1 and day 8 after surgery. Calcemia and phosphoremia are also systematically evaluated on day 1 and day 8.
- The serum PTH level reaches its nadir 4 hours after excision of the adenoma and, in most patients, the serum calcium reaches its lowest level within 48 to 72 hours after surgery. Because the parathyroid exploration is unilateral, postoperative hypoparathyroidism is not observed. However, postoperative hypocalcemia can be observed in patients with severe skeletal depletion of calcium, resulting in "bone hunger." If symptoms appear, calcium and vitamin D derivatives should be administrated.
- Usually, patients are discharged the day after surgery.
- Postoperative vocal cord evaluation must be performed systematically.

OUTCOMES

- After EPLA, more than 95% of patients are normocalcemic. However, it should be kept in mind that these excellent results are obtained in a group of carefully selected patients.[4]
- EPLA does not appear to be clearly superior to other MIP technique in terms of recurrent disease or postoperative complications.[10]
- As with other techniques of single-gland excision through a limited neck exploration, EPLA does not lead to an increased incidence of persistent/recurrent HPT[10]; it is associated with a better postoperative course in terms of pain and it produces better cosmetic results compared to bilateral neck exploration[11] (**FIG 26**). Prevalence and severity of postoperative hypocalcemia are lowered.[12]

FIG 26 ● Cervical scar 1 month after surgery.

COMPLICATIONS

- Hematoma
- Inferior laryngeal nerve injury
- Parathyroid adenoma not found: conversion
- Capsular rupture of adenoma
- False-positive result of preoperative imaging studies
- False-negative result of QPTH assay

Chapter 45 Reoperative Parathyroidectomy

Barnard J. A. Palmer   William B. Inabnet, III

DEFINITIONS

- Reoperative parathyroid surgery occurs in multiple clinical settings but is most frequently performed as the result of failed exploration, recurrent, or persistent hyperparathyroidism.
- Persistent hyperparathyroidism is defined as hypercalcemia that remains or recurs within 6 months of an initial parathyroid operation.
- Recurrent hyperparathyroidism is the reappearance of hypercalcemia after a period of 6 months of postoperative normocalcemia following successful surgery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A detailed history of the patient's disease should be performed, focusing on the management to date.
- Biochemical confirmation of persistent or recurrent hyperparathyroidism is the initial step in management. A 24-hour collection for calcium is recommended.[1,2]
- The benefits of reoperation must be weighed against the risks of continued hyperparathyroidism and the surgical complications for each individual patient. Nonsurgical management can be considered if the sequela of continued parathyroid disease is relatively low risk or the risk of operation is high.
- Surgical history is an essential component of reoperative parathyroid surgery. The surgeon must understand reasons for initial operative failure.[3]
- Operative and pathology reports should be carefully reviewed, focusing on the extent of exploration, glands identified and removed, whether confirmed by biopsy, if marked, and if reimplanted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Extensive preoperative planning is key to successful reoperative surgery.
- Previous operative reports, imaging, and pathology results should be obtained and reviewed to understand the cause of failure.[2]
- Localization studies are an essential portion of preoperative planning and should be performed in all reoperative parathyroid patients. Ultrasound, sestamibi, computed tomography (CT) (parathyroid protocol, 4-D) (**FIG 1**), single-photon emission computed tomography–computed tomography (SPECT/CT), and fluorodeoxyglucose-positron emission tomography (FDG-PET) can be used for localization and to rule out multigland disease. Preoperative location of abnormal glands can significantly alter the operative approach particularly if aberrant glands lie in the mediastinum.
- Fine needle aspiration (FNA) with measurement of parathyroid hormone (PTH) can confirm parathyroid tissue in questionable lesions or parathyroid adenomatosis identified by ultrasound.
- Invasive localization studies such as selective venous sampling (**FIG 2**) or arteriography should be reserved for when noninvasive studies fail to localize pathology.

SURGICAL MANAGEMENT

Preoperative Planning

- The imaging must be thoroughly reviewed to plan the operative approach.
- Prior operative notes are reviewed and operative steps clearly determined prior to reexploration.
- Positively localized lesions lend themselves to focused reexplorations, whereas more extensive exploration is required for multigland or nonlocalized diseases.
- Preoperative flexible laryngoscopy is recommended prior to reoperative surgery to document vocal cord function and guide the extent of surgery.
- Frozen section and intraoperative PTH assays are useful adjuncts to confirm parathyroid identification and biochemical cure.

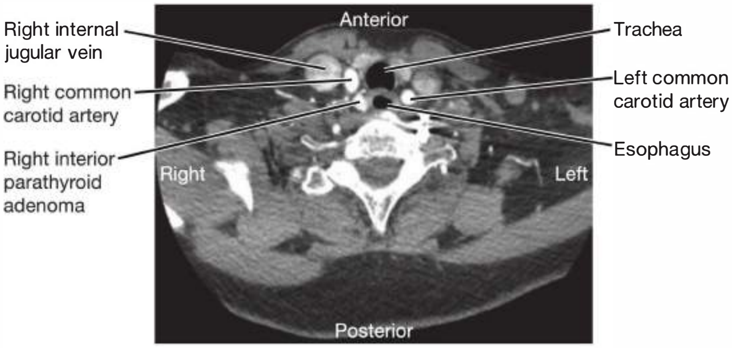

FIG 1 ● Parathyroid CT demonstrates a contrast-enhancing lesion posterior to the right common carotid artery, posterolateral to the trachea, and lateral to the esophagus, representing a right inferior parathyroid adenoma.

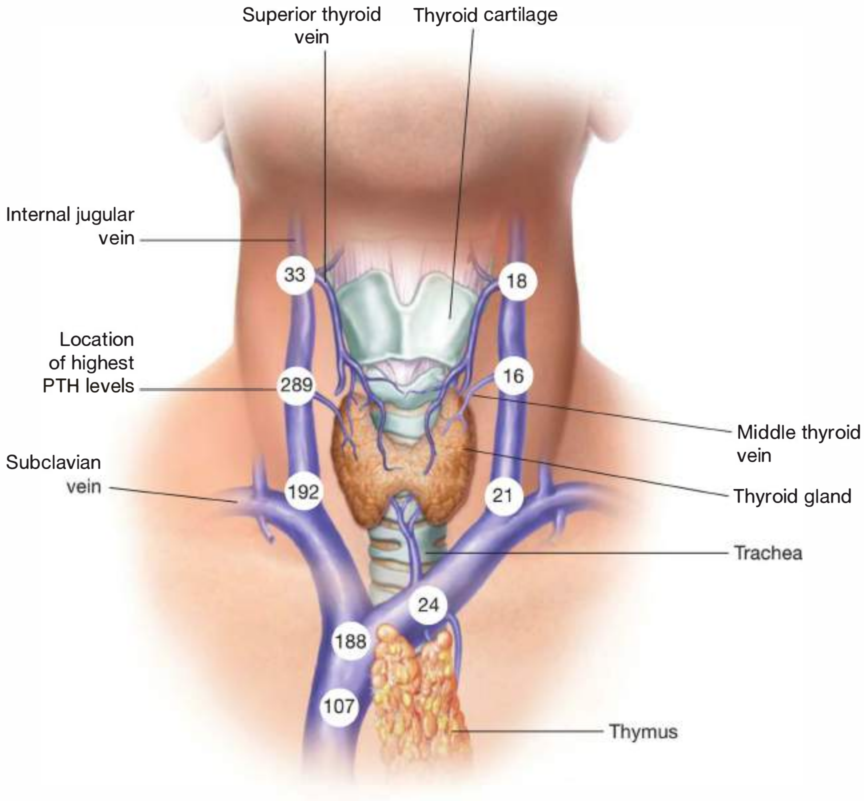

FIG 2 ● Selective venous sampling schematic lists PTH levels at different anatomic locations and is consistent with a right midlobe parathyroid adenoma.

Positioning

- The patient is positioned either supine or in the semi-Fowler position. Both arms are tucked and neck extension is achieved with a shoulder roll (**FIG 3**).
- Surgical prep must be wide enough to allow access superiorly to angle of mandible and inferiorly to xiphoid in the instance that sternotomy is necessary.
- General endotracheal anesthesia permits the use of intraoperative nerve monitoring.

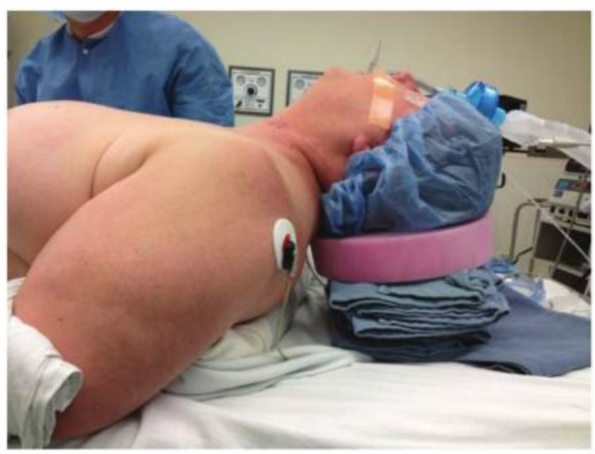

FIG 3 ● The patient is placed supine with both arms tucked. A shoulder roll provides additional neck extension, which elevates the trachea anteriorly and superior mediastinal structures cephalad.

CERVICAL REEXPLORATION

Incision and Flap Elevation

- Skin incisions are placed as indicated by the preoperative localizing studies, preferably in a natural cervical skin crease or the old incision (unless the scar is too low or high). Width of incision is dependent on depth of neck but is large enough to allow access superiorly to the level of the hyoid bone and inferiorly to the anterior mediastinum (**FIG 4**).
- Incisions may be placed over the site of pathology for a directed approach if preoperatively localized.
- Skin and platysma are divided and subplatysmal flaps superficial to the anterior jugular veins are elevated superiorly to the thyroid notch, inferiorly to the sternal notch, and laterally to anterior borders of the sternocleidomastoid muscles (SCM).

Cervical Approach[3]

- Surgical approach to the reoperative neck is done via focused exploration or by classic midline, posterolateral, or thyrothymic ligament approaches.
- Focused explorations for preoperatively localized ectopic glands not accessible via prior cervicotomy should be adjusted to location and surgeon experience with incisions placed according to imaging.
- Revision cervicotomy is indicated when multigland disease is suspected or when abnormal glands are not localized preoperatively. The previous incision is used and the cervical scar revised prior to opening the midline raphe by vertical separation of strap muscles (see Part 5, Chapters 45 and 48).

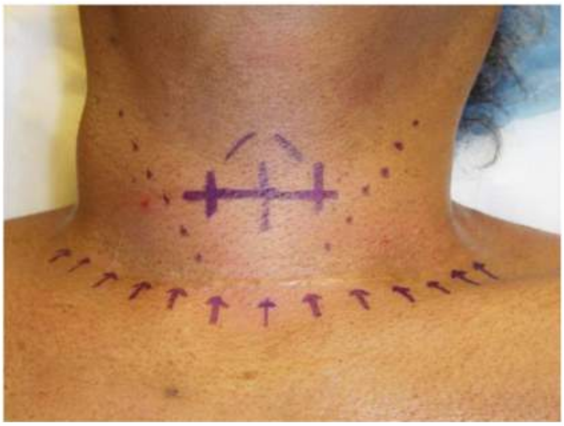

FIG 4 ● Skin incisions are placed in a natural skin crease and is adjusted according to preoperative localization and planned approach. Classic, large, inferior incisions have been substituted by more superior smaller incisions or incisions directly over parathyroid lesions. Lateral incisions can be made for a posterolateral approach with entry between the anterior border of the sternocleidomastoid and lateral border of the strap muscles. *Upward arrows* on the pictures show a classic incision versus a small superior incision as indicated by the *solid transverse line markings*.

- The back door or ***posterolateral*** approach should be considered when there is extensive scar tissue or when seeking a posteriorly localized gland. The lateral portion of a prior wound is used and entry to the neck is achieved between the lateral border of the straps and anterior portion of the SCM (**FIG 5**).

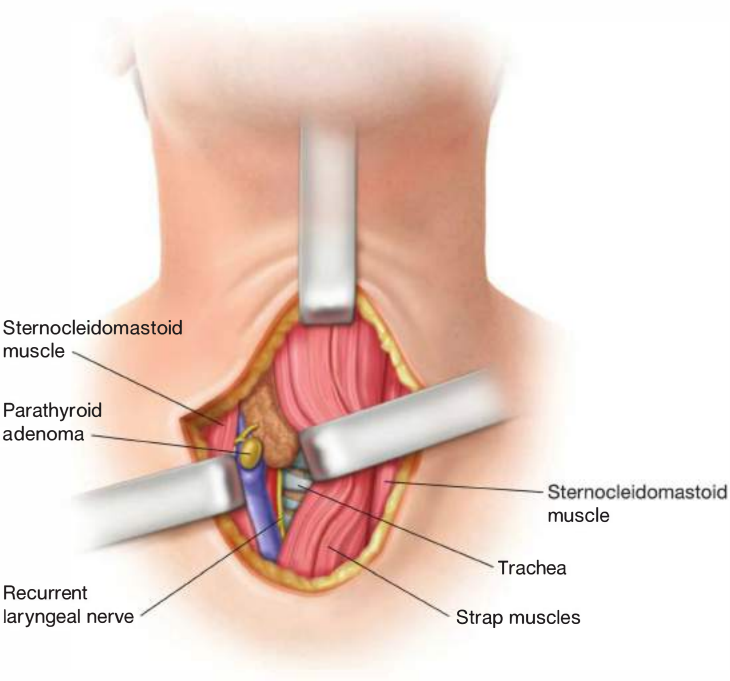

FIG 5 ● The posterolateral approach to the neck is similar to the classic approach except that subsequent access is achieved along the medial border of the SCM and lateral to the sternohyoid-sternothyroid, minimizing dissection through midline scar. The omohyoid muscle is divided as necessary.

- The front door or ***thyrothymic*** ligament approach should be considered when adenomas are localized anteriorly along the inferior thyroid pole or thyrothymic ligament. Infrahyoid muscles may be divided as inferiorly as possible to allow direct access to the thyrothymic ligaments, avoiding dissection between the strap muscles and thyroid capsule.
- Once deep to the strap muscles, retraction of the thyroid involves elevation of the strap muscles off the gland and medial thyroid rotation. A Kittner, thyroid clamp, or figure-of-eight suture assists thyroid retraction.
- The recurrent laryngeal nerve (RLN) is then identified and preserved.

Exploration

- Steps are systematically planned and based on preoperative imaging.
- If an abnormal gland is localized preoperatively, commence with focused exploration.
- Start by exploring the normal locations of the missing glands. The superior glands are generally at the mid to upper one-third of the thyroid in the expected position 85% of the time, at the inferior border of the thyroid cartilage posterior to the RLN and the superior portion of the inferior thyroid artery.
- The inferior glands are classically located near the posterior aspect of the thyroid pole, anterior to the RLN from the inferior thyroid artery to the inferior thyroid pole or along thyrothymic ligament (see Part 5, Chapter 41, **FIG 11**).
- If unable to locate in normal positions, search expected aberrant positions.
- Ectopic superior glands are generally displaced posteriorly or inferiorly, becoming more posterior as they travel inferiorly.
- Search circumferentially around the superior thyroid pedicle and visceral sheath of the thyroid capsule with thyroid palpation.
- Follow the tracheoesophageal groove inferiorly down to the posterior mediastinum (**FIG 6**).
- Inferior glands have a greater range of position but nearly 25% are along the thyrothymic ligament or upper pole of the thymus. They are rarely posterior and become more anterior the lower they are.
- Search and digitally explore the posterior and inferior thyroid gland.
- Inspect the thyrothymic ligament, incise the thymic sheath, and pull the thymic lobe cephalad to inspect the thymus (see **FIG 8**).
- Explore the carotid sheath up to the angle of the mandible (**FIG 7**).

Gland Identification and Excision

- Normal parathyroids are approximately 3 × 2 × 4 mm and tan in appearance.
- Abnormal glands have a characteristic rubbery feel and reddish brown appearance.
- They are freed from the surrounding tissue and the vascular pedicle is clamped and divided.
- Parathyroid confirmation can be achieved through histologic examination. Biopsy of the antihilar tip of the gland using sharp dissection is performed with great care to not disturb the fragile blood supply.

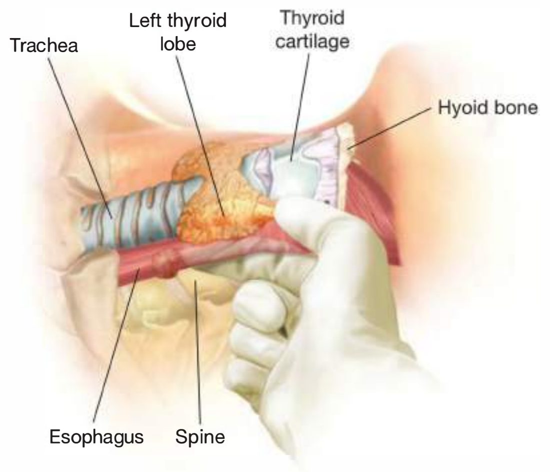

FIG 6 ● The lateral wall of the esophagus and the tracheoesophageal groove are exposed from the hypopharynx superiorly down to the mediastinum. Missing glands may be found in the prevertebral space and the search for parathyroids in this region is augmented by digital palpation.

- Intraoperative PTH monitoring improves the cure rate and guides the extent of exploration.
- A drop in PTH by 50% of baseline and within normal limits at 10 minutes is indicative of cure. If operating for multigland disease (as opposed to a missed adenoma), the PTH level at 10 minutes should also be within normal limits.
- Exploration continues if levels do not fall precipitously and the process is repeated until an appropriate drop is achieved.

Additional Maneuvers

- Because inferior adenomas are usually displaced into the anterior aspect of superior mediastinum, they may be intimately associated with the thymus gland.
- Cervical thymectomy may be performed in the case of absent glands (**FIG 8**). Gentle traction cephalad with sequential grasps and blunt mobilization are used to deliver the thymus into the cervical wound with the aim of removal of thymus tissue to the level of the innominate vein.
- Similarly, thyroid lobectomy on the side of a missing parathyroid may be performed.
- Staged procedures are common with nonlocalized reoperative parathyroid surgery. Closure and relocalization should be performed if the offending gland cannot be found.

Closure

- Meticulous hemostasis is achieved; strap muscles are reapproximated in midline (or to SCM if lateral approach done), followed by platysma reapproximation and skin closure.
- Drains are not regularly used unless there is extensive dissection or exploration.

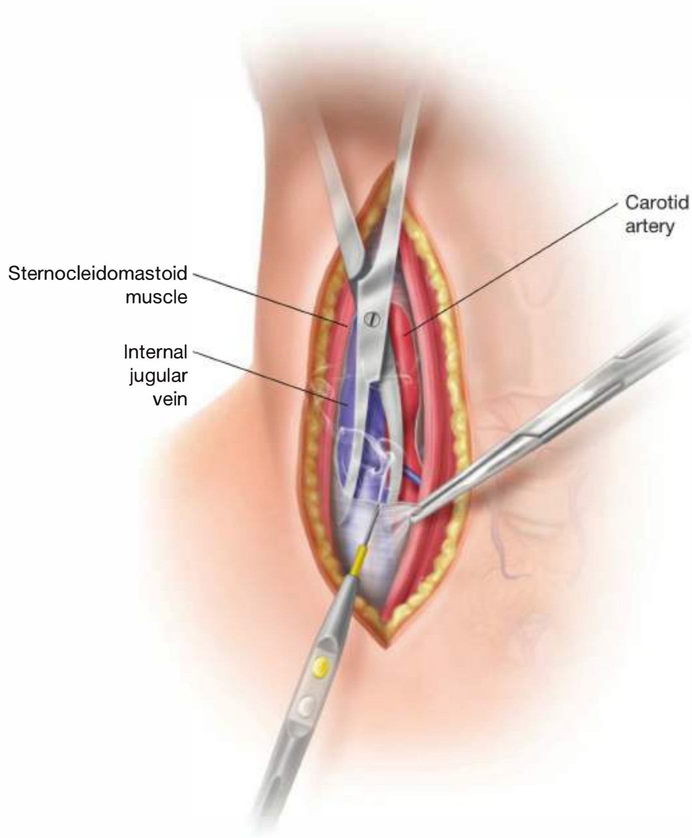

FIG 7 ● If the search fails to disclose an adenoma, the carotid sheath is opened.

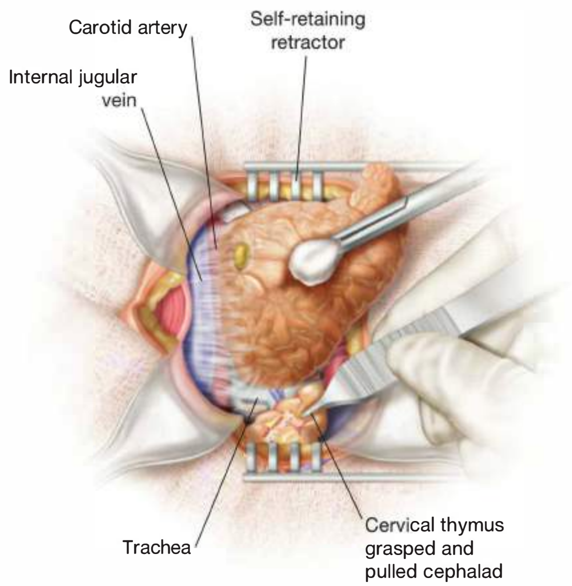

FIG 8 ● Because it is not infrequent that parathyroid glands are found partially embedded in the thymus, cervical thymectomy may be performed in the case of a missing gland. The superior aspect of the thymus is grasped and pulled by continuous traction from the chest. It can be grabbed sequentially and lifted cephalad until the often single posterior vessel is seen and divided. If a gland remains missing, it is the practice of some surgeons to perform a thyroid lobectomy on the affected side. The mediastinum should not be split unless there is definite evidence of a mediastinal tumor by preoperative imaging.

MEDIASTINAL EXPLORATION[1,3]

Approach

- Mediastinal exploration should not be performed without localization evidence of a hyperfunctioning gland in the mediastinum. Preferably, two different localizing studies should identify gland location prior to surgery.
- Most adenomas in the posterior mediastinum or anterior mediastinum above the aortic arch can be approached and excised through neck.
- Those deep in the anterior mediastinum or in the middle mediastinum require a thoracic approach (**FIG 9**).
- Precise localization is paramount and may allow less invasive approaches of anterior mediastinotomy or thoracoscopy rather than partial or median sternotomy (**FIG 10**).
- Choice of approach depends on gland location and surgeon expertise.

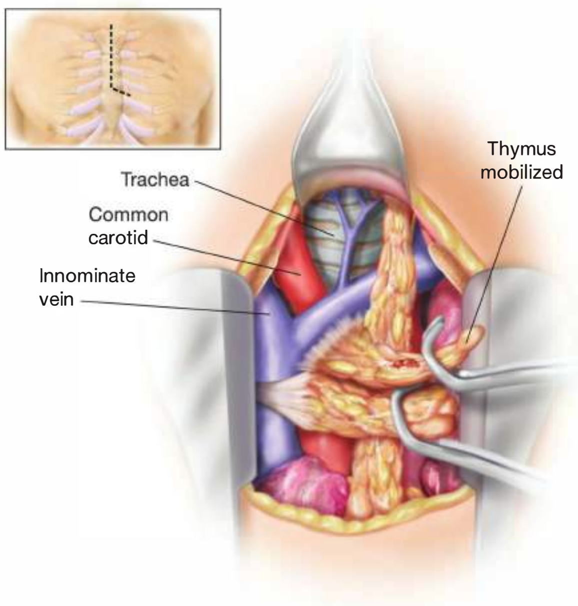

FIG 9 ● Median sternotomy or partial sternotomy to 3 cm below the predicted level of the adenoma provides access to the mediastinum (inset shows where the incision would be on the chest). The area of exploration is bound by the innominate vein superiorly and the pericardium inferiorly. Adenomas commonly lie in the thymic remnant in the anterior mediastinum.

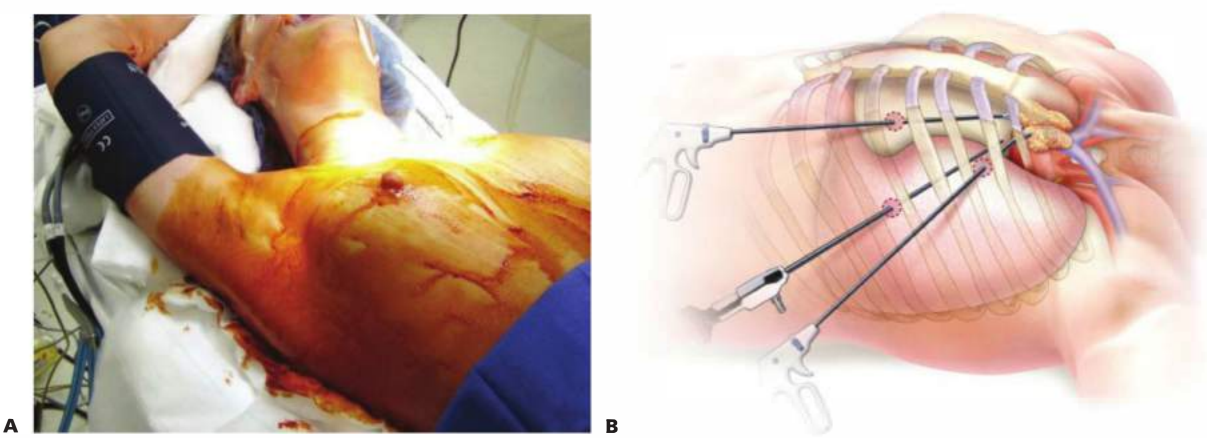

FIG 10 ● Thoracic approaches should not be performed without positive localization studies. **A.** The image indicates positioning for a thoracoscopic approach. The patient is supine, with the ipsilateral arm elevated above the head to allow transthoracic access between ribs. **B.** Position placement for thoracoscopic trocars.

PARATHYROID REIMPLANTATION

Procedure

- For multigland disease or when the vasculature of remaining parathyroid tissue is compromised, parathyroid reimplantation may be performed to preserve function. Grafts have a high success rate but may take several weeks to function.
- Approximately 50 mg of the most normal-appearing parathyroid tissue is minced into 1-mm pieces and placed into muscular pockets in the forearm. Alternatively, it may be placed in the subcutaneous tissue overlying the forearm or anterior chest wall (**FIG 11**).

FIG 11 ● Parathyroid tissue to reimplant is minced into 1-mm pieces and placed into intramuscular pockets in the forearm as seen in the figure. Alternatively, they can be placed subcutaneously in the forearm or on the anterior chest wall.

PEARLS AND PITFALLS

Indications	■ Complete history and physical with symptoms and severity of hypercalcemia should be obtained. Biochemical diagnosis of recurrent or persistent hyperparathyroidism must be confirmed.
Preoperative planning	■ Review of initial operative notes and pathology is required. ■ Preoperative localization provides a map for reoperative surgery.
Placement of incision	■ Incisions are created, keeping in mind the localization of pathology and the operative plan. ■ Cosmesis is improved when placed in a natural skin crease.
Cervical approach	■ Entry into the neck may be via focused, posterolateral, thyrothymic ligament, or revision midline cervicotomy approach.
Exploration	■ Eutopic locations for superior and inferior glands should first be searched. ■ Exploration in expected ectopic sites along the tracheoesophageal groove, carotid sheath, thyrothymic ligament, cervical thymus, and intrathyroid should follow.
Mediastinal lesions	■ Accurate preoperative localization allows the least invasive procedure for lesions in the mediastinum, which may be approached via cervical or thoracoscopic approach.
Additional maneuvers	■ Cervical thymectomy or ipsilateral thyroid lobectomy can be performed when an offending gland cannot be located. ■ Parathyroid reimplantation provides a useful adjunct to patients with multigland disease.
Closure	■ Layered closure without drain

POSTOPERATIVE CARE

- Patients should be monitored for respiratory compromise in the immediate postoperative period.
- Patients with reimplantation, extensive dissection, gland or vascular manipulation, or multiple gland removal are at increased risk of postoperative hypoparathyroidism.
- Postoperative hypocalcemia can be mitigated with calcium and vitamin D prophylaxis versus expectant monitoring of serum calcium and PTH. Calcium supplements are generally continued for 3 to 6 months to avoid reactive secondary hyperparathyroidism from a chronic hypocalcemic state.

OUTCOMES

- Success rates between 82% and 98% are expected of reoperative parathyroid surgery, with rates as low as 37% to 73% in multigland disease.
- RLN injury ranges from 0% to 2.7%, whereas permanent hypocalcemia rates vary from 1% to 18%.

COMPLICATIONS

- Neck seroma
- Hematoma
- Infection
- Voice change
- RLN injury
- Hypocalcemia, hypoparathyroidism
- Failure of cure, recurrence

Chapter 46

Adrenalectomy: Open Anterior

Barbra S. Miller

DEFINITION

- Adrenal masses may be functional or nonfunctional and benign or malignant. Most are incidentally discovered when imaging is obtained for other reasons. Laparoscopic adrenalectomy is the gold standard for appropriately sized benign (most often functional) adrenal masses and for some metastatic tumors to the adrenal gland (see Part 5, Chapters 49 and 50). If adrenocortical carcinoma is a concern, adrenalectomy by an open approach should be performed.[1] Several genetic syndromes are associated with adrenal abnormalities and appropriate testing should be obtained if indicated.

DIFFERENTIAL DIAGNOSIS

- Adenoma
- Metastatic cancer
- Pheochromocytoma
- Ganglioneuroma
- Primary adrenocortical carcinoma
- Cyst
- Adjacent paraganglioma
- Soft tissue tumor

PATIENT HISTORY AND PHYSICAL FINDINGS

- All adrenal abnormalities should be evaluated in a systematic fashion, including a thorough history and physical examination investigating the possibility of a hormone-secreting mass. This includes the possibility of a pheochromocytoma, Cushing's syndrome, primary hyperaldosteronism, and hypertestosteronemia. Specifically, the patient should be questioned regarding poorly controlled hypertension, diabetes, edema, diaphoresis, tachycardia, palpitations, sudden severe headaches, flushing, and easy bruising. The physical exam should look for evidence of central obesity, edema, peripheral wasting, core muscle weakness, a buffalo hump, striae, thin skin, and facial plethora. Because the adrenal gland is situated in the retroperitoneum, unless it is extremely large, palpation of the mass is usually unable to be achieved.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All adrenal masses should undergo appropriate biochemical testing. Even in the absence of signs or symptoms, patients should have at a minimum the following: potassium, aldosterone, renin, plasma fractionated metanephrines (followed by 24-hour urine metanephrines and normetanephrines, catecholamines, and vanillylmandelic acid [VMA] if plasma values are abnormal), 24-hour urine-free cortisol, and adrenocorticotropic hormone (ACTH). Some physicians may also perform a low-dose dexamethasone suppression test and obtain dehydroepiandrosterone-sulfate (DHEA-S) and free testosterone, among other laboratory tests.
- Imaging studies should include an adrenal protocol computed tomography (CT) scan (to assess imaging characteristics and calculate washout percentage of contrast from the tumor) or magnetic resonance imaging (MRI) (to assess for loss of signal intensity between in and out of phase images) and a positron emission tomography (PET) scan if malignancy is questioned (**FIG 1**).
- Additional imaging studies may be required depending on the functionality of the tumor (metaiodobenzylguanidine [MIBG] for pheochromocytoma in select cases, adrenal vein sampling for hyperaldosteronism, etc.).
- Fine needle aspiration or core biopsy is not recommended if adrenocortical carcinoma is suspected but may be useful if metastasis to the adrenal gland is in the differential and the adrenal tumor is the most accessible site of metastasis for biopsy in the setting of multiple sites of metastatic disease. If biopsy is performed, it is imperative to first biochemically rule out a pheochromocytoma.

SURGICAL MANAGEMENT

- Adrenal tumors, if benign appearing by imaging criteria, nonfunctional, and therefore not requiring resection, should be reevaluated with at least one additional CT scan or MRI 6 to 12 months after the initial imaging study to ensure stability in size and internal imaging characteristics. Some advocate for a longer period of follow-up imaging for 2 years with reevaluation of biochemistry for 4 more years.[2]
- Functional tumors leading to hormone excess, indeterminate masses, and those suspected of being adrenocortical carcinoma or isolated metastatic disease from another primary tumor without evidence of widespread metastatic disease should be removed.

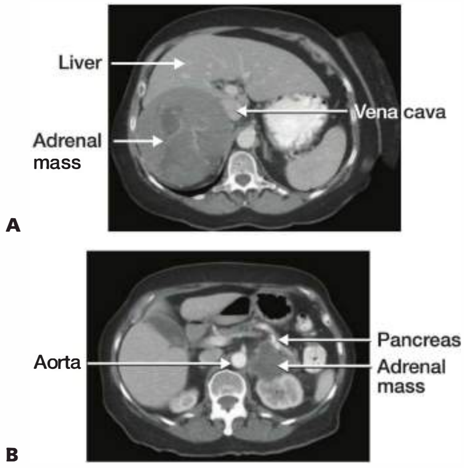

FIG 1 ● **A.** CT scan showing large heterogeneous right adrenal mass concerning for adrenocortical carcinoma. **B.** CT scan showing a large left adrenal mass.

Preoperative Planning

- The surgeon must evaluate available imaging studies for tumor involvement of adjacent organs, vessels, and lymphadenopathy. Invasion of major vessels (vena cava) or adjacent organs may require additional teams or different approaches to the tumor. As CT tends to overestimate invasion of adjacent vessels, MRI with magnetic resonance venogram can be especially helpful to assess for vena cava invasion or intracaval tumor thrombus.
- The risks, benefits, and alternatives to surgery are discussed with the patient, including potential need for steroid supplementation in the postoperative setting. Patients with pheochromocytomas should be adequately alpha blocked and volume replete. Beta blockade may also be necessary. In patients with hyperaldosteronism, a potassium level should be checked the morning of surgery and treated if necessary.
- Routine prophylactic antibiotics and deep vein thrombosis (DVT) prophylaxis is administered prior to surgery, and sequential compression devices are applied.
- A general endotracheal anesthetic is administered and an epidural is often placed for postoperative pain management.
- Common to all approaches, skin preparation with clipping rather than shaving is preferred, and the surgical area is prepped and draped in a sterile fashion.

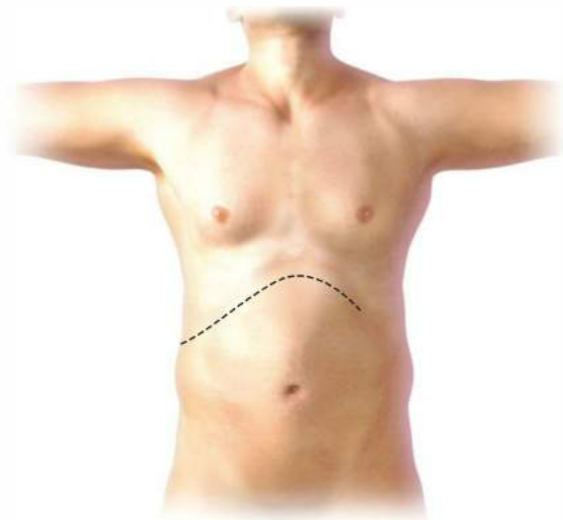

FIG 2 • The patient is placed supine on the table with arms out. Pressure points are padded. An incision is marked 2 cm inferior to the costal margin and carried from the lateral abdominal wall across the midline to facilitate exposure.

Positioning

- The patient is placed supine on the table with arms out to the side, and all pressure points are padded appropriately (**FIG 2**).

TECHNIQUES

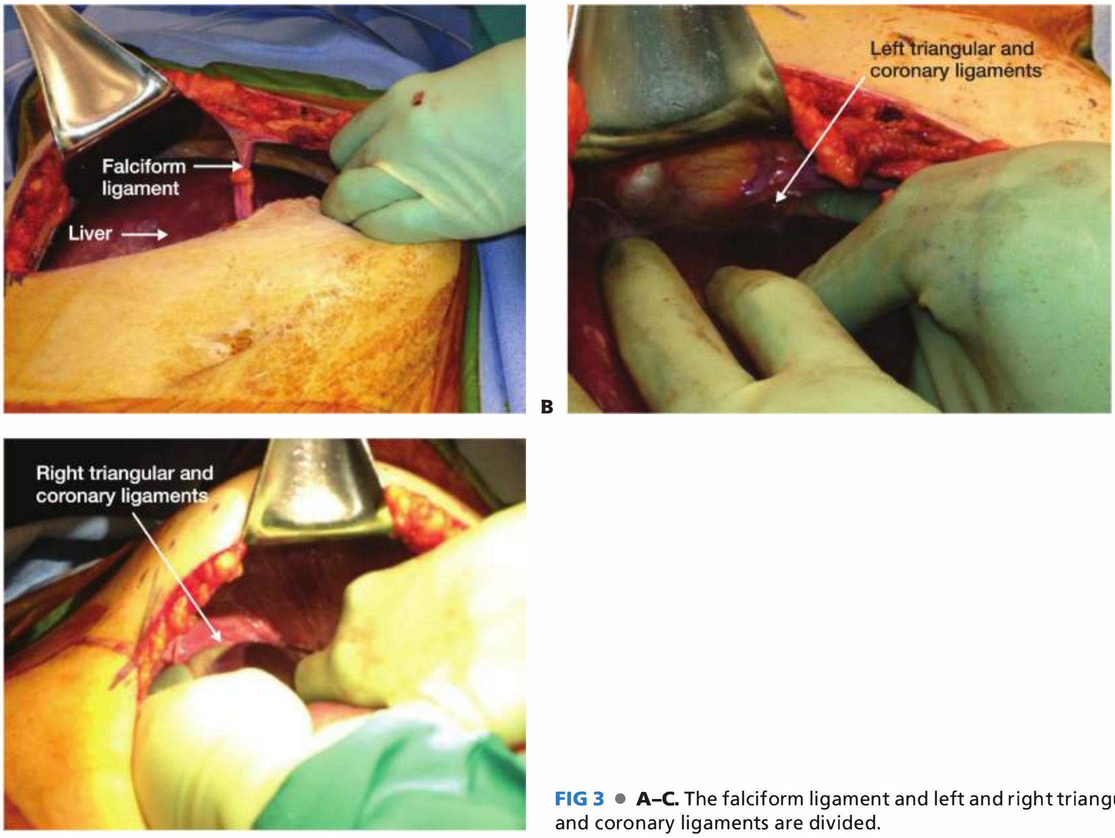
RIGHT ADRENALECTOMY

Exposure

- A wide right subcostal incision is made and carried across the midline to the midleft abdomen. The subcutaneous fat, fascia, abdominal wall musculature, and posterior fascia are incised with cautery. The peritoneum is entered sharply with scissors and the incision opened to its full length. The ligamentum teres is divided between sutures and the peritoneal cavity is inspected in a systematic manner, assessing for evidence of metastatic disease or other abnormalities. The falciform ligament, triangular, and coronary ligaments of the left and right lobes of the liver are divided to allow for full mobility of the liver during retraction (**FIGS 3** and **4**).
- Ultrasound of the liver is also performed to assess for metastatic disease not identified on preoperative imaging, and the vena cava may also be evaluated sonographically for evidence of intracaval tumor thrombus or direct tumor invasion.
- The hepatic flexure of the colon may need to be mobilized, and if a Kocher maneuver is needed, it should be done at this time. The right lobe of the liver is retracted medially to expose the retroperitoneum and allow access to the area of the tumor and vena cava. A retractor system is placed. The Omni retractor provides excellent retraction as well as the critically important ability to retract the costal margin and ribs as superiorly and anteriorly as possible. A large saline-soaked towel is placed against the bowel with retractors to not only provide exposure but also to exclude the rest of the peritoneal cavity and minimize potential seeding of the peritoneal cavity by a malignant tumor (**FIG 5**).

Dissection

- The posterior peritoneal lining over the retroperitoneum is incised over the superior half of the right kidney and carried from medial to lateral out to the side of the abdominal wall. Medial dissection should proceed carefully to the vena cava, making sure not to divide branches of the renal artery supplying the upper portion of the kidney or venous branches draining to the renal vein. Small branches supplying and draining the adrenal gland should be carefully ligated and divided. Any lymph nodes posterior to the renal hilum should be included in the dissection (**FIGS 6** and **7**).
- The fat overlying and just superior to the kidney is mobilized from inferior to superior, making this tissue the inferior margin, using cautery, silk sutures, and other hemostatic devices as needed, making sure not to create a nonexistent plane between the inferior aspect of the tumor and the superior aspect of the kidney. The peritoneal lining should remain intact over the anterior



A B C

FIG 3 ● **A–C.** The falciform ligament and left and right triangular and coronary ligaments are divided.

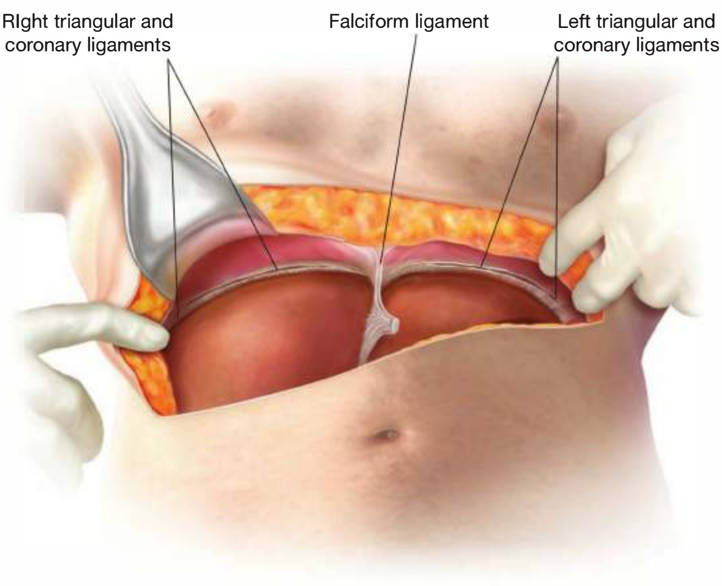


FIG 4 ● With the ligamentum teres, falciform ligament, and triangular and coronary ligaments divided, this allows adequate retraction of the liver and access to the tumor and vena cava.

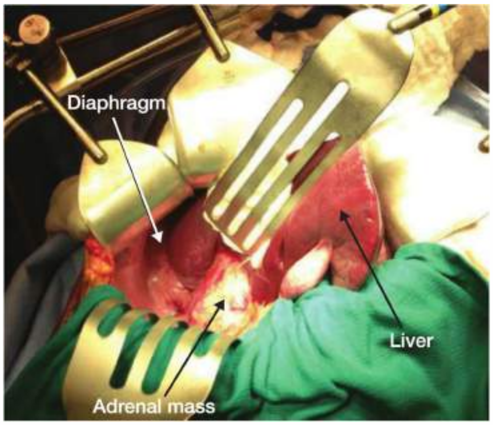

FIG 5 ● A retractor system is placed to retract the ribs superiorly and anteriorly and to retract the liver medially. A moist towel is placed inferiorly to retract the bowel and exclude the rest of the peritoneal cavity.

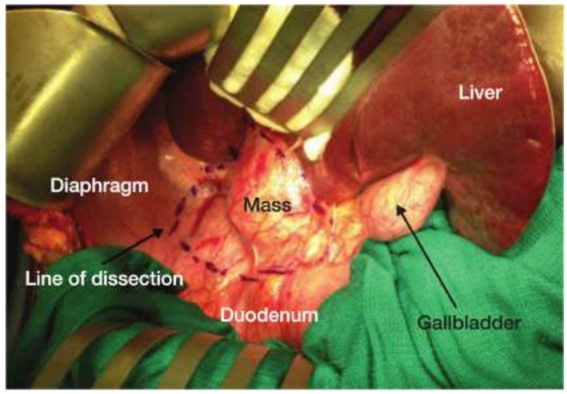

FIG 7 ● The intended line of dissection to include the tumor and all retroperitoneal soft tissue is marked.

aspect of the tumor to serve as the anterior margin if not already invaded by the tumor (**FIG 8**).

- The dissection continues superiorly along the diaphragm, making sure to ligate and divide any feeding vessels, most commonly branches from the inferior phrenic vessels.
- Posterior dissection should proceed from lateral to medial, making sure to remove all fat posterior to the tumor in an en bloc fashion. If the tumor invades the muscle, a portion of the muscle should be included with the tumor to ensure negative margins.
- The anterior surface of the vena cava should be identified and the peritoneal lining overlying this should be incised along its length. Using a vein retractor to retract the vena cava medially, soft tissue attachments medial to the gland and posterior to the vena cava, including lymphatics, are ligated and divided. As the midpoint of the adrenal gland is reached, the right adrenal vein should be identified, ligated, and divided (**FIG 9**). The vein should be inspected and carefully palpated to assess for any tumor thrombus so that the tumor thrombus

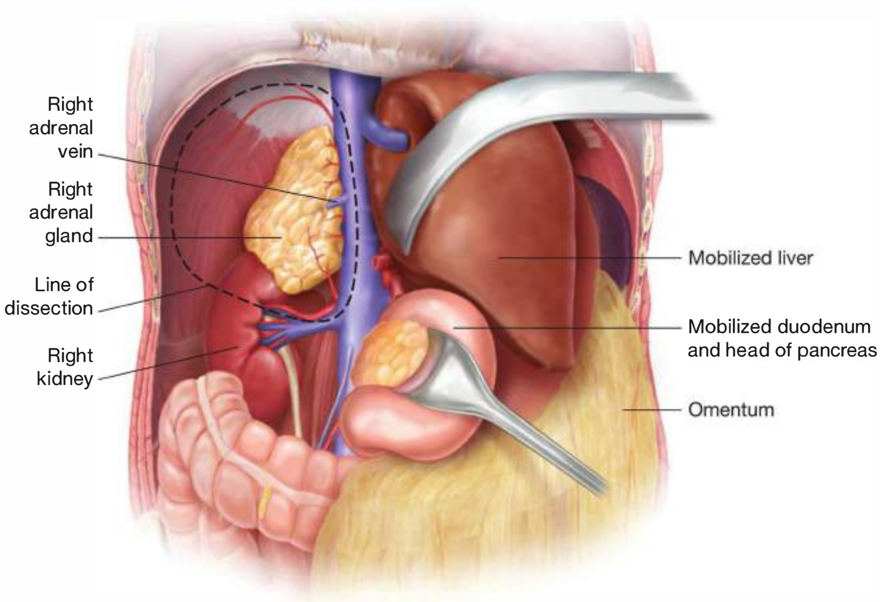

FIG 6 ● With the liver retracted medially, the adrenal vein and inferior vena cava are exposed. The *dotted line* demonstrates the intended line of dissection.

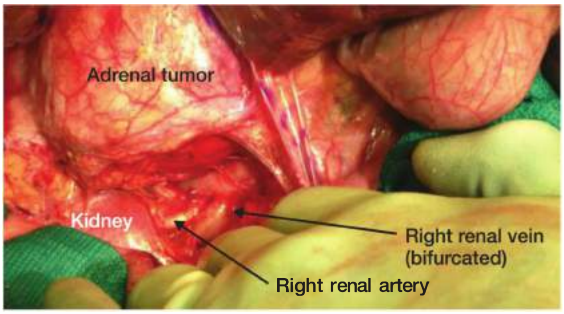

FIG 8 ● The inferior portion of the dissection is shown. A branch of the right renal artery is seen between two branches of the right renal vein.

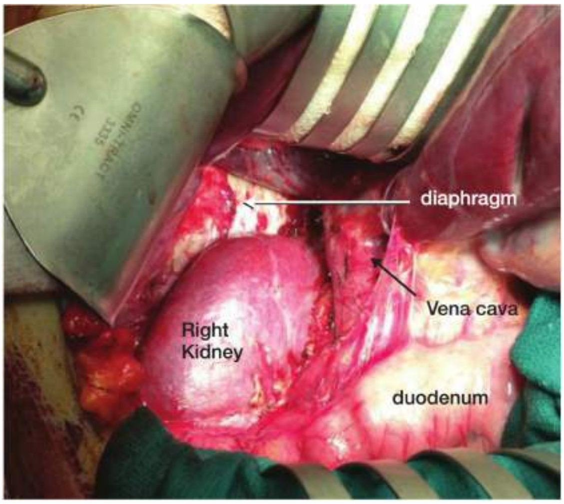

FIG 10 ● The adrenal tumor and all retroperitoneal soft tissue has been removed en bloc. The right kidney has migrated superiorly against the diaphragm to fill the space.

can be included with the specimen in an en bloc fashion. Advanced techniques for managing large tumor thrombi within the vena cava are beyond the scope of this chapter. If removing a pheochromocytoma, the anesthesiologist should be warned well in advance prior to ligating the adrenal vein in anticipation of ensuing hypotension. The dissection is continued superiorly until all medial attachments have been released (**FIG 10**).

- The adrenal gland and the periadrenal soft tissue are removed, marked with orienting sutures for the pathologist, and sent to the pathology lab (**FIG 11**).

Closure

- A small amount of water should be used for irrigation and final hemostasis is achieved. The area encompassed by the dissection should be marked with large clips to assist with postoperative external beam radiation therapy if needed.
- A drain may be placed if desired but is not required in many cases.
- The retractor system is removed, the organs replaced in their normal anatomic positions, and the abdominal wall musculature is closed in two separate layers. The subcutaneous tissue may be reapproximated with interrupted absorbable sutures if needed and the skin closed with staples or suture. A sterile dressing is applied.

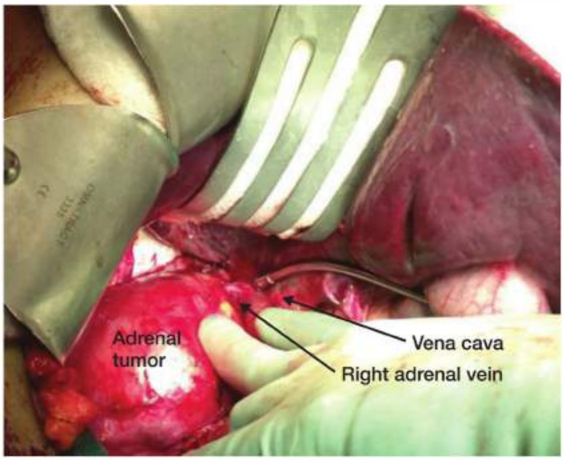

FIG 9 ● The right adrenal vein has been dissected free of its attachments. More superiorly along the vena cava, a second vein from the adrenal to the inferior vena cava has been clipped and divided.

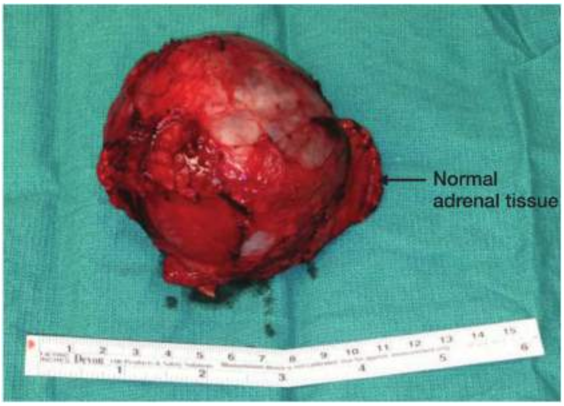

FIG 11 ● A small portion of normal adrenal tissue remains and is seen at the right side of the gland in this image. Surrounding soft tissue and the overlying anterior peritoneal lining remain on the anterior surface of the gland.

LEFT ADRENALECTOMY

Exposure

- A wide left subcostal incision is made and carried across the midline to the midright abdomen (FIG 12). The subcutaneous fat, fascia, abdominal wall musculature, and posterior fascia are incised with cautery. The peritoneum is entered sharply with scissors and the incision opened to its full length. The ligamentum teres is divided between sutures and the peritoneal cavity is inspected in a systematic manner, assessing for evidence of metastatic disease or other abnormalities.
- Ultrasound of the liver is also performed to assess for metastatic disease and the vena cava may also be evaluated for evidence of intracaval tumor thrombus from the left adrenal and renal veins.
- The falciform ligament and left triangular and coronary ligaments of the left lobe of the liver are divided to allow for mobility of the liver during retraction (FIG 13).
- The descending colon is mobilized along the line of Toldt and the colon reflected medially. The mobilization is continued superiorly to divide the splenic attachments to the abdominal side wall and the diaphragm. The spleen, stomach, pancreas, splenic flexure, and colon should be reflected medially, allowing exposure of the left retroperitoneum (FIG 14). A retractor system is placed. A large saline-soaked towel with retractors is placed against the bowel, pancreas, spleen to not only provide exposure but also to exclude the rest of the peritoneal cavity to minimize potential seeding of the peritoneal cavity by a malignant tumor. The left side of the aorta should be clearly appreciable if the exposure is adequate.

Dissection

- Because the peritoneal covering on the left has been reflected with the spleen and pancreas, the surgeon should make every effort to manipulate the tumor surface as little as possible (no-touch technique). The soft tissue overlying the superior half of the left kidney is incised and carried from medial to lateral out to the side of the abdominal wall. Inferior dissection should proceed carefully to the aorta medially along the left renal vein, making sure not to divide branches of the posteriorly situated renal artery supplying the upper portion of the kidney or venous branches draining to the renal vein. Small branches supplying and draining the adrenal gland should be carefully ligated and divided. Any lymph nodes posterior to the renal hilum should be included in the dissection.
- The left adrenal vein will be identified at the medial aspect of the left renal vein as it courses anterior to the aorta (FIG 15). It generally enters the adrenal gland in the 7 o'clock position. It should be ligated and divided. The adrenal vein and renal vein should be inspected and carefully palpated to assess for any tumor thrombus so that the tumor thrombus can be included with the

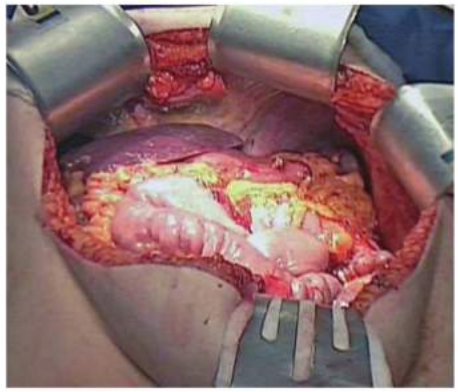

FIG 13 ● The falciform ligament and left triangular and coronary ligaments are divided, allowing exposure of the left upper abdomen and mobility of the liver.

FIG 12 ● The patient is placed supine on the table with arms out. Pressure points are padded. A wide left subcostal incision is marked 2 cm inferior to the costal margin and carried across the midline to the right abdomen to facilitate exposure.

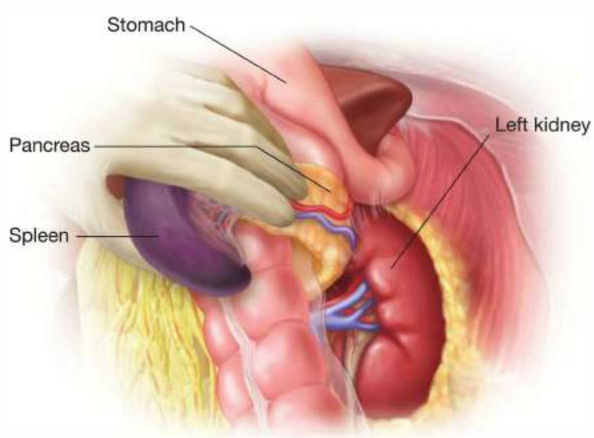

FIG 14 ● The spleen, stomach, and pancreas are mobilized medially.

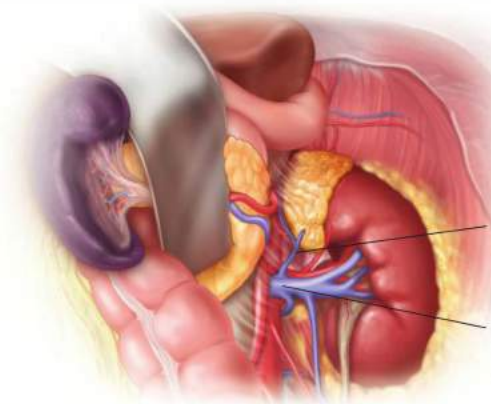

FIG 15 ● With retractors in place, the left retroperitoneum is exposed and excluded from the rest of the peritoneal cavity. The left side of the aorta, renal vein, and adrenal vein are visualized, with the left adrenal vein identified at the medial aspect of the left renal vein. The adrenal vein can be ligated and divided at its junction with the renal vein.

specimen in an en bloc fashion. Advanced techniques for managing large tumor thrombi within the renal vein and vena cava are not discussed in this chapter.

- The fat overlying and just superior to the kidney is mobilized from inferior to superior, making this tissue the inferior margin, using cautery, silk sutures, and other hemostatic devices as needed, making sure not to create a nonexistent plane between the inferior aspect of the tumor and the superior aspect of the kidney.
- Lateral dissection should continue along the abdominal side wall. The dissection continues superiorly along the diaphragm, making sure to ligate and divide any feeding vessels, most commonly branches from the inferior phrenic vessels.
- Posterior dissection should proceed from lateral to medial, making sure to remove all fat and any involved muscle posterior to the tumor in an en bloc fashion.
- The left lateral surface of the aorta should be identified, and the soft tissue attachments including small vessels and lymphatics are ligated and divided. If removing a pheochromocytoma, the anesthesiologist should be warned well in advance prior to ligating the adrenal vein in anticipation of ensuing hypotension. The dissection is continued superiorly until all medial attachments have been released. Any lymph nodes along the aorta or identified near the superior mesenteric artery or celiac axis should be included with the specimen.
- The adrenal gland and the periadrenal soft tissue are removed, marked with orienting suture for the pathologist, and sent to the pathology lab.

Closure

- A small amount of water should be used for irrigation and final hemostasis is achieved. The area encompassed by the dissection should be marked with large clips to assist with postoperative external beam radiation therapy if needed. A drain may be placed.
- The retractor system is removed, the organs replaced in their normal anatomic position, and the abdominal wall musculature is closed in two separate layers. The subcutaneous tissue may be reapproximated with interrupted absorbable sutures if needed and the skin closed with staples or suture. A sterile dressing is applied.

PEARLS AND PITFALLS

Bleeding—arterial and venous	■ May result from disruption of the vena cava, renal vein or artery, and aorta. Kitners, sponge sticks, and vascular clamps are helpful. Obtain proximal and distal control prior to potentially dangerous maneuvers.
Liver mobilization	■ Mobilize right and left lobes to obtain best exposure for right adrenalectomy. Mobilize left lobe to obtain best exposure for left adrenalectomy.
Tumor capsule penetration	■ Avoid this as penetration leads to peritoneal spread, which will result in recurrence and often shortened survival compared to alternate sites of recurrence. En bloc resection is critical to prevent creating a plane through microscopically positive tumor margins.

POSTOPERATIVE CARE

- Most patients will not need intensive care unit (ICU) care, although pheochromocytoma patients often need closer monitoring for the first 24 hours, depending on intraoperative stability and volume status.
- Hydrocortisone should be given administered to patients with overt Cushing's syndrome. A cosyntropin stimulation test can be performed the morning after surgery in subclinical or mild Cushing's cases if there is a question about the requirement for steroid supplementation.
- Electrolytes should be checked the morning after surgery. Patients undergoing surgery for primary hyperaldosteronism may experience rebound hyperkalemia.
- After bilateral adrenalectomy, high-dose intravenous (IV) hydrocortisone should be weaned to replacement

dose oral hydrocortisone and fludrocortisone 0.1 mg daily.

- Antihypertensive medications are withheld in the immediate postoperative setting and reinstituted as needed.
- Routine postoperative care is pursued and patients are discharged 3 to 7 days after surgery.
- Follow-up is typically 1 to 2 weeks after surgery with endocrine testing as needed.

OUTCOMES

- Although laparoscopic surgery has become the gold standard for benign adrenal disease due to decreased bleeding, infection, pain, and hospital stay, open adrenalectomy is still performed if conversion from laparoscopic adrenalectomy is required for various reasons, for very large adrenal tumors, and when adrenocortical carcinoma is in the differential diagnosis, as some studies have found a significantly higher incidence of incomplete positive margin resections, a higher incidence of and shorter time to tumor bed and peritoneal cavity recurrence, and decreased survival compared to laparoscopic surgery.[3–5] A greater number of oncologic principles of resection can be respected with open surgery for adrenal cancer compared to a laparoscopic approach.

COMPLICATIONS

- Bleeding
- Infection
- Adrenal insufficiency in those with Cushing's syndrome
- Postoperative hypotension in those with pheochromocytoma
- Rebound hyperkalemia in those with Conn's syndrome
- Lymphatic leak
- Pneumothorax
- Neurogenic pain
- Abdominal wall laxity

Chapter 47

Adrenalectomy: Open Thoracoabdominal

Barbra S. Miller

DEFINITION

- Adrenal masses may be benign or malignant. If adrenocortical carcinoma is a concern, adrenalectomy by an open approach should be performed. Adrenal masses may be functional or nonfunctional with regard to excess hormone secretion. Several genetic syndromes are associated with adrenal abnormalities and should be evaluated if indicated.

DIFFERENTIAL DIAGNOSIS

- Primary adrenal adenoma
- Primary adrenocortical carcinoma
- Cyst
- Metastatic cancer
- Pheochromocytoma
- Ganglioneuroma
- Adjacent paraganglioma
- Soft tissue tumor

PATIENT HISTORY AND PHYSICAL FINDINGS

- All adrenal abnormalities should be evaluated in a systematic fashion, including a thorough history and physical examination investigating the possibility of a hormone-secreting mass. This includes the possibility of a pheochromocytoma, Cushing's syndrome, primary hyperaldosteronism, and hypertestosteronemia. Specifically, the patient should be questioned regarding poorly controlled hypertension, diabetes, edema, diaphoresis, tachycardia, palpitations, sudden severe headaches, flushing, and easy bruising. The physical exam should look for evidence of central obesity, edema, peripheral wasting, core muscle weakness, a buffalo hump, striae, thin skin, and facial plethora. Because the adrenal gland is situated in the retroperitoneum, unless it is extremely large, palpation of the mass is usually unable to be achieved.

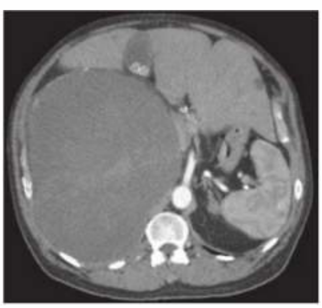

FIG 1 • CT image (axial cut) showing large heterogeneous right adrenal mass concerning for adrenocortical carcinoma.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All adrenal masses should undergo appropriate biochemical testing. Even in the absence of signs or symptoms, patients should have at a minimum the following: potassium, aldosterone, renin, plasma fractionated metanephrines (followed by 24-hour urine metanephrines and normetanephrines, catecholamines, and vanillylmandelic acid [VMA] if plasma values are abnormal), 24-hour urine-free cortisol, and adrenocorticotropic hormone (ACTH). Some physicians may also perform a low-dose dexamethasone suppression test, dehydroepiandrosterone-sulfate (DHEA-S), and free testosterone, among other laboratory tests.
- Imaging studies (**FIGS 1** and **2**) should include an adrenal protocol computed tomography (CT) scan (noncontrast, contrast, 15-minute–delayed scan to calculate washout percentage of contrast from the tumor) or magnetic resonance imaging (MRI) (to assess for loss of signal intensity between in and out of phase images) and a positron emission tomography (PET) scan if malignancy is questioned.
- Additional imaging studies may be required depending on the functionality of the tumor (metaiodobenzylguanidine [MIBG] for pheochromocytoma in select cases, adrenal vein sampling for hyperaldosteronism, etc.).
- Fine needle aspiration or core biopsy is not recommended if adrenocortical carcinoma is possible but may be useful if metastasis to the adrenal gland is in the differential and the adrenal tumor is the most accessible site of metastasis in the setting of multiple sites of metastatic disease. If biopsy is performed, it is imperative to first biochemically rule out pheochromocytoma as a diagnosis.

FIG 2 • CT image (coronal cut) showing large heterogeneous right adrenal mass concerning for adrenocortical carcinoma.

SURGICAL MANAGEMENT

- Adrenal tumors, if benign appearing by imaging criteria and hormonally nonfunctional, should be reevaluated with at least one additional CT scan or MRI 6 to 12 months after the initial imaging study to ensure stability in size and internal imaging characteristics. Some advocate for a longer period of follow-up imaging for 2 years with reevaluation of biochemistry for 4 more years.[1]
- Functional tumors leading to hormone excess, indeterminate masses, and those suspected of being adrenocortical carcinoma or isolated metastatic disease from another primary tumor without evidence of widespread metastatic disease should be removed.
- Adrenalectomy may be performed by anterior, posterior, or thoracoabdominal approach. The thoracoabdominal approach is particularly useful for providing excellent exposure and access to large adrenal tumors.[2–5] Although excellent exposure can be achieved by an anterior approach in most cases, the thoracoabdominal approach is most beneficial in patients who have undergone prior abdominal surgery, thereby avoiding the time and potential morbidity associated with extensive lysis of adhesions.

Preoperative Planning

- The surgeon must evaluate available imaging studies for possible involvement of adjacent organs and vessels and lymphadenopathy. Invasion of major vessels (vena cava) or adjacent organs may require additional teams or different approaches to the tumor. As CT tends to overestimate invasion of adjacent vessels, MRI with magnetic resonance venogram can be especially helpful to assess for vena cava invasion or intracaval tumor thrombus.
- The risks, benefits, and alternatives to surgery are discussed with the patient including potential need for steroid supplementation in the postoperative setting. Patients with pheochromocytomas should be adequately alpha blocked and volume replete. Beta blockade may also be necessary. A potassium level should be checked the morning of surgery and treated as necessary in patients with hyperaldosteronism.
- Routine prophylactic antibiotics and deep vein thrombosis (DVT) prophylaxis are administered prior to surgery, and sequential compression devices are applied.
- A general endotracheal anesthetic is administered. A dual lumen endotracheal tube may be placed for improved exposure but in general is not required.
- An epidural is often placed for postoperative pain management.
- Common to all approaches, skin preparation with clipping rather than shaving is prepared, and the surgical area is prepped and draped in a sterile fashion.

Positioning

- For a right adrenalectomy, the patient is placed in semi–left lateral decubitus position on a beanbag with an axillary roll beneath the left axilla. The right arm is held in place parallel over the left arm with a thoracic arm holder (**FIG 3**). For a left adrenalectomy, the opposite setup is performed. The pelvis remains flat. This allows access to the chest and abdomen. The bed is flexed to increase the space between the ribs and the pelvis.
- All pressure points are padded appropriately.
- The patient is prepped and draped.

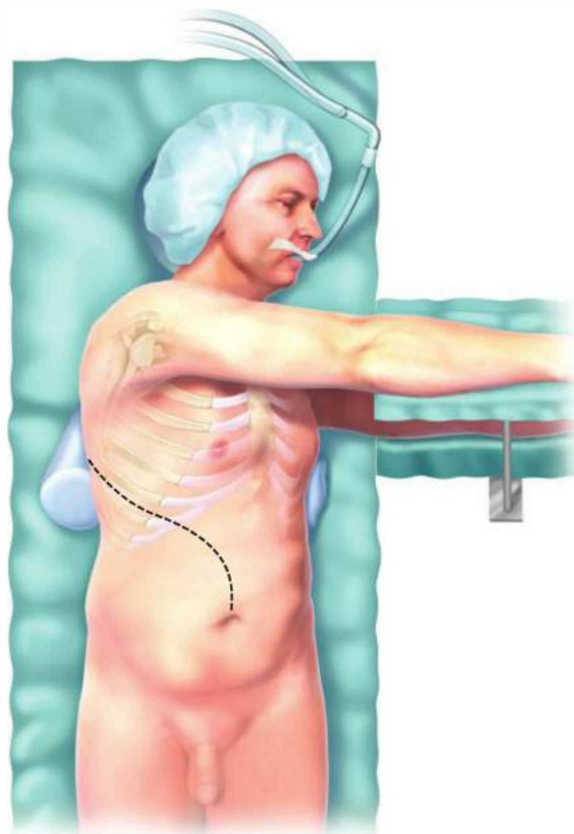

FIG 3 ● The patient is placed in semi–left lateral decubitus position on a beanbag with an axillary roll beneath the left axilla. The chest is nearly fully lateral, and the pelvis remains flat (corkscrew twist). The right arm is held in place parallel over the left arm with a thoracic arm holder.

RIGHT ADRENALECTOMY

Exposure

- An incision is made 2 cm inferior to the tip of the right scapula and extended to a point midway between the xiphoid process and the umbilicus (**FIG 4**). If necessary, the incision can then be carried inferiorly along the midline of the abdomen. The subcutaneous tissue and muscle are divided, sparing the latissimus dorsi and incising the serratus anterior. The chest is entered at the 8th intercostal space, the pulmonary ligament divided, and the lung retracted superiorly. The diaphragm is incised 2 to 4 cm from its attachments, sparing the phrenic nerve. Several marking stitches should be placed intermittently on either side of the divided diaphragm to aid with reapproximation at the end of the case (**FIG 5**). The costochondral cartilage is divided. A portion may be excised. The abdominal incision is extended and the peritoneal cavity is entered. A self-retaining retractor system can be placed.
- The diaphragmatic attachments to the right lobe of the liver are released with electrocautery as is the falciform ligament. The ligamentum teres is ligated and divided with silk ligatures. If the adrenal tumor is adherent to the diaphragm, that portion of the diaphragm should be removed en bloc with the tumor and can be reconstructed with mesh or other material. Inspection of the peritoneal cavity is performed as much as possible in a systematic

FIG 5 ● **A.** The diaphragm is incised 2 to 4 cm from its attachments, sparing the phrenic nerve. **B.** Several marking stitches *(arrows)* can be placed intermittently on either side of the divided diaphragm to aid with reapproximation at the end of the case.

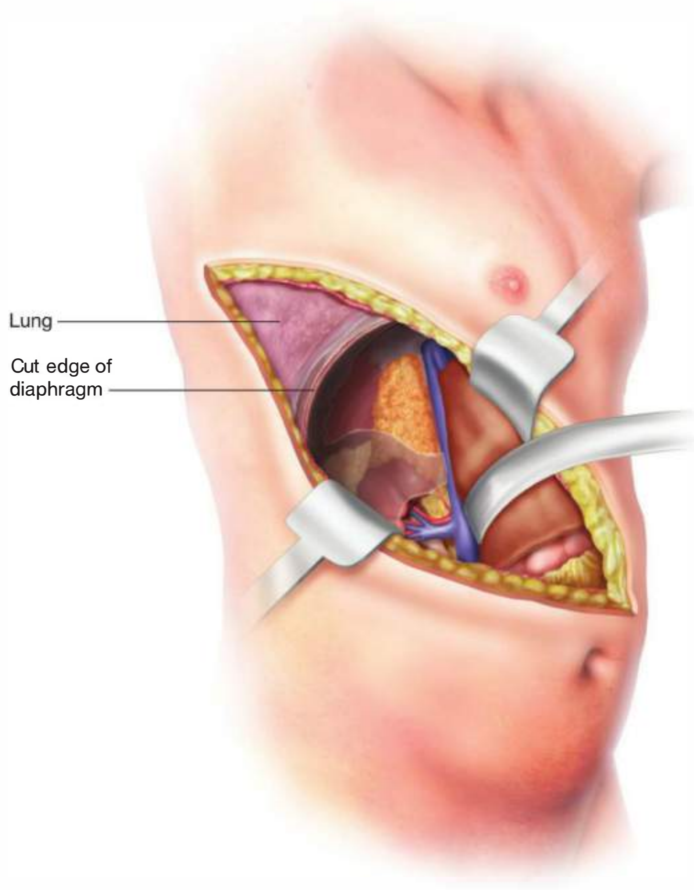

FIG 6 ● The diaphragmatic attachments to the right lobe of the liver are released with electrocautery as is the falciform ligament. Both lobes of the liver are mobilized. A portion of the diaphragm should be removed en bloc with any adherent tumor.

fashion and an ultrasound of the liver is performed. The right lobe of the liver is retracted toward the left side, allowing access to the retrohepatic inferior vena cava (**FIG 6**).

Dissection

- The posterior peritoneal lining over the retroperitoneum in incised over the superior half of the right kidney and carried from medial to lateral out to the side of the abdominal wall (**FIG 7**). Medial dissection should proceed carefully to the vena cava, making sure not to divide branches of the renal artery supplying the upper portion of the kidney or venous branches draining to the renal vein. Small branches supplying and draining the adrenal gland should be carefully ligated and divided. Any lymph nodes posterior to the renal hilum should be included in the dissection.
- The fat overlying and just superior to the kidney is mobilized from inferior to superior, making this tissue the

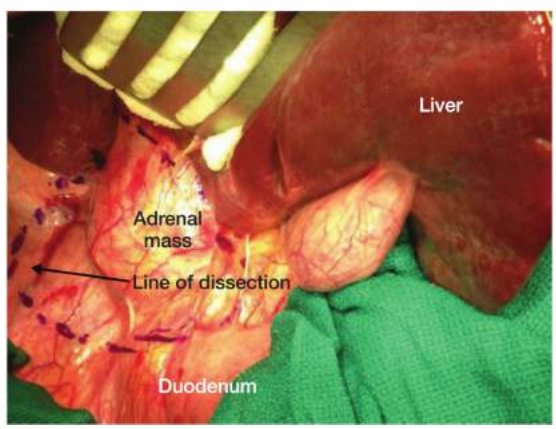

FIG 7 ● The posterior lining over the retroperitoneal fat and kidney is incised over the superior half of the right kidney and carried from medial to lateral out to the side of the abdominal wall.

inferior margin, using cautery, silk sutures, and other hemostatic devices as needed, making sure not to create a nonexistent plane between the inferior aspect of the tumor and the superior aspect of the kidney. The peritoneal lining should remain intact over the anterior aspect of the tumor to serve as the anterior margin if not already invaded by the tumor. The dissection continues superiorly along the diaphragm, making sure to ligate and divide any feeding vessels, most commonly branches from the inferior phrenic vessels. Posterior dissection should proceed from lateral to medial, making sure to remove all fat posterior to the tumor in an en bloc fashion. If the tumor invades the muscle, a portion of the muscle should be included with the tumor to ensure negative margins.

- The anterior surface of the vena cava should be identified and the peritoneal lining overlying this should be incised along its length. Using a vein retractor to retract the vena cava medially, soft tissue attachments, including small vessels and lymphatics, are ligated and divided. As the midpoint of the adrenal gland is reached, the right adrenal vein should be identified, ligated, and divided. The vein should be inspected and carefully palpated to assess for any tumor thrombus so that the tumor thrombus can be included with the specimen in an en bloc fashion. Advanced techniques for managing large tumor thrombi within the vena cava are not discussed in this chapter. If removing a pheochromocytoma, the anesthesiologist should be warned well in advance prior to ligating the adrenal vein in anticipation of ensuing hypotension. The dissection is continued superiorly until all medial attachments have been released. Retraction of the vena cava allows access to posterior tissue, which should be removed as well. The adrenal gland and the periadrenal soft tissue are removed, marked with orienting suture for the pathologist, and sent to the pathology lab.

Closure

- A small amount of water should be used for irrigation and final hemostasis is achieved. The area encompassed by the dissection should be marked with large clips to assist with postoperative external beam radiation therapy if needed. A drain may be placed in the adrenal bed, and a chest tube is placed.
- Closure is begun, and the bed is taken out of the flexed position. A chest tube is placed. The diaphragm is repaired with no. 1 polydioxanone (PDS) suture in a running locking or interrupted fashion.
- At the junction of the diaphragm and abdominal fascia, a no. 2 Vicryl figure-of-eight suture is used to reapproximate the tissue en masse. If a portion of the costochondral cartilage has not been excised, it may be reapproximated using a microdrill and a no. 2 Vicryl suture. The ribs are also reapproximated with no. 2 Vicryl sutures, with or without the microdrill (**FIGS 8** and **9**).

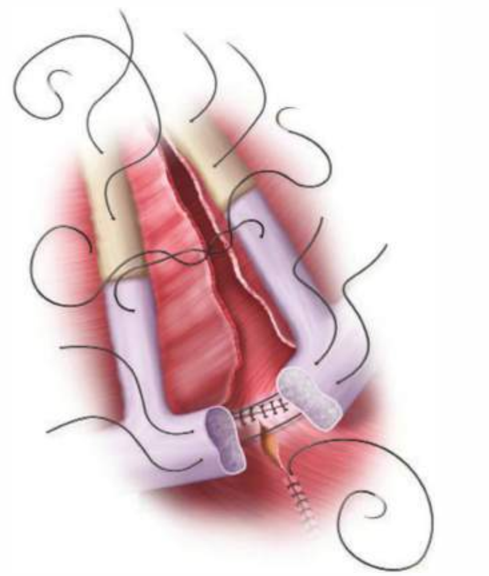

FIG 8 ● A portion of the costal margin can be excised to minimize postoperative rubbing of the ends and costochondritis. If a portion of the costochondral cartilage has not been excised, it may be reapproximated using a microdrill and a no. 2 Vicryl suture. The ribs are reapproximated with no. 2 Vicryl sutures, with or without the microdrill.

A rib approximator device helps decrease the tension required to tie the sutures. The abdominal midline is reapproximated with running no. 1 PDS suture. The chest wall musculature is closed in two separate layers using no. 1 Vicryl suture. The skin is closed with staples and a sterile dressing is applied (**FIG 10**).

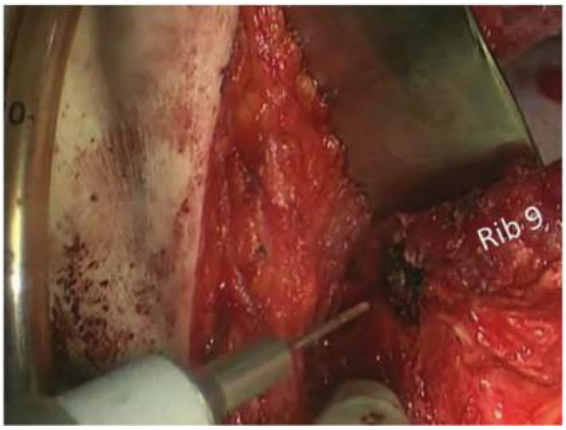

FIG 9 ● The microdrill is used to help reapproximate the ribs.

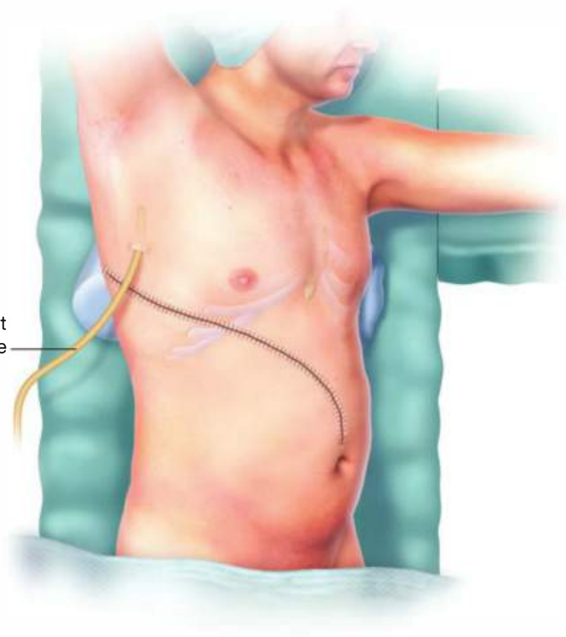

FIG 10 ● During closure, a chest tube is inserted. The abdominal midline is reapproximated in a single layer. The chest wall musculature is closed in several layers. The skin is closed with staples and a sterile dressing is applied.

LEFT ADRENALECTOMY

Exposure

- An incision is made 2 cm inferior to the tip of the right scapula and extended to a point midway between the xiphoid process and the umbilicus (**FIGS 11** and **12**). If necessary, the incision can then be carried inferiorly along the midline of the abdomen. The subcutaneous tissue and muscle are divided, sparing the latissimus dorsi and incising the serratus anterior. The chest is entered at the 8th intercostal space, the pulmonary ligament divided, and the lung retracted superiorly. The diaphragm is incised 2 to 4 cm from its attachments, sparing the phrenic nerve. Several marking stitches should be placed intermittently on either side of the divided diaphragm to aid with reapproximation at the end of the case. The costochondral cartilage is divided. A portion may be excised. The abdominal incision is extended and the peritoneal cavity is entered. A self-retaining retractor system is placed.
- The diaphragmatic attachments to the spleen are released with electrocautery and reflected toward the right side along with the stomach and pancreas. If the adrenal tumor is adherent to the diaphragm, that portion of the diaphragm should be removed en bloc with the tumor and can be reconstructed with mesh or other material. The splenocolic attachments will require release and the omentum is released from the colon. The ligamentum teres is ligated and divided with silk ligatures.
- Inspection of the peritoneal cavity is performed as much as possible in a systematic fashion, and an ultrasound of the liver is performed.
- The left lobe of the liver is retracted toward the right side, allowing for better mobilization of the stomach, spleen, and pancreas.
- A large saline-soaked towel with retractors is placed against the bowel, pancreas, and spleen to not only provide exposure but also to exclude the rest of the

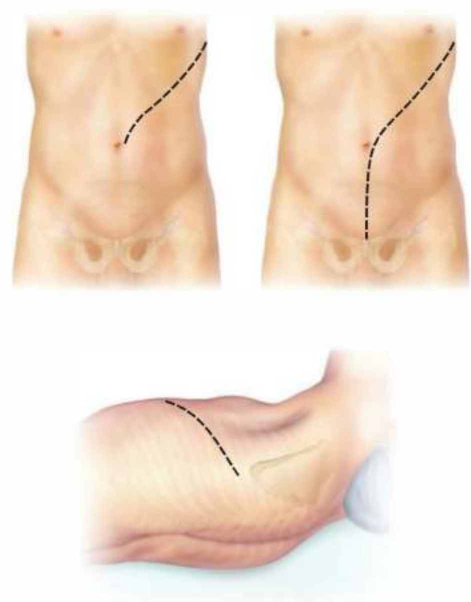

FIG 11 ● Options for left thoracoabdominal incision for adrenalectomy.

FIG 12 ● An incision is made 2 cm inferior to the tip of the right scapula and extended to a point midway between the xiphoid process and the umbilicus.

peritoneal cavity to minimize potential seeding of the peritoneal cavity. The left side of the aorta should be appreciable if the exposure is adequate (**FIG 13**).

Dissection

- Because the peritoneal covering on the left has been reflected with the spleen and pancreas, the surgeon should make every effort to manipulate the tumor surface as little as possible (no-touch technique). The soft tissue overlying the superior half of the left kidney is incised and carried from medial to lateral out to the side of the abdominal wall. Inferior dissection should proceed carefully to the aorta medially along the left renal vein, making sure not to divide branches of the posteriorly situated renal artery supplying the upper portion of the kidney or venous branches draining to the renal vein. Small branches supplying and draining the adrenal gland should be carefully ligated and divided. Any lymph nodes posterior to the renal hilum should be included with the dissection. The left adrenal vein will be identified at the medial aspect of the left renal vein as it courses anterior to the aorta. It generally enters the adrenal gland in the 7 o'clock position. It should be ligated and divided. The adrenal vein and renal vein should be inspected and carefully palpated to assess for any tumor thrombus so that the tumor thrombus can be included with the specimen in an en bloc fashion. Advanced techniques for managing large tumor thrombi within the renal vein and vena cava are not discussed in this chapter. The fat overlying and just superior to the kidney is mobilized from inferior to superior, making this tissue the inferior margin, using cautery, silk sutures, and other hemostatic devices as needed, making sure not to create a nonexistent plane between the inferior aspect of the tumor and the superior aspect of the kidney. Lateral dissection should continue along the abdominal side wall. The dissection continues superiorly along the diaphragm, making sure to ligate and divide any feeding vessels, most commonly branches from the inferior phrenic vessels. Posterior dissection should proceed from lateral to medial, making sure to remove all fat posterior to the tumor in an en bloc fashion. If the tumor invades the muscle, a portion of the muscle should be included with the tumor to ensure negative margins. The left lateral surface of the aorta should be identified, and the soft tissue attachments including small vessels and lymphatics are ligated and divided. If removing a pheochromocytoma, the anesthesiologist should be warned well in advance prior to ligating the adrenal vein in anticipation of ensuing hypotension. The dissection is continued superiorly until all medial attachments have been released. Any lymph nodes along the aorta or identified near the superior mesenteric artery or celiac axis should be included with the specimen. The adrenal gland and the periadrenal soft tissue is removed, marked with orienting suture for the pathologist, and sent to the pathology lab.

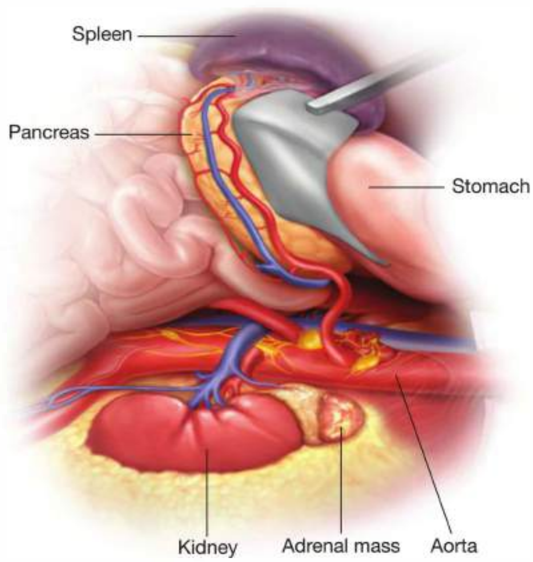

FIG 13 ● With the stomach, pancreas, and spleen retracted medially, the aorta, adrenal mass, and kidney are exposed and excluded from the rest of the peritoneal cavity.

Closure

- A small amount of water should be used for irrigation and final hemostasis achieved. The area encompassed by the dissection should be marked with large clips to assist with postoperative external beam radiation therapy if needed. A drain may be placed in the adrenal bed, and a chest tube is placed. Closure is begun, and the bed is taken out of the flexed position. The diaphragm is repaired with no. 1 PDS suture in a running locking or interrupted fashion. At the junction of the diaphragm and abdominal fascia, a no. 2 Vicryl figure-of-eight suture is used to reapproximate the tissue en masse. If a portion of the costochondral cartilage has not been excised, it may be reapproximated using a microdrill and a no. 2 Vicryl suture. The ribs are also reapproximated with no. 2 Vicryl sutures, with or without the microdrill. A rib approximator device helps decrease the tension required to tie the sutures. The abdominal midline is reapproximated with running no. 1 PDS suture. The chest wall musculature is closed in two separate layers using no. 1 Vicryl suture. The skin is closed with staples and a sterile dressing is applied.

PEARLS AND PITFALLS

Atelectasis	▪ Ensure excellent respiratory care and pulmonary toilet due to increased pain limiting respiratory effort.
Bleeding	▪ Access to the suprahepatic inferior vena cava is improved during left adrenalectomy with this approach, allowing for easier vascular control.
Pain	▪ Thoracoabdominal incisions are associated with greater pain than other incisions. Local anesthetic blocks may be helpful.
Neurovascular bundle of rib	▪ Avoid transection of the bundle and damage to the nerve by incising along the superior border of the rib.
Phrenic nerve palsy	▪ Take care to stay away from the phrenic nerve when incising the diaphragm.

POSTOPERATIVE CARE

- Most patients will need intensive care unit (ICU) care for 24 to 48 hours, either for pulmonary care or for resuscitation. The chest tube may be managed in standard fashion and removed when appropriate.
- Hydrocortisone should be administered to patients with overt Cushing's syndrome. A cosyntropin stimulation test can be performed the morning after surgery in subclinical or mild Cushing's cases if there is a question about the requirement for steroid supplementation. After bilateral adrenalectomy, high-dose intravenous (IV) hydrocortisone should be weaned to replacement dose oral hydrocortisone and fludrocortisone 0.1 mg daily. Electrolytes should be checked the morning after surgery. Patients undergoing surgery for primary hyperaldosteronism may experience rebound hyperkalemia. Antihypertensive medications are withheld in the immediate postoperative setting and reinstituted as needed. Routine postoperative care is pursued and patients are discharged approximately 5 to 7 days after surgery. Follow-up is typically 1 to 2 weeks after surgery with endocrine testing as needed.

OUTCOMES

- Excellent outcomes can be expected with low morbidity if aggressive respiratory care and pain control is initiated early in the postoperative period.

COMPLICATIONS

- Prolonged atelectasis: 21%
- Prolonged ileus: 9%
- Phrenic nerve injury and diaphragmatic paralysis
- Chronic pain

Chapter 48

Adrenalectomy: Open Posterior

Barbra S. Miller

DEFINITION

- Adrenal masses may be benign or malignant and functional or nonfunctional with regard to excess hormone secretion. An open posterior approach should be considered if:
  - An anterior, lateral, or posterior retroperitoneoscopic approach is not feasible in a patient with a benign or metastatic adrenal tumor.
  - An open anterior approach is not feasible in patients who have undergone previous extensive upper abdominal surgery and are presumed to have dense adhesions limiting access.
  - Conversion from a retroperitoneoscopic posterior approach to an open approach is required.
  - Both adrenals need to be removed and repositioning of the patient during the case is to be avoided.

DIFFERENTIAL DIAGNOSIS

- Primary adrenal adenoma
- Primary adrenocortical carcinoma
- Cyst
- Metastatic cancer
- Pheochromocytoma
- Ganglioneuroma
- Adjacent paraganglioma
- Soft tissue tumor

PATIENT HISTORY AND PHYSICAL FINDINGS

- All adrenal abnormalities should be evaluated in a systematic fashion, including a thorough history and physical examination investigating the possibility of a hormone-secreting mass. This includes the possibility of a pheochromocytoma, Cushing's syndrome, primary hyperaldosteronism, and hypertestosteronemia. Specifically, the patient should be questioned regarding poorly controlled hypertension, diabetes, edema, diaphoresis, tachycardia, palpitations, sudden severe headaches, flushing, and easy bruising. The physical exam should look for evidence of central obesity, edema, peripheral wasting, core muscle weakness, a buffalo hump, striae, thin skin, and facial plethora. Because the adrenal gland is situated in the retroperitoneum, unless it is extremely large, palpation of the mass is usually unable to be achieved.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All adrenal masses should undergo appropriate biochemical testing. Even in the absence of signs or symptoms, patients should have at a minimum: potassium, aldosterone, renin, plasma fractionated metanephrines (followed by 24-hour urine metanephrines and normetanephrines, catecholamines, and vanillylmandelic acid (VMA) if plasma values are abnormal), 24-hour urine-free cortisol, and adrenocorticotropic hormone (ACTH). Some physicians may also perform a low-dose dexamethasone suppression test and obtain dehydroepiandrosterone Sulfate (DHEA-S) and free testosterone, among other laboratory tests.
- Imaging studies should include an adrenal protocol computed tomography (CT) scan (to assess imaging characteristics and calculate washout percentage of contrast from the tumor) or magnetic resonance imaging (MRI) (to assess decrease in signal between in and out of phase images) and 18F-Fluorodeoxyglucose (18FDG) positron emission tomography (PET) CT if malignancy is questioned (**FIG 1**).
- Additional imaging studies may be required depending on the functionality of the tumor (metaiodobenzylguanidine [MIBG] for some pheochromocytoma patients, adrenal vein sampling for hyperaldosteronism, etc.).
- Fine needle aspiration or core biopsy is not recommended if adrenocortical carcinoma is questioned. FNA may be useful if metastasis to the adrenal gland is in the differential and the adrenal tumor is the most accessible site of metastasis in the setting of multiple sites of metastatic disease. If biopsy is performed, it is imperative to first biochemically rule out pheochromocytoma.

SURGICAL MANAGEMENT

- Adrenal tumors, if benign appearing by imaging criteria, nonfunctional, and therefore not requiring resection, should be reevaluated with at least one additional CT scan or MRI 6 to 12 months after the initial imaging study to ensure stability in size and internal imaging characteristics. Some advocate for a longer period of follow-up imaging for 2 years with reevaluation of biochemistry for 4 years.[1]
- Functional tumors leading to hormone excess, indeterminate masses, and those suspected of being adrenocortical carcinoma or isolated metastatic disease from another primary tumor without evidence of widespread metastatic disease should be removed.

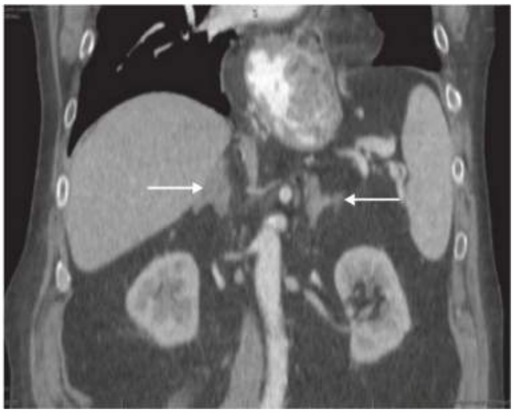

FIG 1 ● Bilateral hyperplastic adrenal glands *(arrows)* with benign imaging characteristics are shown in an obese patient with Cushing's disease requiring bilateral adrenalectomy.

Preoperative Planning

- The surgeon must evaluate available imaging studies for possible adrenocortical carcinoma or tumor involvement of adjacent organs, vessels, and lymphadenopathy. An open posterior approach is not optimal for removing adrenocortical carcinomas or large tumors, as the working space is limited by the rib cage and does not allow for multivisceral resections. These types of tumors should be approached by an open anterior or thoracoabdominal approach.
- The surgeon should evaluate the position of the adrenal gland with respect to the overlying rib that will need to be resected as well as any visible vasculature supplying or draining the adrenal gland.
- The risks, benefits, and alternatives to surgery are discussed with the patient including potential need for steroid supplementation in the postoperative setting. Patients with pheochromocytomas should be adequately alpha blocked and volume replete. Beta blockade may also be necessary. A potassium level should be checked the morning of surgery and treated as necessary in patients with Conn's syndrome (hyperaldosteronism).
- Routine prophylactic antibiotics and deep vein thrombosis (DVT) prophylaxis are administered prior to surgery, and sequential compression devices are applied.
- A general endotracheal anesthetic is administered.
- Common to all approaches, skin preparation with clipping rather than shaving is prepared, and the surgical area is prepped and draped in a sterile fashion.

Positioning

- Patients are intubated and a Foley catheter is placed prior to placing the patient in a modified prone position. Several methods for positioning may be used, including use of the Wilson frame, the Cloward surgical saddle, gel rolls, and flexion of the table (**FIG 2**). All of these have the common goal of creating a gentle flexion of the spine. Space is also created for the abdominal contents to shift away from the retroperitoneum.
- All pressure points are padded appropriately.

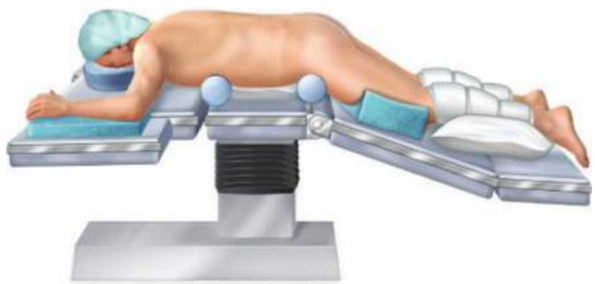

FIG 2 • The patient is placed in a modified prone position. Pressure points are padded.

TECHNIQUES

LEFT ADRENALECTOMY

Exposure

- A curvilinear incision is made from a paramedian position (4 to 5 cm from the spine) over the left 10th rib and carried inferolaterally toward the iliac crest. Alternatively, a straighter incision over the 11th or 12th rib, depending on the position of the gland on CT scan, with a more vertical upward incision medially may be made (**FIGS 3** and **4**).
- The subcutaneous tissue and musculature (latissimus dorsi and lumbodorsal fascia) are divided. The sacrospinalis is retracted medially with a handheld retractor. The 12th rib (and occasionally the 11th rib) is cleared of its attachments in a subperiosteal fashion using cautery and a Doyen or periosteal elevator, making sure to preserve the neurovascular bundle (**FIGS 5** and **6**). The rib is transected as far medially as possible with bone cutters and removed in its entirety. Bone wax may be used to assist with hemostasis.
- Entrance into the diaphragm and pleura should be avoided and the diaphragm is reflected superiorly. The retroperitoneal fat will be evident (**FIG 7**).

Dissection

- Using retractors to separate the tissue and rib(s), Gerota's fascia is incised after identifying the upper pole of the kidney. The surgeon's hand places downward (inferior and toward the peritoneal cavity) pressure on the kidney to facilitate exposure of the adrenal gland (**FIG 8**).
- The inferior, lateral, superior, and medial attachments may be divided in similar fashion to the standard open anterior approach, but the peritoneum overlying the anterior surface of the gland as described in the anterior open approach is not included with the specimen. The inferior attachments should be left until last, as they assist in retraction and exposure of the gland.
- The left adrenal vein should be ligated and divided when encountered during the course of dissection of the inferior attachments and will be found medially near the junction of the superior aspect of the left renal vein with the lateral aspect of the aorta in a 5 o'clock position due to the prone position. The left adrenal vein will be slightly posterior while in the prone position beneath some of the fatty attachments between the adrenal gland and left renal vein.
- The adrenal gland with the periadrenal soft tissue is removed en bloc, marked with orienting sutures for the pathologist, and sent to the pathology lab.

Closure

- A small amount of water should be used for irrigation and final hemostasis is achieved. A drain may be placed if desired but is not required in most cases.
- The musculature and subcutaneous tissue are closed in layers and the skin closed with staples or suture. A sterile dressing is applied.

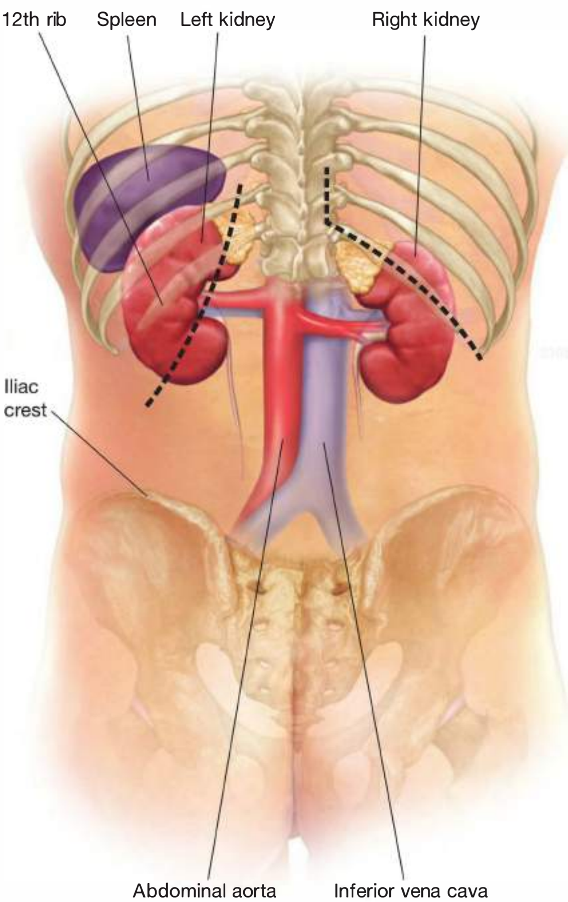

FIG 3 ● The incision can be made in a linear or curvilinear fashion to facilitate access to the 11th and 12th ribs.

FIG 4 ● Intraoperative image of curvilinear incision carried from 10th rib medially across the 11th rib and inferior to the 12th rib laterally.

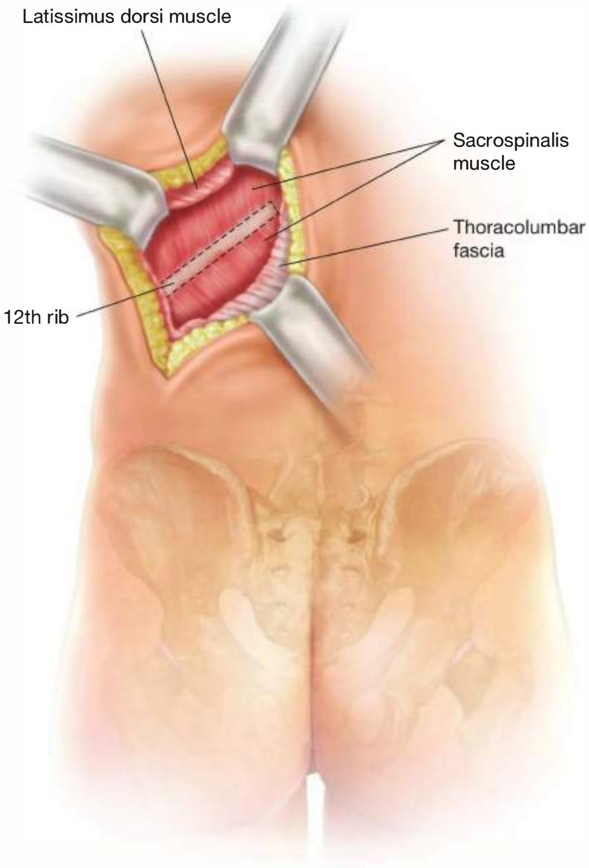

FIG 5 ● Schematic of exposure of the 12th rib that is cleared of its attachments in a subperiosteal fashion using cautery and a Doyen or periosteal elevator, making sure to preserve the neurovascular bundle.

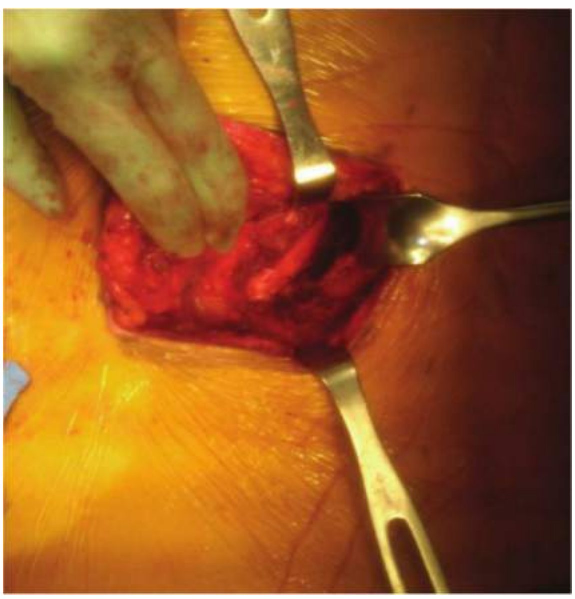

FIG 6 ● Intraoperative photo showing exposure of the 12th rib.

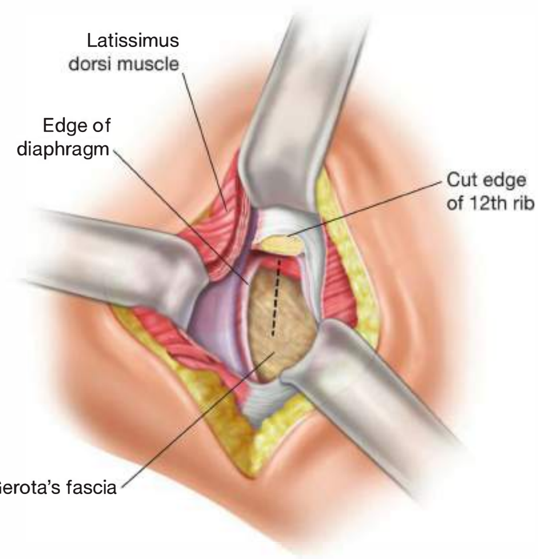

FIG 7 ● After removal of the 12th rib, Gerota's fascia and the retroperitoneal fat is evident.

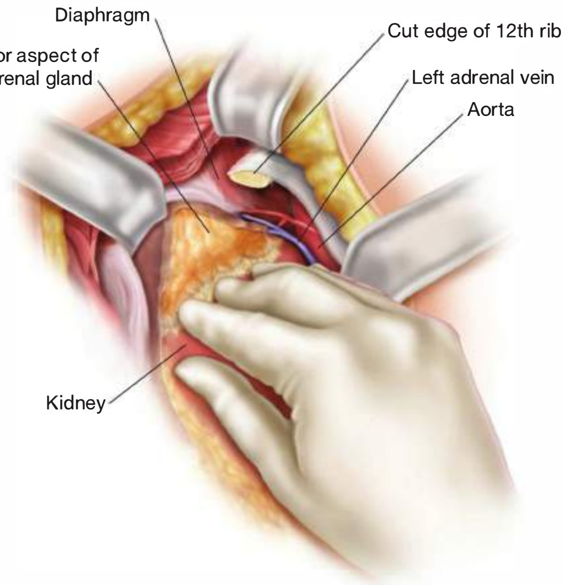

FIG 8 ● The left adrenal gland is best exposed using retractors and downward retraction using the hand on the upper pole of the kidney. The left adrenal vein is located in a 5 o'clock position.

RIGHT ADRENALECTOMY

Exposure

- A curvilinear incision is made from a paramedian position (4 to 5 cm from the spine) over the right 10th rib and carried inferolaterally toward the iliac crest. Alternatively, a straighter incision over the 11th or 12th rib, depending on the position of the gland on CT scan, with a more vertical upward incision medially may be made.
- The subcutaneous tissue and musculature (latissimus dorsi and lumbodorsal fascia) are divided. The sacrospinalis is retracted medially with a handheld retractor. The 12th rib (and occasionally the 11th rib) is cleared of its attachments in a subperiosteal fashion using cautery and a Doyen or periosteal elevator, making sure to preserve the neurovascular bundle. The rib is transected as far medially as possible with bone cutters and removed in its entirety. Bone wax may be used to assist with hemostasis.
- Entrance into the diaphragm and pleura should be avoided and is reflected superiorly. The retroperitoneal fat will be evident.

Dissection

- Using retractors to separate the tissue and rib(s), Gerota's fascia is incised after identifying the area of the upper pole of the kidney. The surgeon's hand places downward (inferior and toward the peritoneal cavity) pressure on the kidney to facilitate exposure of the adrenal gland (**FIG 9**).

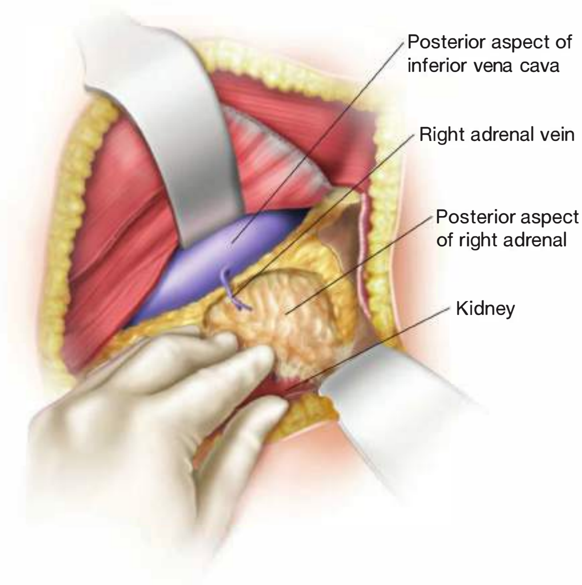

FIG 9 ● The right adrenal gland is best exposed using retractors and downward retraction using the hand on the upper pole of the kidney. The right adrenal vein is located in a 9 o'clock position.

- The right adrenal vein will be found along the medial aspect of the gland in a more anterior position off of the inferior vena cava (IVC) due to the prone position of the patient and should be ligated and divided.
- The inferior, lateral, superior, and medial attachments may be divided in similar fashion to the standard approach, but the peritoneum overlying the anterior surface of the gland as described in the anterior open approach is not included with the specimen. The inferior attachments should be left until last, as they assist in retraction and exposure of the gland.
- The adrenal gland with the periadrenal soft tissue is removed en bloc, marked with orienting sutures for the pathologist, and sent to the pathology lab.

Closure

- A small amount of water should be used for irrigation and final hemostasis is achieved.
- A drain may be placed if desired but is not required in many cases.
- The musculature and subcutaneous tissue are closed in layers and the skin closed with staples or suture. A sterile dressing is applied.

PEARLS AND PITFALLS

Bleeding—arterial and venous	■ May result from disruption of the vena cava, renal vein or artery, and aorta. A laparoscopic knot pusher, Allis clamp, and/or Kitner may be helpful given limited access due to the overlying ribs.
Diaphragmatic penetration	■ May occur upon entry to the retroperitoneum. May be closed in standard fashion.
Neurovascular bundle injury	■ Chronic pain may result if care is not taken to spare the bundle when removing the rib or upon closure of the wound.

POSTOPERATIVE CARE

- Most patients will not need intensive care unit (ICU) care, although pheochromocytoma patients often need closer monitoring for the first 24 hours, depending on intraoperative stability and volume status.
- Hydrocortisone should be given to patients with overt Cushing's syndrome. A cosyntropin stimulation test can be performed the morning after surgery in subclinical or mild Cushing's cases if there is a question about the requirement for steroid supplementation.
- Electrolytes should be checked the morning after surgery. Patients undergoing surgery for primary hyperaldosteronism may experience rebound hyperkalemia.
- After bilateral adrenalectomy, high-dose intravenous (IV) hydrocortisone should be weaned to replacement dose oral hydrocortisone and fludrocortisone 0.1 mg daily.
- Routine postoperative care is pursued. Diets may be begun early, as ileus is not usually an issue due to the entirely retroperitoneal dissection. Patients are discharged 2 to 3 days after surgery.
- Follow-up is typically 1 to 2 weeks after surgery with endocrine testing as indicated.

OUTCOMES

- Outcomes in general are quite good; however, hospital stay is longer, pain is greater, and morbidity can be higher compared to other approaches.[2]
- Neurologic changes due to injury of the neurovascular bundle coursing along the inferior aspect of the rib can be problematic.

COMPLICATIONS

- Bleeding
- Infection
- Adrenal insufficiency in those with Cushing's syndrome
- Postoperative hypotension in those with pheochromocytoma
- Rebound hyperkalemia in those with Conn's syndrome
- Lymphatic leak
- Pneumothorax
- Neurogenic pain
- Laxity of flank musculature

Chapter 49

Laparoscopic Retroperitoneal Adrenalectomy

Michael G. Johnston James A. Lee

INDICATIONS

- Adrenalectomy is indicated for a variety of different clinical scenarios, including patients with (1) a functional tumor; (2) a solid adrenal mass larger than 3 to 4 cm, due to increasing risk of adrenocortical carcinoma; (3) growth of 0.5 cm or greater in 6 months based on serial cross-sectional imaging, again due to a risk of adrenocortical carcinoma; and (4) isolated metastasis from a remote primary malignancy.
- Laparoscopic adrenalectomy is now considered standard practice due to its shorter duration of postoperative pain, shorter hospitalization, and faster return to work compared to an open procedure.
- Contraindications to the transabdominal laparoscopic approach include severe cardiopulmonary disease and coagulopathy. Relative contraindications include prior intraabdominal surgery and very large tumor size.
- The laparoscopic retroperitoneal approach is based on the historical open posterior approach. This approach is gaining popularity as it offers advantages over a laparoscopic transabdominal approach. These advantages include faster operating times, potentially less postoperative pain, a lower risk of complications (especially of incisional hernia), and improved intraoperative hemostasis as the surgeon has the ability to increase the insufflation pressure to 30 mmHg (a maneuver not feasible in a laparoscopic transabdominal approach given the negative impact on central venous return and renal perfusion).
- The laparoscopic retroperitoneal approach does have some potential drawbacks. There is a slightly longer learning curve associated with the nontraditional "back-door" anatomic view. This approach may also be more difficult in patients with large tumors or who are morbidly obese.
- The posterior approach is the ideal approach for bilateral procedures because it eliminates the need for patient repositioning. It is also preferable for patients who have had previous transabdominal operations.
- Absolute contraindications to the laparoscopic retroperitoneal approach include the need to explore the rest of the abdomen and coagulopathy.
- Relative contraindications include an adrenal mass greater than 8 cm due to the smaller working space, patient body mass index greater than 45 due to the patient's pannus and visceral fat compressing the retroperitoneal working space. Severe cardiopulmonary disease is also a relative contraindication but may be less of an issue than for the transabdominal laparoscopic approach, as the diaphragm is not compressed to the same extent. Theoretically, increased ocular pressures are also a relative contraindication, as an extended time in a prone position would put the optic nerve at risk. This is usually only a problem for very long operations, however, and the vast majority of laparoscopic retroperitoneal adrenalectomies should not threaten the optic nerve.

PREOPERATIVE PLANNING

- As with any endocrine disease, the workup of adrenal disease typically follows a logical progression, from making a biochemical diagnosis to localizing the lesion to determining the indications for an operation. In deciding if an operation is indicated, the two principal questions to be answered are (1) "Is the mass functional?" and (2) "What is the risk for cancer (either primary or metastatic disease)?" Most functional tumors and most malignant lesions should be considered for resection, taking into account the patient's overall health, prognosis, and preferences.
  - Aldosteronoma. Ideally, the potassium level should be normalized preoperatively. Potassium supplements and/or aldosterone antagonists may be employed to achieve this goal. Maintain or optimize the antihypertensive regimen preoperatively.
  - Pheochromocytoma. Give the patient an α-blocker such as phenoxybenzamine. Start at 10 mg twice daily and increase the frequency and dose as tolerated until the patient becomes slightly symptomatic (including mild orthostasis and stuffy nose). A selective α-blocker is a good alternative in an older male patient due to less reflex tachycardia and potential prostatism benefits. In addition, some patients may be candidates for calcium channel therapy instead. As α-blockade proceeds, it is critical to replete the intravascular space with liberal fluid and some additional salt intake preoperatively. β-Blockade may be started a few days prior to the operation if the patient becomes tachycardic. Do *not* start β-blockade prior to adequate α-blockade or the resulting unopposed α-mediated vasoconstriction may cause stroke, myocardial infarction, and even death. Close communication with the anesthesia team is critical throughout the operation as manipulation of the tumor may cause wide swings in hemodynamics. Ensure that the anesthesia team is equipped with short-acting vasoactive agents to control or support intraoperative blood pressure as needed.
  - Cortisol-producing tumor. Give stress-dose steroids prior to induction. The patient will require a careful steroid taper postoperatively and endocrinology consultation is recommended. Although no level I data is available, perioperative antibiotics should be considered due to the relative immunosuppressed state in a patient with cortisol excess.
  - Adrenocortical carcinoma. Primary adrenal cancers may manifest any or all of the biochemical irregularities found in the aforementioned tumors and should be addressed as appropriate. It is important to assess the vasculature for evidence of venous invasion and tumor thrombus, ideally with a magnetic resonance venogram or formal venogram. The

laparoscopic retroperitoneal approach should not be used in cases of very large or locally invasive adrenal tumors.

ANATOMY

- The retroperitoneal space is bounded by the peritoneum laterally, the paraspinous muscle medially, the rib cage posteriorly (i.e., away from table), the kidney/adrenal gland/peritoneum anteriorly (i.e., toward the table), and the diaphragm superiorly.
- The superior pole of the kidney and the paraspinous muscle serve as the major landmarks.

TECHNIQUES

PATIENT POSITIONING

- A modification of the "Walz position"
- Intubate, obtain intravenous/arterial access as indicated, and place a urinary catheter while patient is still on stretcher. Administer stress-dose steroids and perioperative antibiotics if indicated.
- Place patient prone on two noncompressible bolsters with the lower bolster positioned at the break in the operating room (OR) table. The hips rest on the lower bolster. The lower ribcage rests on the upper bolster. The pannus should hang freely in between the bolsters to allow for the greatest amount of retroperitoneal working space. Place the operative side of the patient flush with that side of the table so that the table will not hinder the full range of motion of instruments, especially in the lateral-most port. If performing a bilateral adrenalectomy, the only patient repositioning necessary will be to shift the patient to the other edge of the bed (**FIG 1**).
- The lower back should be in a completely horizontal plane. This can be accomplished by lowering the leg portion of the OR table as much as possible to stretch the back and counter the natural convexity of the lower back.
- Raising the leg extension with the knees flexed and lower legs horizontal/parallel to the floor will help to prevent the patient from slipping further down on the bed.
- Flex arms at elbows, pad pressure points, and secure patient in place. Prep from midchest to just above buttocks.

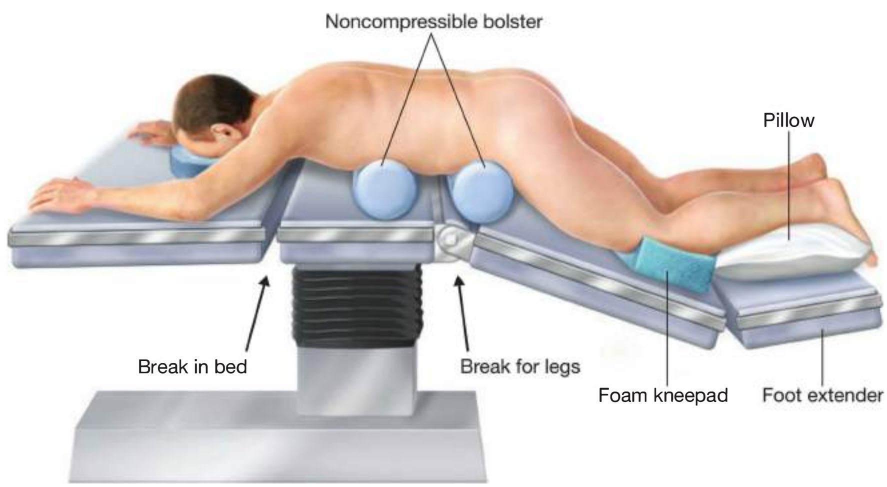

FIG 1 ● Patient positioning for a laparoscopic retroperitoneal adrenalectomy.

PORT PLACEMENT

- Three ports (lateral, middle, and medial) (**FIG 2**)
  - Medial: 5-mm "pediatric" or short port. Place this just lateral to paraspinous muscle and a few centimeters inferior to the costal margin.
  - Middle: 10-mm port with a "donut" balloon. Place this halfway in between the medial and lateral ports.
  - Lateral: 5-mm pediatric or short port. Place this as laterally as possible.
- The middle port is placed first via a direct cutdown by making a transverse incision just large enough to admit a finger immediately inferior to the tip of 12th rib or the costal margin. The position of this port is determined as discussed earlier.
- Dissection proceeds through the subcutaneous tissue to the muscle just inferior to the costal margin by spreading with a Metzenbaum scissors. The retroperitoneal space is entered by blunt dissection with the Metzenbaum scissors through the fascia and muscle using a technique similar to placing a chest tube (except that the hole is made directly *inferior* to the costal margin). Feeling the smooth undersurface of the ribs provides confirmation that the correct space has been entered. Use blunt dissection with the finger both laterally and medially to develop space for the placement of the subsequent 5-mm ports

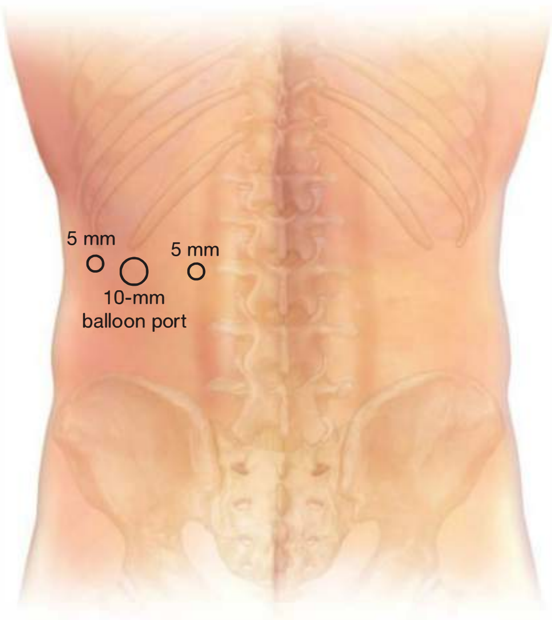

FIG 2 ● Right-sided port placement.

under direct palpation. Dissection should not be carried superiorly as this can make entering Gerota's fascia more challenging.

- Place the medial port 3 to 4 cm inferior to the costal margin just lateral to the paraspinous muscle entering the retroperitoneal space on a bias/angle cephalad of approximately 45 degrees such that the port enters the retroperitoneal space just inferior to the inferior margin of 12th rib. This angling of the port will improve visualization, obviating the need to torque the port.
- Place the lateral port just inferior to the costal margin as far laterally as possible.
- Place a balloon port in the middle port site to form a seal for the retroperitoneal insufflation.

DISSECTION OF THE RETROPERITONEAL SPACE

- Insufflate to 20 mmHg, liberally increasing as needed to maximum of 30 mmHg.
- Place camera into the middle port and a sealing device into the lateral port.

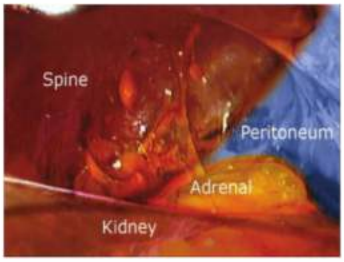

FIG 3 ● Retroperitoneoscopic view of the spatial relationships during initial dissection of a right adrenal gland. (Image courtesy of www.coachsurgery.com.)

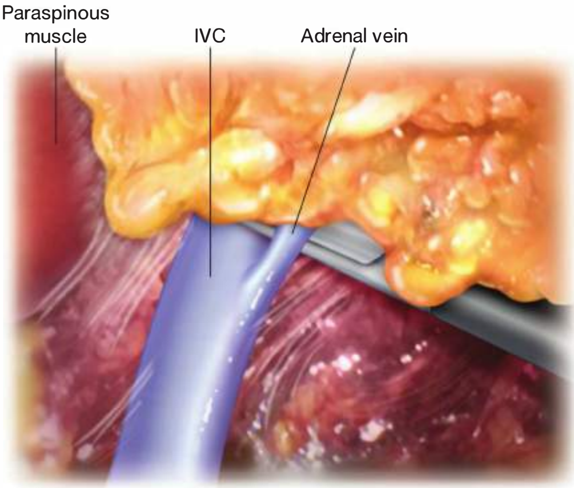
- Enter Gerota's fascia bluntly and open it widely from left to right.
- Sweep the filmy posterior attachments of the periadrenal and perirenal fat anteriorly (i.e., toward the table). Continue this dissection to expose the peritoneum laterally, paraspinous muscle medially, and peritoneum superiorly.
- Switch camera to medial port and place a grasper into the middle port (**FIG 3**).
- Identify the superior border of the kidney. Starting laterally, divide the adrenal-renal connections using a combination of blunt and sharp dissection. Carry this dissection toward the paraspinous muscle following the superior contour of the kidney, which will allow the kidney to be retracted inferomedially.
- Carefully dissect the filmy plane between the adrenal gland and the paraspinous muscle medially to allow identification of the inferior vena cava during a right adrenalectomy or the inferior phrenic vein during a left adrenalectomy. The adrenal arteries will be in a plane that is posterior (i.e., away from the table) to the level of the adrenal vein. These arteries may be ligated with a sealing device.

IDENTIFICATION OF THE ADRENAL VEIN

- Right adrenal vein (**FIG 4**). Once the inferior vena cava is identified, follow the cava superiorly. The adrenal vein can typically be found entering the adrenal gland at the junction of the middle and superior third of the adrenal gland. The adrenal vein enters the adrenal gland anteriorly (i.e., toward the table). Divide the vein with clips or a sealing device.
- Left adrenal vein (**FIG 5**). Identify the adrenal vein either by tracing the inferior phrenic vein from superiorly to inferiorly or by dissecting the inferior border of the adrenal gland from lateral to medial until the confluence



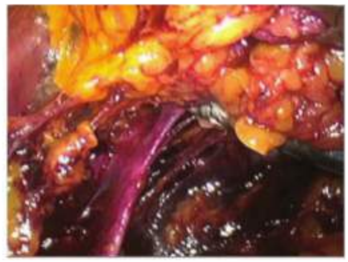


FIG 4 ● The short right adrenal vein is seen here at the end of the instrument in the middle of the picture. Note the relatively flat inferior vena cava due to the insufflation pressure. (Image courtesy of www.coachsurgery.com.)

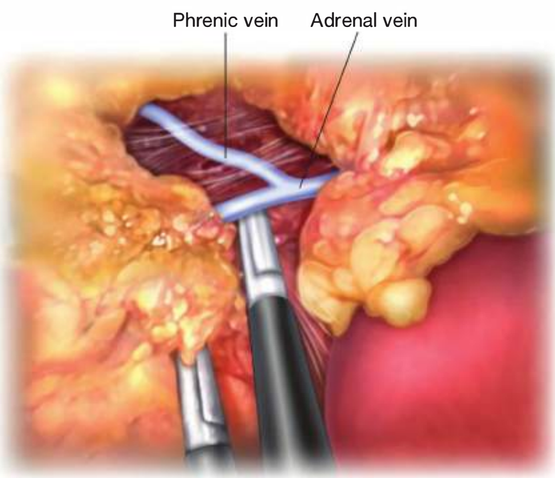
of the adrenal vein and inferior phrenic vein is encountered. Ensure that the inferior-medial border of the adrenal gland is fully dissected from the surrounding tissue, as there is often a tongue of adrenal tissue extending toward the renal hilum. Divide the left adrenal vein with clips or a sealing device. The inferior phrenic vein may be either ligated or spared.

- Once the vein is divided, the remainder of the adrenal gland can be dissected with mostly blunt dissection and a minimum of sharp dissection.



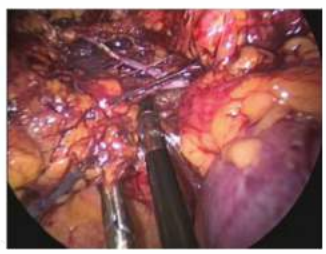


FIG 5 ● The left adrenal gland (notable for its distinct color that differentiates it from surrounding retroperitoneal fat) seen here at the end of the left adrenal vein (directly above the instrument in the middle of the picture). The left phrenic vein joins at an angle from above and can often be spared. The red-toned structure in the right foreground is the paraspinous muscle. (Image courtesy of www.coachsurgery.com.)

SPECIMEN EXTRACTION

- The adrenal gland can be placed in a specimen bag and removed through the middle port site, usually without the need to enlarge this site.
- Replace the middle port and inspect for hemostasis. Decrease insufflation to 5 to 7 mmHg to assist in identification of bleeding.
- A closed suction drain is not normally necessary.
- Remove the ports and close the middle port site fascia with a single absorbable figure-of-eight stitch, taking care to avoid the subcostal nerve.
- Close the skin with subcuticular stitches.

PEARLS AND PITFALLS

Patient positioning	■ Proper patient positioning is critical. ■ Make sure the rib cage and hips rest on the bolsters with the pannus hanging freely. ■ Place the operative side flush with the side of the table. ■ Lower the leg portion of the OR table to stretch the back so it is completely horizontal. Then raise the leg extension with the knees flexed to prevent the patient slipping down the bed.
Port placement and insufflation	■ The middle port is placed just inferior to the tip of 12th rib. Use blunt dissection with Metzenbaum scissors and fingers to enter the correct plane and allow the other two ports under direct palpation. ■ Make liberal use of increased insufflation pressures (20 to 30 mmHg) to improve visualization and hemostasis.
Dissection	■ Because of the nontraditional view of the anatomy, there is a longer learning curve associated with this approach. ■ Dissecting the superior pole of the kidney from lateral to medial and then retracting the kidney inferomedially allows for the best exposure to the adrenal gland and adrenal vein.

POSTOPERATIVE MANAGEMENT

- Remove the urinary catheter 4 to 6 hours postoperatively.
- Patients may ambulate and eat a regular diet on the day of surgery.
- Aldosteronoma. Draw potassium, aldosterone, and renin levels the morning after surgery. Stop potassium supplements and aldosterone antagonists. Implementation of the antihypertensive regimen differs from patient to patient. Some clinicians will choose to stop all antihypertensives and add them back as needed, whereas others will cut the patient's typical doses in half and add them back as needed. Typically, beta-blockers are continued postoperatively.
- Pheochromocytoma. Monitor hemodynamics closely and treat as indicated until stabilized. Stop all α-blockade. After removal of a pheochromocytoma, the major hemodynamic change to watch for is hypotension.
- Cortisol-producing tumor. Begin steroid taper. Consider keeping patients in-house for a day or two to begin the steroid taper under observed conditions.

COMPLICATIONS

- Bleeding. Significant bleeding occurs in less than 1% of cases. Increasing insufflation pressures as high as 30 mmHg often tamponades small bleeding sites. Even with a significant caval injury, increasing the insufflation pressure can cause tamponade that allows time either to repair the injury laparoscopically or to convert to an open procedure.
- Significant intraoperative hypertension occurs in 1% to 2% of cases.
- Conversion to an open operation occurs in approximately 1% of cases. Emergent conversion (such as for significant bleeding) should be done through a posterior approach, obviating the need for patient repositioning and minimizing the dissection needed to get to the affected area. Resection of the 12th rib improves exposure to the retroperitoneal space significantly. If conversion is not emergent, conversion to a laparoscopic transabdominal adrenalectomy or an open lateral approach should be considered.
- Incisional hernia, pneumothorax, and wound infection occur in less than 1% of cases.
- Hyperesthesia and abdominal wall laxity occur in approximately 5% to 8% of cases but are usually temporary.

RESULTS

- Walz et al. reported in 2006 a prospective study of 560 laparoscopic retroperitoneal adrenalectomies on 520 patients, demonstrating a 2% conversion rate, a median operating time of 55 minutes that decreased throughout the study, and a median intraoperative blood loss of 10 mL.
- More recently, Dickson et al. reported a prospective series of 118 laparoscopic retroperitoneal adrenalectomies on 109 patients. A conversion rate of 6.6% was reported, mainly due to a failure to maintain an adequate working space with CO_2 insufflation, not due to uncontrolled bleeding.

Chapter **50**

Laparoscopic Adrenalectomy—Lateral Approach

Geoffrey B. Thompson   Anna Kundel

DEFINITION

- Lateral laparoscopic adrenalectomy is defined as a minimally invasive procedure to remove all or part of an adrenal gland via a lateral transperitoneal approach with the patient in a nearly full decubitus position.

ANATOMY

- The adrenal glands lie partially anterior, medial, and superior to the upper pole of the kidneys. The caudal limb of the left adrenal gland often lies in close proximity to the left renal hilum.
- The left adrenal vein frequently joins with the medially located inferior phrenic vein to form a common channel entering the left renal vein. This anatomic configuration, resulting in hormonal dilution within the common channel, is very important in understanding and interpreting the results of adrenal venous sampling (**FIG 1**).
- The right adrenal vein is short, often wide, and empties directly into the posterolateral aspect of the inferior vena cava. On occasion, additional right adrenal veins may drain directly into the inferior vena cava or the right hepatic vein. Arterial inflow to the adrenals is less predictable but generally arises as small arteries originating from the renal artery (inferior adrenal artery), the aorta (middle adrenal artery), and the inferior phrenic artery (superior adrenal artery).
- Paired small veins may accompany these arteries. It is these anatomic findings that allow for cortical-sparing adrenalectomy in familial pheochromocytoma syndromes, such as von Hippel-Lindau (vHL), neurofibromatosis type 1 (NF1), and multiple endocrine neoplasia type 2 (MEN-2) (**FIG 2**).
- Rarely, small rests of adrenocortical tissue may be found at sites near the adrenal bed or within the gonads. This has particular importance when treating corticotropin-dependent hyperadrenocorticism.

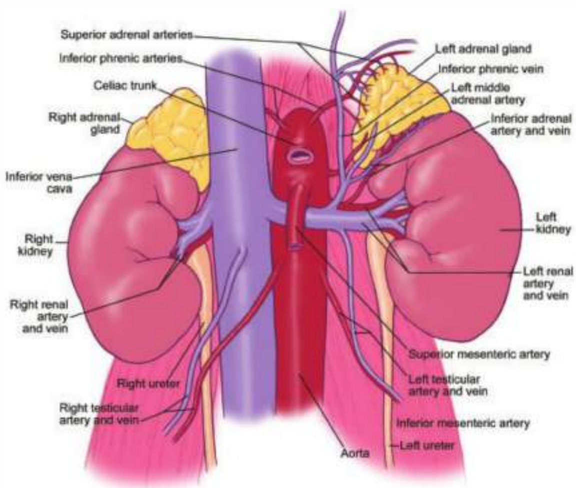

FIG 1 ● Vascular anatomy of the adrenal glands.

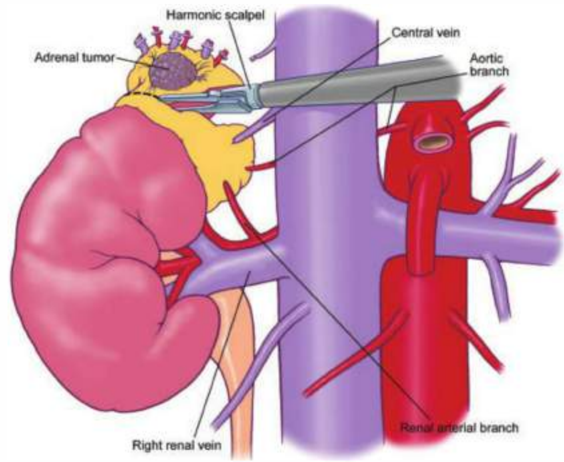

FIG 2 ● Cortical-sparing adrenalectomy.

PATHOGENESIS

- Pheochromocytomas, aldosteronomas, and cortisol-secreting tumors produce catecholamines and hormones in an uncontrolled fashion, resulting in potentially life-threatening hormonal sequelae. Some of these tumors are seen in familial cases (MEN, vHL, NF1); most occur sporadically.

NATURAL HISTORY

- Untreated functional tumors can lead to death and disability. Undiagnosed adrenocortical carcinomas are most often fatal.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Laparoscopic adrenalectomy is used for small functional and nonfunctional adrenal tumors, the latter being removed because of suspicion of underlying malignancy (either primary or metastatic).
- Adrenal incidentalomas are incidentally discovered (asymptomatic) adrenal masses, typically picked up on cross-sectional imaging studies performed for some other reason. For example, a patient comes to the emergency room with renal colic and a computed tomography (CT) with stone protocol is performed, revealing a ureteral calculus and an incidentally discovered 4-cm right adrenal mass.
- Indications for removal an adrenal incidentaloma include (1) a functional lesion because of the risk associated with excess hormonal sequelae; (2) a growing lesion or a lesion greater than 4 cm in diameter because of the risk of adrenocortical malignancy; or (3) an abnormal radiographic phenotype, which can be an indicator of an underlying malignancy.

Table 1: Absolute Contraindications to the Laparoscopic Approach

Obvious, large adrenocortical carcinomas
Pheochromocytomas >8 cm or clearly malignant pheochromocytomas associated with direct invasion, nodal metastases, or distant metastases
Extensive upper abdominal surgery in which the surgeon should consider a posterior endoscopic approach (see Part 5, Chapter 49)

- Absolute contraindications to the lateral laparoscopic approach are described in Table 1.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Diagnostic Studies

- Evaluation of an adrenal incidentaloma should include a 24-hour urine collection for fractionated catecholamines and total metanephrines or plasma metanephrines and normetanephrines.
- In patients who are hypertensive, regardless of their serum potassium level, plasma aldosterone concentration (PAC) divided by plasma renin activity (PRA) should be calculated to screen for primary aldosteronism. In the case of a high PAC:PRA ratio, confirmation of primary aldosteronism is obtained by salt loading and demonstration of a failure to suppress urinary aldosterone in a 24-hour sample. Autonomous cortisol secretion should be ruled out with an overnight 1 mg or 8 mg dexamethasone suppression test. The demonstration of autonomous cortisol secretion is confirmed by a two-day low-dose dexamethasone suppression test.
- Other studies available include a 24-hour urinary free cortisol level or demonstration of loss of diurnal variation between a.m. and p.m. plasma cortisol levels.
- Midnight salivary cortisol levels are also being used with increasing frequency for case detection of cortisol hypersecretion.
- Studies for estrogen and androgen excess are obtained when clinically indicated but are not routinely done.

Imaging

- Imaging of pheochromocytomas (**FIG 3**), aldosteronomas, cortisol-secreting tumors, and adrenocortical carcinomas is best performed with CT or magnetic resonance imaging (MRI). Tumors that are round, homogeneous, and low in Hounsfield units on CT scan with rapid washout of intravenous contrast are thought to represent lipid-rich cortical adenomas (**FIG 4**).
- Malignancies tend to be large and heterogeneous, with areas of hemorrhage or necrosis associated with high Hounsfield units on CT and delayed washout of intravenous contrast (**FIG 5**). These lesions appear bright on T2 weighted MRI images.
- Approximately 25% of lesions 6 cm and greater are likely to be malignant, whereas 6% of lesions between 4 and 6 cm turn out to be primary malignancies. It is for this reason that the 4-cm cutoff is used. This avoids taking out an excessive amount of nonfunctional cortical adenomas while missing very few adrenocortical carcinomas.
- CT imaging is also valuable in picking up small aldosteronomas, but because of the high incidence of nonfunctional incidentalomas in patients older than 50 years of age, adrenal venous sampling has become the localizing procedure of choice for determining lateralization of an aldosterone-producing adenoma or hyperplasia.
- Metaiodobenzylguanidine (MIBG) scanning is useful for detecting occult pheochromocytomas, paragangliomas, metastatic disease, and multiple tumors in familial cases.

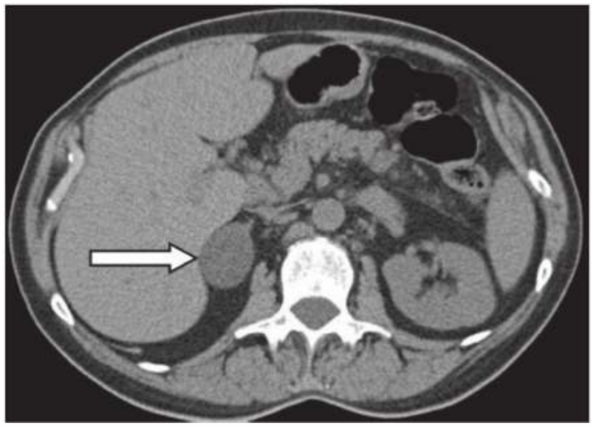

FIG 4 • CT scan of benign cortical adenoma.

FIG 3 • CT scan of pheochromocytoma.

FIG 5 • CT scan of left adrenocortical carcinoma.

NONOPERATIVE MANAGEMENT

- Pheochromocytomas can be managed, albeit less effectively, with medical blockade (α-blockers). Aldosteronomas can be treated with mineralocorticoid receptor blockers, but this is not an ideal choice for younger patients.

SURGICAL MANAGEMENT

Preoperative Considerations

- Laparoscopic adrenalectomy via a lateral approach is indicated in the following circumstances:
  - All benign, functional adrenal masses less than 6 cm in maximal diameter (aldosteronomas, cortisol-secreting tumors) and pheochromocytomas less than 8 cm in diameter
  - All nonfunctional adrenocortical tumors greater than 4 cm but less than 6 cm in diameter
  - All nonfunctional tumors less than 4 cm in diameter demonstrating interval growth by cross-sectional imaging (CT or MRI)
  - All tumors regardless of size with a worrisome radiographic phenotype (high Hounsfield units on noncontrast CT, poor washout of intravenous contrast on CT, bright image on T2 weighted MRI)

Preoperative Preparation

- For pheochromocytomas, pharmacologic blockade (α-blockade for 7 to 10 days, then β-blockade for 24 to 48 hours preoperatively for atrial tachyarrhythmias and calcium channel blockers) is instituted. Effective circulating volume is restored using salt loading and increased fluid intake over a period of 10 to 14 days. α-Methyl-para-tyrosine, Demser® (Valeant Pharmaceuticals International, Inc, Montreal, Quebec, Canada), can be added in refractory cases.
- When treating aldosteronomas, optimal blood pressure control must be achieved and hypokalemia should be corrected. Mineralocorticoid receptor blockade is often instituted.
- The patient with Cushing's syndrome undergoes perioperative steroid preparation as well as prophylaxis for deep venous thrombosis, stress ulcer, and opportunistic infection.

Table 2: Equipment Typically Recommended to Perform a Lateral Laparoscopic Adrenalectomy

Four 10-mm trocars
An OptiView port
10-mm scopes, both straight and 30 degrees (occasionally 45-degree scopes are necessary)
Insufflator, light source, and camera
Two monitors: InsideView (LSI Solutions, Victor, NY)
5-mm Harmonic scalpel
L cautery tip
10-mm clip applier
Suction/irrigation apparatus

Surgical Equipment

- The equipment typically used to perform a lateral laparoscopic adrenalectomy in my practice is shown in Table 2.

Preoperative Steps

- In addition to one or two large-bore peripheral intravenous lines, a radial artery line should also be placed preoperatively. A central line should be used in the elderly, the infirmed, and select pheochromocytoma patients.
- General endotracheal anesthesia is used. Antibiotics and deep venous prophylaxis are administered.
- Nitroprusside, labetalol, nicardipine, and intravenous pressors should be readily available for pheochromocytoma patients.
- An orogastric tube is placed.

Positioning and Port Placement

- The patient is placed in (near-complete) lateral decubitus position with the side of the tumor facing.
- Three to four ports are placed on the left; the fourth port is used for a fan retractor in obese patients and the most medial port is used for a liver retractor for right-sided tumors. The ports should be spread out between the midaxillary line and the midabdomen, approximately two to three fingerbreadths below the costal margin.
- The OptiView® (Ethicon Endo-Surgery, Cincinnati, OH) system and a straight scope are used for introduction of the first trocar, typically along the anterior axillary line.
- Patient pressure is maintained between 14 and 18 mmHg.

LEFT ADRENALECTOMY

- The splenic flexure is mobilized using the L cautery with caudal displacement of the large bowel (FIG 6).
- The lateral splenic attachments are divided with medial rotation of the spleen and body and tail of the pancreas, exposing Gerota's fascia and the adrenal gland.
- The surgeon opens the avascular plane between the posterior aspect of the pancreas and the adrenal gland, much like opening a book. The adrenal vein often can be found directly across the "valley" from the splenic vein.
- The adrenal vein, inferior phrenic vein, and common channel are exposed.

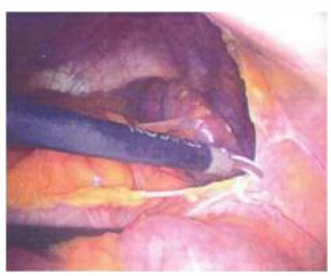

FIG 6 ● Mobilization of splenic flexure.

- No attempts should be made to dissect out the renal artery and vein.
- The surgeon doubly clips the veins and divides them (FIG 7).
- The caudal tip of the adrenal gland is elevated away from the area of the renal hilum; very often, renal artery pulsation is visible.
- The surgeon dissects up along the medial aspect of the gland using the Harmonic scalpel. If the inferior phrenic vein does not fall away from the dissection, it may require further division between clips at this level.
- Arterial tributaries from the aorta can be divided using the Harmonic scalpel as can the inferior phrenic artery tributaries, as dissection is carried around the superior aspect of the gland (FIG 8).
- The plane between the adrenal gland and the kidney is dissected using the Harmonic scalpel. This can be performed just outside the edge of the adrenal gland or, when thin, just inside Gerota's fascia.
- The gland is then elevated anteriorly and a small arterial branch from the renal artery, often present, is divided with the Harmonic scalpel.
- Any remaining areolar attachments are divided and the gland is removed using a commercially available retrieval device (FIG 9).
- The adrenal bed is irrigated and aspirated completely, and hemostasis is ensured. A sheet of a topical hemostatic agent can be left within the adrenal bed for added hemostasis.

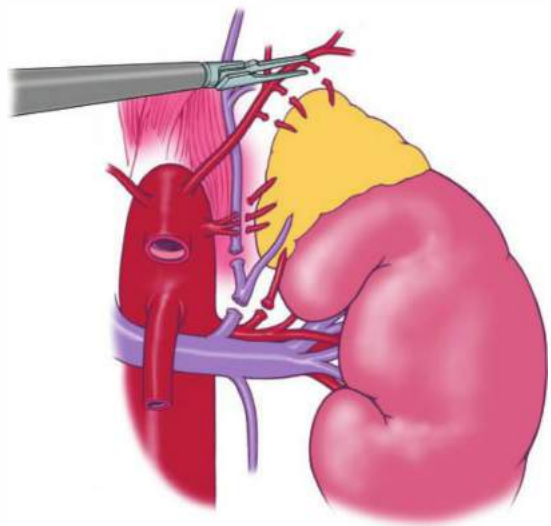

FIG 8 ● Division of arterial tributaries.

- If bladeless ports are used and dilation was not necessary for specimen retrieval, no deep fascial sutures are placed.
- Dilated port sites undergo fascial closure with interrupted suture, using a fascial closure device.
- Skin incisions are closed in a subcuticular fashion with an absorbable suture and are covered with Steri-Strips.
- Sterile dressings are applied.

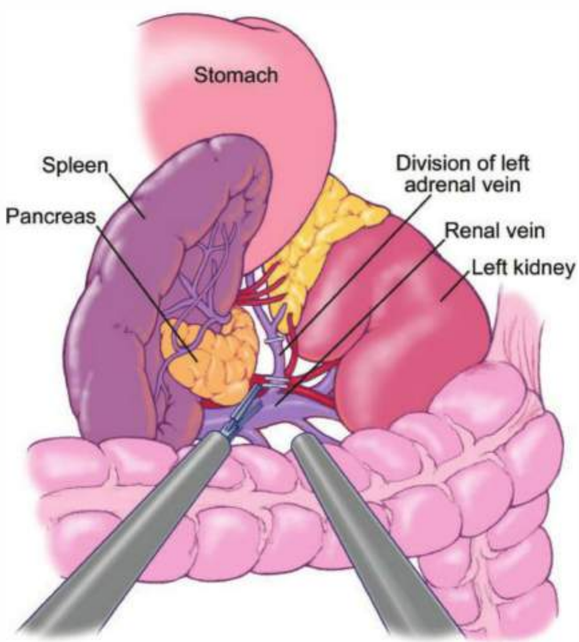

FIG 7 ● Division of left adrenal vein.

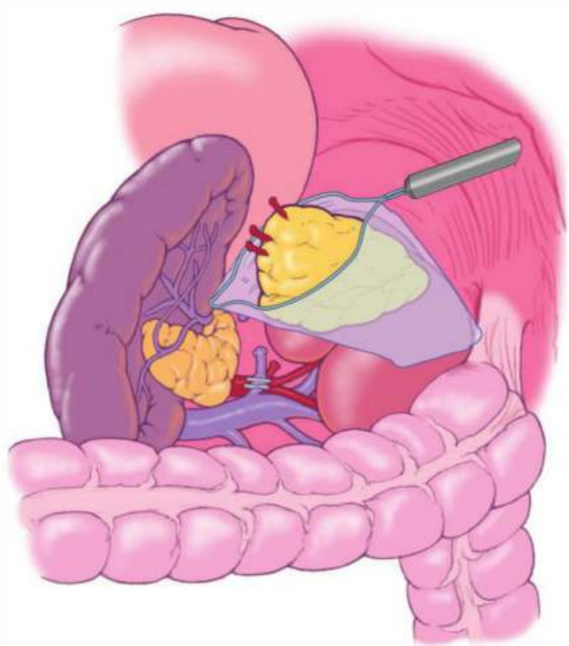

FIG 9 ● Retrieval of resected adrenal gland.

RIGHT ADRENALECTOMY

- Attachments to the right lobe of the liver are divided using the Harmonic scalpel so as to allow the liver to be fully retraced medially. This brings the adrenal gland and inferior vena cava into view (**FIG 10**).
- The peritoneum overlying the lateral border of the inferior vena cava is incised using the L cautery on a low setting.
- If possible, the right renal vein is exposed to define the lower limit of the dissection.
- A blunt-ended instrument is used to gently retract the adrenal gland away from the inferior vena cava (**FIG 11**).
- Using the L cautery or Harmonic scalpel, the areolar tissue posterior and lateral to the inferior vena cava is divided. This may contain arterial tributaries directly from the aorta.
- The dissection is carefully carried out along the lateral border of the inferior vena cava up to the level of the adrenal vein (**FIG 12**).
- If the adrenal vein is easily exposed at this stage, it can be doubly clipped and divided; otherwise, it can be done later when visualization is optimal (**FIGS 13, 14**).
- In a larger pheochromocytoma, the adrenal vein really should be divided after the gland has been mobilized to avoid venous congestion and bleeding.
- The superior pole, including its inferior phrenic artery branches, is mobilized using the Harmonic scalpel to free the gland from the diaphragm posteriorly. Care must be taken to control additional veins at the junction of the medial and superior portions of the gland.
- Using the distal right renal vein as a landmark, the caudal aspect of the gland is exposed, dissected, and elevated, often revealing a renal artery branch to the adrenal, which is divided using the Harmonic scalpel.
- Final step in the dissection is freeing the lateral aspect of the gland from the kidney using cautery or Harmonic scalpel.

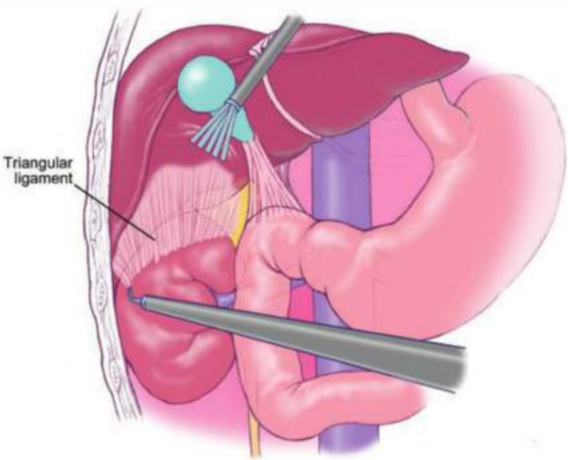

FIG 10 ● Liver retractor placement and division of triangular ligament.

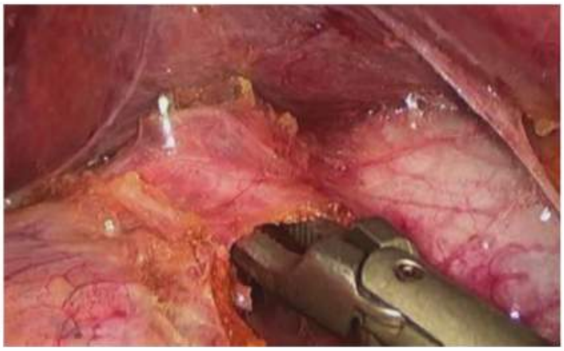

FIG 12 ● The right adrenal vein is encircled.

FIG 11 ● A right-sided pheochromocytoma is separated from the inferior vena cava.

FIG 13 ● The right adrenal vein is doubly clipped and divided.

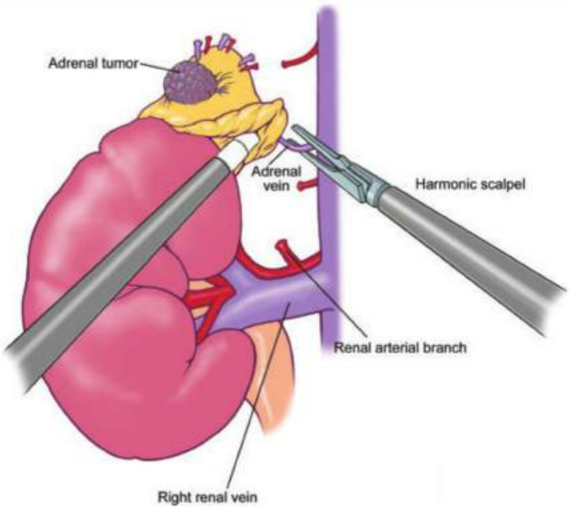

FIG 14 ● Division of right adrenal vein.

PEARLS AND PITFALLS

Adrenal vein	■ The adrenal vein does not have to be ligated as a first step in adrenalectomy; do it when it is safe and easy, even in patients with pheochromocytoma.
Accessory renal arteries	■ When dissecting on the posterior aspect of the adrenal gland, watch out for accessory renal arteries. If a large vessel is present, follow its course before considering ligation.
Low pressure bleeding	■ If bleeding occurs, remember that most of the time, it is low pressure bleeding. Pack the area with a sheetlike hemostatic agent. Work above and below the area, in which case, oftentimes, the bleeding site will become clear and manageable.
Renal hilum	■ Once the adrenal vein has been divided on the left side, never dissect caudally or posterior to the plane of the adrenal vein stump. This will avoid injury to the renal hilum.

POSTOPERATIVE CARE

Pheochromocytoma

- Pheochromocytoma (**FIG 15**) patients will often be mildly hypotensive, with systolic blood pressures in the 90s for 8 to 12 hours postoperatively. Greater or more prolonged falls in blood pressure accompanied by oliguria or tachycardia should prompt investigation for bleeding.
- All blood pressure medications should be stopped after the morning preoperative doses have been administered; the exception being β-blockers used long-term for ischemic heart disease. Rarely, pressors may be required, although volume replacement may be all that is necessary for a short period of time.
- Plasma metanephrines and normetanephrines are drawn prior to dismissal.

Primary Aldosteronism

- Patients with primary aldosteronism (**FIG 16**) may require decreasing antihypertensive agents for weeks and will need careful monitoring.

FIG 15 ● Pheochromocytoma.

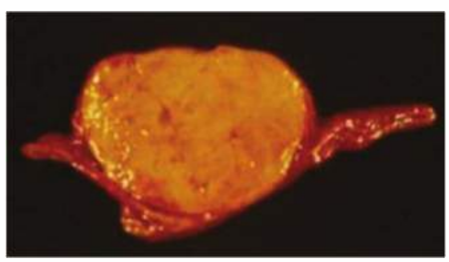

FIG 16 ● Aldosteronoma.

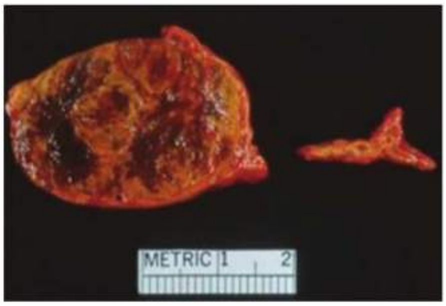

FIG 17 ● Cortical-secreting tumor.

- Potassium supplements should be withheld and only given on an as-needed basis because severe hyperkalemia may otherwise ensue with ongoing supplementation.
- PAC is collected prior to dismissal, and serum potassium levels are checked weekly for the first month.

Cushing's Syndrome

- Patients with Cushing's syndrome (**FIG 17**) are released on a tapering steroid dose to be monitored and adjusted by their endocrinologist.
- Resumption of oral intake is rapid.
- Dismissal usually occurs within 24 to 48 hours after surgery.
- Hemoglobin, electrolytes, and creatinine are checked the day after surgery, along with a serum amylase in left adrenal gland patients to rule out pancreatic injury.
- Patients undergoing bilateral adrenalectomy for adrenocorticotropic hormone (ACTH)–dependent Cushing's syndrome require lifelong replacement of glucocorticoids and mineralocorticoids, with increased doses during times of stress (illness, trauma, surgery).

OUTCOMES

- Outcomes for laparoscopic adrenalectomy are no different than open procedures with regard to cure rates. Morbidity is certainly less (pain, return to work, paresthesias, hypesthesias, and bulging flank muscles).

COMPLICATIONS

- Bleeding
- Spleen, pancreatic, renal, colon, and gastric injury (rare)
- Diaphragmatic injury (pneumothorax)

Chapter 51 Insulinomas

Douglas L. Fraker

DEFINITION

- Insulinomas are neoplasms arising from the beta cells of the pancreas. The vast majority are benign, sporadic, and unifocal.[1,2] These neoplasms release insulin in a dysregulated manner and therefore cause decreased blood sugar, resulting in neuroglycopenic symptoms. Surgical excision uniformly provides long-term cure for the majority of benign insulinomas and corrects all of the associated symptoms.

ANATOMY

- The beta cells of the pancreas are distributed amongst the pancreatic islets uniformly throughout the pancreas. For this reason, insulinomas can occur in all areas of the pancreas. Virtually all large series of insulinomas demonstrate that there is a uniform distribution related to the volume of pancreatic tissue.[3–5] Half of insulinomas occur in the pancreatic head, neck, and uncinate process and the other half are distributed across the body and tail of the pancreas. Most series report insulinomas only occurring within the parenchyma of the pancreas. They can be exophytic and extend off the surface and these exophytic lesions may not be appreciated by standard cross-sectional imaging. There are reports of less than 2% of insulinomas being located outside of the pancreas parenchyma.[1] Virtually all of these lesions are found in the wall of the duodenum and presumably, they occur within embryologic pancreatic rest tissue that is physically separate from the pancreatic parenchyma, such that the insulinoma occurs within the duodenal wall with a similar appearance to duodenal gastrinomas.
- In most surgical series, insulinomas are small, measuring under 2 cm in cross-sectional diameter. Because symptomatology is caused by release of hormone and not by direct effects of tumor mass, lesions as small as 5 to 6 mm may present with significant clinical symptoms. In most series, 90% to 97% of insulinomas are benign. The average size of malignant insulinomas is over 6 cm and the majority of those present with concurrent regional lymph node or hepatic metastases.[1,2]

NATURAL HISTORY

- Insulinomas cause virtually all of their symptoms due to excess circulation of insulin and the subsequent hypoglycemic effects. The first clinical case of insulinoma was described in 1927 when a patient who had severe hypoglycemic episodes had an abdominal operation with a large tumor of the pancreas and lymph node and liver metastases.[2] Extracts of this tumor actually were injected into animals and caused hypoglycemia. Allen Whipple described the triad carrying his name that is known to define the symptoms of insulinoma in 1938. *Whipple's triad* consists of hypoglycemia, documentation of hypoglycemia during periods of fasting, and relief of symptoms with administration of glucose. On analysis, this constellation of signs and symptoms is not truly a distinct triad but rather makes a single point of symptoms related to low blood sugar.[6]
- The majority of symptoms experienced by patients relate to lack of blood glucose to the central nervous system. These are called *neuroglycopenic symptoms* and can range from mild confusion to coma. Patients may experience visual disturbances and there are numerous reports in the literature of insulinoma being misdiagnosed as an epileptic seizure. A second set of symptoms relate to the sympathetic nervous system release of adrenaline due to the effects of the hypoglycemia. This catecholamine release leads to palpitations, diaphoresis, and tremors. In most series, the onset of symptoms initially noted by the patient may be years before the specific time of diagnosis of the insulinoma. The average interval from onset of symptoms to diagnosis is between 2 to 3 years but sometimes may exist for over 10 years. Patients adapt and know that when they experience their symptoms, intake of food, particularly carbohydrates, provide rapid relief; however, this practice of glucose intake may not be elicited when taking a clinical history. Although the majority of patients exhibit weight gain in the anabolic state of hyperinsulinemia, some patients maintain a normal weight.
- The vast majority of patients with insulinoma have sporadic tumors with no family history. A small proportion is associated with multiple endocrine neoplasia type 1 (MEN-1).[5] The most common functional neuroendocrine tumor in MEN-1 is gastrinoma; outnumbering insulinoma by three- or fourfold. Insulinoma is the second most common pancreatic tumor in this syndrome. Because patients with MEN-1 may have multifocal nonfunctional neuroendocrine tumors throughout the pancreas, it may be difficult to distinguish the lesion making insulin versus other tumors. Typically, the dominant neuroendocrine tumor is the insulinoma but occasionally, patients will have multiple large lesions. Intraoperative measurement of insulin from direct tumor aspiration has been reported as an adjunct to insulinoma identification in this unusual situation.

LABORATORY DIAGNOSIS

- The key to diagnosis of insulinoma is not with imaging but rather with biochemical testing. The cornerstone of diagnosing hypoglycemia is detecting glucose levels typically below 40 mg/dL. Additional blood tests that should be obtained are insulin levels, proinsulin levels, and C-peptide levels.[7] Virtually all patients will have a plasma insulin concentration greater than 5 μU/mL at the time of low blood glucose. The vast majority of patients have insulin levels greater than 10 μU/mL. The insulin to glucose ratio can define hypoglycemia due to insulinoma as opposed to other causes with high specificity and sensitivity.[8] The measurements of proinsulin levels and C peptide are helpful in eliminating the diagnosis of surreptitious insulin abuse. The majority of patients have a proinsulin to insulin ratio greater than 25% and a C-peptide concentration greater than 1.7 ng/mL.

- The gold standard for confirming the diagnosis of an insulinoma is a monitored 48-hour or 72-hour fast.[9,10] Patients are typically in the inpatient setting given intravenous normal saline without glucose or allowed to drink noncaloric compounds while monitored for clinical symptoms and sequential blood analysis. The vast majority of patients who truly have an insulinoma causing hypoglycemia become symptomatic within the first 24 hours of the fast and virtually 100% of patients will become symptomatic by 72 hours. As time progresses, patients' symptoms include decreased mental acuity, confusion, or other neuroglycopenic symptoms, which are documented by the nursing staff and physicians during the monitored fast. When symptoms reach a significant level, blood is drawn for glucose, insulin, and proinsulin before administering glucose to relieve the neurologic symptoms.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of hypoglycemia includes surreptitious use of either insulin or oral hypoglycemic agents and noninsulinoma pancreatogenous hypoglycemia syndrome (NIPHS).[7,11] In general, blood tests for proinsulin, C peptide, as well as specific tests for sulfonylureas can eliminate the use of surreptitious agents. NIPHS is distinguished from insulinoma by the timing of hypoglycemia. These patients often do not become symptomatic during a 72-hour monitored fast but will become profoundly hypoglycemic after ingesting glucose orally.[7] Pathology often shows significant beta cell hypertrophy but does not show a mass on imaging.

IMAGING

- The vast majority of insulinomas are small and are located within the substance of the pancreatic parenchyma. The three choices of imaging that have been highly specific for identifying the insulinoma are contrast-enhanced computed tomography (CT) scan, magnetic resonance imaging (MRI) scan, or endoscopic ultrasound.[12,13] Insulinomas are hypervascular with very well-defined margins and have a classic appearance on enhanced CT and MRI scans (**FIGS 1** and **2**). They are

FIG 1 ● Axial cut of MRI scan demonstrating an insulinoma in the body tail junction of the pancreas (marked by *arrows*). The insulinoma is small, oval shaped, and hypervascular compared to the surrounding pancreas.

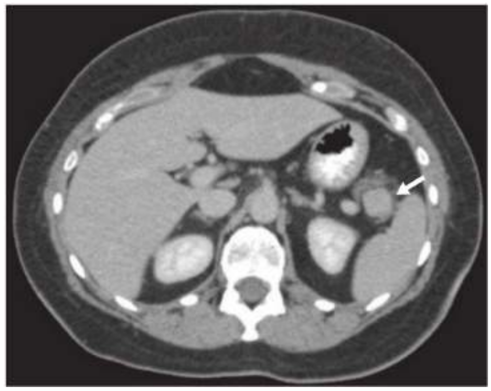

FIG 2 ● Axial cut of a CT scan demonstrating a 2-cm insulinoma in the tail of the pancreas (marked by *arrow*). This scan, an MRI scan, and an endoscopic ultrasound all reported this lesion to be an accessory spleen as it was exophytic off the pancreas tail and had identical imaging characteristics as the spleen on all three imaging modalities.

oval-shaped, well-marginated, and show a characteristic vascular blush.[12] The limitations of imaging relate to the size of the lesions. Again, insulinomas may cause symptoms that mandate surgical resection for correction with sizes smaller than 5 to 6 mm. Small insulinomas are ones that would be potentially missed on cross-sectional imaging studies. Also, exophytic lesions which may not be surrounded by pancreatic parenchyma may be a challenge to identify on CT or MRI, particularly if they are small. Insulinomas located near the tip of the pancreatic tail are the most common location for false-negative imaging; insulinomas may be incorrectly identified as lymph nodes, accessory spleens, and splenic vessels.

- Since the early 1990s, a variety of institutions with large experience in insulinoma have used endoscopic ultrasound as the primary imaging technique.[12,13] Endoscopic ultrasound allows for direct imaging in three dimensions with very close field ultrasonography of the head, neck, and uncinate process. The pancreatic body is less well imaged as it can only be seen from the placement of the ultrasound probe within the stomach and depending on the patient's body habitus, the tail may be a blind zone for endoscopic ultrasound. The ultrasound appearance of insulinoma is an oval hypoechoic mass with well-defined margins (**FIG 3**). Endoscopic ultrasound also allows a relatively straightforward fine needle

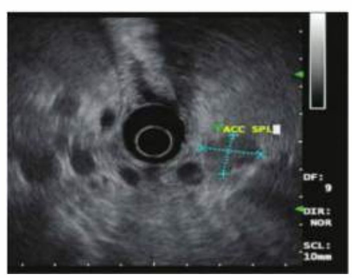

FIG 3 ● Endoscopic ultrasound image of the same patient in **FIG 2**. The insulinoma is oval shaped and hypoechoic. The gastroenterologist has incorrectly labeled the insulinoma as accessory spleen.

aspiration biopsy, which would produce neuroendocrine cells on cytology to confirm the diagnosis. Positive imaging may occur with identification of peripancreatic lymph nodes that are often embedded on the surface of the pancreas or accessory spleen, which can be found on the surface or actually within the parenchyma of the pancreas primarily in the tail region. Standard fluorodeoxyglucose-positron emission tomography (FDG-PET) scans have been shown to be of limited value in insulinomas as these may not be particularly hypermetabolic lesions.[14] A recent report showed a specific targeting agent of indium-labeled glucagonlike peptide-1 receptor that was sensitive for insulinomas and also could allow the use of a handheld intraoperative probe to detect these lesions.[15] This technique is being developed in Switzerland and has not been widely adapted elsewhere.

- Despite the high sensitivity of cross-sectional imaging and endoscopic ultrasound, a portion of patients with well-documented biochemical insulinoma may have no lesions imaged.[16,17] Historically, an interventional radiology invasive procedure called portal venous sampling was used in which a transhepatic portal vein cannulation was performed and blood was drawn from various regions and tributaries from the portal vein and assayed for insulin.[18,19] Portal venous sampling has now been replaced by intraarterial calcium stimulation with hepatic vein sampling. In this technique, two catheters are placed: one in the right hepatic vein and a second standard arterial angiogram catheter advanced into arterial branches feeding the pancreas. Calcium is injected into branches of the splenic artery supplying the body or tail or branches of the superior pancreaticoduodenal artery off the gastroduodenal artery or the inferior pancreaticoduodenal artery off the superior mesenteric artery. Blood is drawn from the right hepatic vein at 0 second, 30 seconds, and 60 seconds after calcium infusion and an increased gradient of greater than twofold in the hepatic vein insulin levels is significant.[18] This procedure does not image insulinoma but rather identifies the region of production of insulin. It is a highly specific test and may be helpful in focusing efforts in the operating room to one area or the other. It may justify performance of a blind distal pancreatectomy for patients without imaged lesions that have gradient in the body and tail, but a blind pancreaticoduodenectomy is virtually never indicated.

NONOPERATIVE MANAGEMENT

- The choices for nonoperative management include diet modification or hypoglycemic agents. One approach for management of hypoglycemic symptoms is small frequent meals, particularly of slowly absorbed carbohydrates to provide more of a steady level particularly while patients are sleeping.[2,5] Diazoxide is a benzothiazide analog with antihypertensive effects but also with potent hyperglycemic effects. It inhibits insulin release from the beta cells and enhances glycogenolysis to also contribute to elevation of blood sugar. Side effects include sodium retention causing edema and some patients have nausea. A second agent that has been used for control of hypoglycemic symptoms in insulinoma is somatostatin analogs. However, due to relatively low expression of somatostatin receptors on most well-differentiated insulinomas, these have not been markedly effective.

PREOPERATIVE PLANNING

- The cornerstone to performing an insulinoma resection is being absolutely certain the patient has the disease proven by definitive biochemical workup. In patients who have imaged lesions, particularly if they are biopsied as neuroendocrine tumors or have classic appearance on CT or MRI, this provides very good evidence that the patient has the disease. In patients who have no definitive imaging of the site of the lesion, the surgeon has to review in detail the preoperative blood chemistries. This analysis includes reviewing the data related to a 72-hour fast, looking at concurrent glucose, insulin, and proinsulin levels as described earlier.
- It is very important for patients to either be the first case of the day or to be admitted to the hospital and have dextrose solution running so that they do not suffer from severe hypoglycemia while they are nil per os (NPO) prior to general anesthesia. In general, for abdominal procedures, anesthesiologists do not administer glucose-containing fluids as they are infused at a relatively rapid rate and patients are catabolic. When operating on patients with insulinoma, it is very important to communicate to the anesthesia team that dextrose needs to be administered often and frequent analysis of glucose levels need to be performed.

SURGICAL APPROACH AND PATIENT POSITIONING

- Over the past few decades, the majority of patients in most surgical series have been treated with an open surgical technique. There have been many recent reports of laparoscopic excision of insulinomas, particularly in the body and tail, with high success rate. We will describe primarily identification and resection of insulinomas using an open technique and also provide information on laparoscopic approaches.
- The approach for the open resection of an insulinoma is performed with the patient lying supine with either an upper midline incision or a bilateral subcostal incision. The vast majority of the substance of the pancreas can be assessed with an upper midline incision with the exception of the far distal tail, which may be somewhat difficult particularly in obese patients. For patients with a well-localized insulinoma in the head and neck, uncinate process, or proximal body, a midline incision is preferred if the patient's body habitus is appropriate. Any patient can be approached with a bilateral subcostal incision.

EXPOSURE OF THE PANCREAS

- The initial steps of an insulinoma resection is to briefly assess the liver, although insulinoma is a benign disease in the vast majority of patients, and if liver metastases existed, they should have been identified on preoperative imaging. The next step is exposure of the pancreas parenchyma. Exposure of the head and neck of the pancreas as well as uncinate process can be achieved with a Kocher maneuver (**FIG 4**). The duodenum and head of the pancreas are brought up from the retroperitoneal location to allow bimanual palpation for mass lesions as well as visual inspection of both the anterior and posterior surfaces of the pancreatic head. The greater omentum is taken off the transverse colon along its entire length using energy devices with the omentum reflected superiorly, pulling the stomach off the pancreas. There are avascular attachments of the posterior stomach to the anterior pancreas that can be divided sharply. There is always a bridge of vascular tissue from the right gastroepiploic to the middle colic vessels, which crosses anterior to the neck and proximal pancreatic body that needs to be controlled with either energy devices or suture ligation. By dissection along the inferior border of the pancreatic body and tail, the posterior surface can be exposed and the majority of the substance of the pancreatic body and tail can be palpated between two digits (**FIG 5**). By doing these maneuvers, 95% of the pancreatic parenchyma is accessible for palpation and virtually all of the anterior surface and most of the posterior surface of the body and proximal tail are accessible for visual inspection as well. The only inaccessible area is the very tip of the tail of the pancreas, which may be located completely behind the spleen and require dividing the lateral margins of the splenic ligaments to reflect the spleen medially and expose that area of the very tip of the pancreatic tail.
- Insulinomas are identified by a combination of visual inspection, palpation, and intraoperative ultrasound. Insulinomas are uniformly red-brown in color against the yellow-gray background of the pancreas and lesions near the surface or exophytic lesions can be easily identified by visual inspection (**FIG 6**). Neuroendocrine tumors have

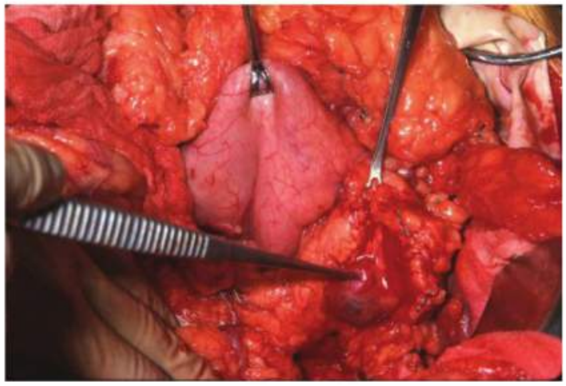

FIG 5 ● The lesser sac is exposed by reflecting the stomach and omentum superiorly and the transverse colon inferiorly. By dividing the retroperitoneum at the inferior edge of the pancreatic body and tail, the posterior surface of the pancreas is visualized as well. A large posterior body insulinoma is seen pointed at by the forceps.

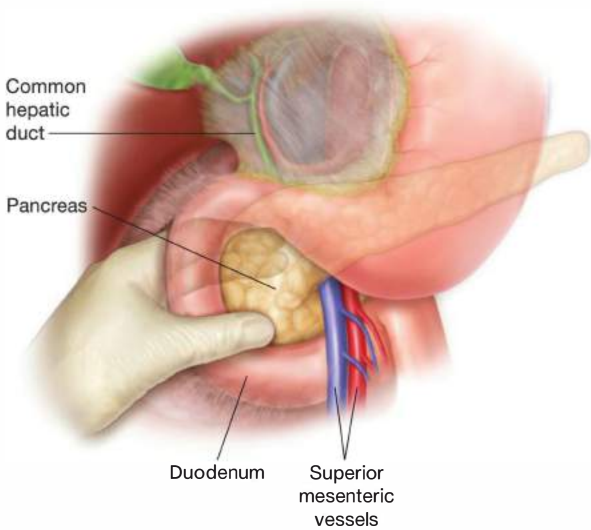

FIG 4 ● The lateral retroperitoneal attachments of the duodenum are divided along the entire length of the duodenum from the pylorus to the superior mesenteric vessel. By doing the Kocher maneuver, the entire head and uncinate process can be palpated between two fingers. By clearing the surface, all of the anterior head and uncinate process and most of the posterior surface can be visually inspected.

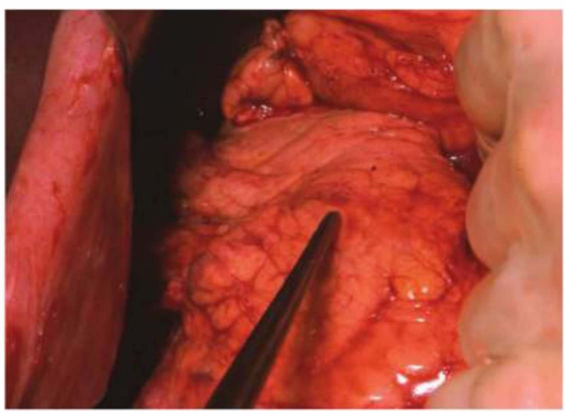

FIG 6 ● The anterior surface of the body and tail of the pancreas is skeletonized and exposed by retracting the stomach superiorly (posterior stomach on the left side of the picture) and the transverse colon inferiorly (retracted by the hand on the right side of the picture). The forceps is pointing at a red-brown insulinoma near the surface of the body of the pancreas.

a classic ultrasound appearance and intraoperative ultrasound is a key to management (FIG 7). Even in patients with lesions of the head and uncinate process of the pancreas that are well seen by preoperative endoscopic ultrasound, it is mandatory to have intraoperative ultrasound available. The reason for having intraoperative ultrasound available is because if the small lesion is deep within the parenchyma of the pancreas, it is essential to know exactly where the insulinoma is located so an appropriate enucleation can be performed. It is impossible to use preoperative imaging alone to know where to cut into the pancreas in the same way breast surgeons need intraoperative localizing techniques to remove nonpalpable breast tumors.

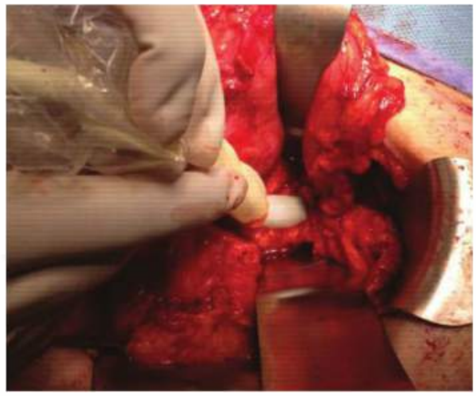

FIG 7 ● The head, neck, body, tail, and uncinate process of the pancreas are exposed and the intraoperative ultrasound probe is placed directly on the pancreatic surface. Ultrasound not only identifies the insulinoma but can also demonstrate precise relationships to the pancreatic duct and main vessels.

EXCISION OF THE INSULINOMA

- After exposure and identification of the insulinoma, the choices for excision of the lesion are enucleation versus a segmental pancreatic resection. In most surgical series, the majority of insulinomas are removed by enucleation, with one-third or more removed by distal pancreatectomy with or without splenic preservation and a very small fraction removed with pancreaticoduodenectomy or a Whipple procedure. The ability to enucleate an insulinoma relates to how close the insulinoma is located to the pancreatic duct. For patients who have their lesion identified by preoperative imaging, the proximity of the insulinoma to the main pancreatic duct is known prior to surgery. The pancreatic duct generally runs along the length of the midline of the pancreas slightly superior and slightly toward the dorsal or deep side of the pancreas. The duct can virtually always be identified on intraoperative ultrasound as a tubular structure with no vascular flow within on color Doppler. Even in the case of insulinomas that are well localized on the pancreatic surface, routine use of intraoperative ultrasound is helpful, partly to look for additional lesions and mostly to identify the proximity of the insulinoma to the duct.
- For lesions that are on the surface or visible from the surface, enucleation is relatively straightforward (FIG 8). The reddish brown color of the insulinoma is easily differentiated from the glandular tissue of the pancreas. The plane on the capsule of the insulinoma is quite distinct and easily separated from the parenchyma with gentle traction. The attachment of the insulinoma to the pancreatic tissue can be controlled with ties, clips, or use of energy device such as a Harmonic scalpel. The large bleeding vessels could be treated with a suture ligature. Even lesions as large as 4 to 5 cm when they are exophytic off the surface can be enucleated as long as they are not near the main pancreatic duct such that all exocrine pancreas duct branches are controlled to prevent postoperative fistula.

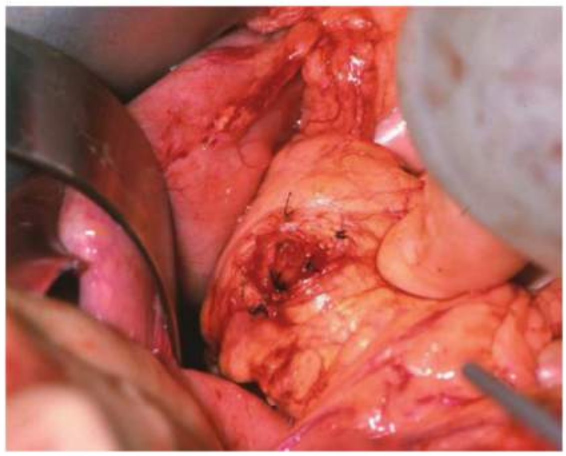

FIG 8 ● Enucleation of the insulinoma seen in FIG 6. Ultrasound confirms the lesion does not abut the pancreatic duct and the insulinoma is enucleated on the capsule of the tumor.

- Enucleation of an insulinoma that is deep in the parenchyma and not seen by inspection requires continuous use of intraoperative ultrasound. Generally, insulinomas are softer in terms of their substance compared to the tissue density of the normal pancreas and therefore, unless lesions are quite large, they cannot be felt by manual palpation with a finger behind and a finger in front of the pancreas. Ultrasound is used to mark the precise location of the lesion and the distance from the pancreatic surface to the closest margin of the insulinoma can be accurately measured to know exactly how deep to go for an enucleation (FIG 9). In general, a cruciate incision centered

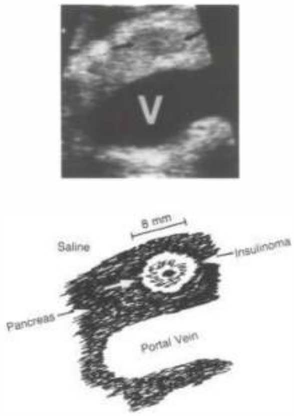

FIG 9 ● The *top panel* shows an image from an intraoperative ultrasound demonstrating the hypoechoic insulinoma indicated by the *black arrows*. The drawing on the *lower panel* shows the 8-mm insulinoma and the precise distance between the tumor and the underlying portal vein.

right over the mass is made using an energy device such as a Harmonic scalpel. Any sizable vessels are controlled with small hemoclips or ties as needed. Ultrasound is continuously used to monitor the progress of the enucleation to make certain the defect in the pancreas is aimed toward the tumor until the capsule of the insulinoma is seen. Once a small surface area of the tumor is definitely visualized, ultrasound becomes unnecessary as the tumor enucleation is completed, staying right on the capsule of the lesion just as for lesions located on the surface (**FIG 10**). Again, specific knowledge of the main pancreatic duct anatomy is crucial as an injury to the main duct by either making a defect in it or transecting it may lead

A

B

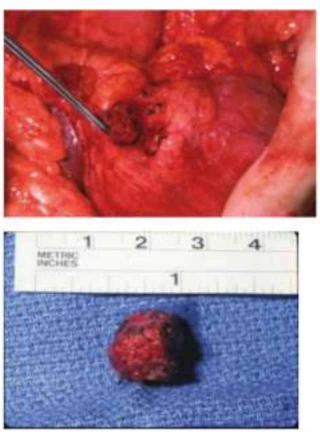

FIG 10 ● **A.** Enucleation of an insulinoma from the deep tissue of the head of the pancreas. Once the capsule of the insulinoma is seen, intraoperative ultrasound is no longer needed to guide the dissection. **B.** Intact pancreatic head insulinoma after enucleation. Small amounts of pancreatic parenchyma are attached to the lesion.

A

B

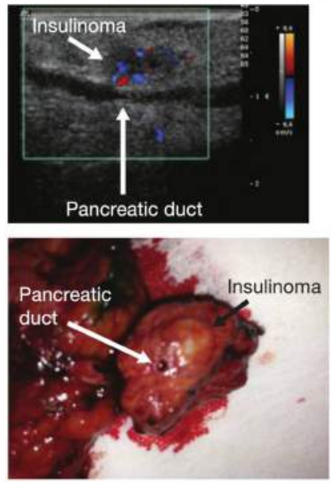

FIG 11 ● The patient had a small midbody insulinoma seen by CT scan. Intraoperative ultrasound **(A)** shows the insulinoma clearly but it indents the main pancreatic duct. Color Doppler ultrasound identifies the duct as there is no blood flow and the insulinoma is hypervascular. Due to the proximity of the main pancreatic duct to the insulinoma, a distal pancreatectomy was performed. **B** shows the insulinoma bordering a mildly dilated pancreatic duct. If the insulinoma was enucleated, there would be a high likelihood of a significant pancreatic leak.

to a significant pancreatic or cutaneous fistula that may require reoperation.

- For larger lesions or lesions that abut or distort the main pancreatic duct located in the body and tail of the pancreas, there is no question that the appropriate operation is a distal pancreatectomy (**FIG 11**). Again, intraoperative ultrasound is used to map the transection of the pancreas to the right of the lesion to get a margin. This resection can be either spleen preserving or a distal pancreatectomy plus splenectomy, depending on the preference of the operating surgeon. There are some minor advantages of preserving the spleen in adult patients but the incidence of postsplenectomy sepsis is exceedingly rare. Again, the location of the lesion is mapped out or if it is not visible on the surface, mapped using ultrasound. Distal pancreatectomy is generally done by dissecting the short gastric vessels along the greater curvature of the stomach using an energy device. At this point, when doing a distal pancreatectomy plus splenectomy, a large silk tie is placed around the splenic artery at the site of pancreatic transection to control blood inflow to the spleen. The lateral margins of the spleen are divided and the spleen and tail of the pancreas are reflected medially. The spleen and tail and body of the pancreas are reflected up and to the right off the left adrenal gland to the point of the targeted pancreatic transection line. The artery is then double ligated and divided, and the splenic vein is either stapled separately with vascular staples or stapled with the stapling device used to transect the pancreas.

A gas-powered stapler in which pressure can slowly be applied over 30 to 60 seconds to close the jaws of the stapling device minimizes fracturing the pancreatic parenchyma before firing the stapler load. Always inspect the margin and ensure complete excision of the insulinoma either by cutting into the pancreas on the back table or by having the pathologist do a gross evaluation of the specimen.

- Only for very large lesions in the head of the pancreas that abut the main pancreatic duct would a pancreaticoduodenectomy be performed for a benign insulinoma (**FIGS 11** and **12**). A Whipple procedure for insulinoma is a generally relatively straightforward procedure in terms of the resection portion as major vascular structures are virtually never invaded and can be done with pylorus-preserving technique. It may be somewhat more challenging to do the reconstruction as these patients typically have normal-sized pancreatic duct and bile duct, as even large insulinomas do not cause ductal obstruction, as well as a soft normal pancreas increasing the incidence of pancreatic leak.
- The most challenging situation for a surgeon is to be in the operating room and to be unable to identify the insulinoma.[17] Understanding the correct interpretation of the biochemical diagnosis of insulinoma should avoid the pitfall of operating on a patient who does not have the disease, which is a procedure obviously destined for failure. Historically, performance of a stepwise blind distal pancreatectomy with interval checks of blood glucose was advocated by some. In the era of high-resolution ultrasound, this blind resection of tissue should never be done. The key to success in this situation is the use of intraoperative ultrasound and evaluating areas where small insulinomas may be difficult to identify. Specifically, the very tip of the pancreatic tail lateral to the spleen, the uncinate process adjacent to the superior mesenteric vein, and the neck of the pancreas under the vascular bridge between the right gastroepiploic middle colic vessels should be closely examined.
- In the unusual or rare case of a malignant insulinoma, tumor debulking may be very beneficial in terms of controlling hypoglycemic symptoms. In general, this would require either a pancreaticoduodenectomy or distal pancreatectomy to remove the primary lesion and lymph node metastases. If there is limited number of liver metastasis, simultaneous liver resection or ablation may be performed. Chemoembolization also has benefit in controlling the hormone output from these hypervascular lesions and benefits the patients in terms of hypoglycemic control.

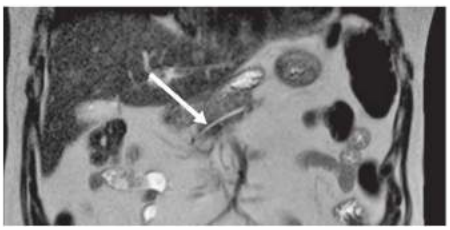

FIG 12 ● A coronal MRI scan shows a 2-cm insulinoma in close proximity to the main pancreatic duct in the head of the pancreas *(white arrow)*. After confirmation of the duct by intraoperative ultrasound, a pylorus-preserving pancreaticoduodenectomy was performed.

LAPAROSCOPIC RESECTION OF INSULINOMAS

- Although the majority of insulinomas are excised using standard open techniques described earlier, several surgeons have reported successful excision of insulinomas using laparoscopic techniques over the past two decades.[19–21] The precise location of the insulinoma and the success of preoperative localization studies are the keys to patient selection for laparoscopic excision.
- Insulinomas located in the body and proximal tail are the ones that are best approached by laparoscopy. Patients are positioned supine and a 30-degree scope is used in a central periumbilical port. The gastrocolic ligament is divided and the omentum and stomach are retracted superiorly to expose the pancreas at the base of the lesser sac. Laparoscopic ultrasound is used in an identical manner to intraoperative ultrasound in open procedures both to identify the insulinoma and the main pancreatic duct. Either enucleation or distal pancreatectomy is chosen based on tumor location again with the same decision-making process as in open procedures.
- Several studies, including a meta-analysis, have confirmed that laparoscopic removal of insulinomas is safe and has advantages over open excision. In institutional comparative studies, there was no difference in operative time, overall cure rate (which is uniformly 100%), and the incidence of pancreatic fistula. Length of hospital stay and blood loss generally favors laparoscopic excision. For surgeons who have experience in managing insulinomas and who have advanced laparoscopic skills, selected patients should have their insulinomas resected laparoscopically. However, as opposed to adrenalectomy in which video-assisted techniques are absolutely the standard of care, insulinoma procedures are much less common and the majority of procedures are still done with an open technique.

PEARLS AND PITFALLS

Indications	■ Confirm definitive biochemical diagnosis by review of primary laboratory reports including glucose levels with simultaneous insulin, proinsulin, and C-peptide levels. ■ Insist on a 72-hour monitored fast with appropriate documentation of symptoms and biochemical disease in patients with equivocal diagnosis and negative imaging.
Imaging	■ Obtain cross-sectional imaging with either contrast-enhanced CT scan or MRI scan to look for hypervascular lesion. ■ For image-negative patients, have endoscopic ultrasound performed by skilled invasive gastroenterologist. ■ If definitive diagnosis and negative imaging by CT and endoscopic ultrasound (EUS), consider calcium-stimulated angiogram with hepatic vein sampling.
Exposure of pancreas	■ Expose head and uncinate process by doing a complete Kocher maneuver all the way to the fourth portion of the duodenum. ■ Expose body and tail by dividing gastrocolic ligament and reflecting omentum and stomach superiorly and colon inferiorly. ■ Expose tip of pancreatic tail by dividing lateral attachments of the spleen.
Resection	■ Be certain to have intraoperative ultrasound available to evaluate the insulinoma and the proximity of the main pancreatic duct. ■ Decide between enucleation versus segmental pancreatectomy based on tumor size and relationship to the pancreatic duct.
Enucleation techniques	■ For surface lesions, stay right on the capsule of the insulinoma using energy device or clips to divide and seal tissue. ■ For deep lesions, continuously monitor progress with intraoperative ultrasound as pancreatic parenchyma is divided.

POSTOPERATIVE MANAGEMENT AFTER INSULINOMA RESECTION

- After excision of the entire insulinoma, patients recover almost instantaneously in terms of their glucose metabolism. Typically, blood sugars may rise to between 150 and 200 mg/dL or higher in the recovery room and for the first 24 to 48 hours, patients should be placed on appropriate sliding scale of insulin. It is certainly possible and has been reported that resection of an insulinoma may unmask a patient who has developed diabetes but the majority of these patients correct and normalize their glucose metabolism within 2 to 3 days.[22,23]
- The major postoperative complication from either a distal pancreatectomy or enucleation, either laparoscopic or open, is a pancreatic fistula.[24] The standard practice is to leave a closed suction drain adjacent to the enucleation site or the staple line and to leave that in until the patient is eating at least a low-fat diet. The color and character of the drain fluid can be monitored. If it is a serosanguineous color, it is likely to have a low pancreatic amylase content. Pancreatic fistulas normally present with a dishwater-gray discoloration and can be confirmed by measuring drain content amylase levels. Standard maneuvers to decrease pancreas secretion including nonfat diets or even using total parenteral nutrition should decrease pancreatic fistula outputs.

OUTCOMES AND ALTERNATIVES TREATMENT TO SURGERY FOR TREATMENT OF INSULINOMA

- In virtually all of the surgical series resecting insulinoma, there is uniformly a 100% long-term cure rate after excision of these small benign lesions.[3,4,25] The only exception would be inability to identify an occult insulinoma resulting in immediate operative failure. Because the vast majority of patients are cured by surgery, there has been no impetus to use nonsurgical treatments. Two percutaneous or endoscopic techniques have been reported.
- Ethanol injection to ablate insulinomas[26] and radiofrequency ablation[27] of lesions may provide nonsurgical resolution of hypoglycemic symptoms. Only for very selected patients who are poor surgical candidates should these ablative techniques be offered.

Chapter 52 Surgery for Glucagonoma

Richard A. Prinz   Catherine A. Madorin

DEFINITION

- Glucagonomas are pancreatic neuroendocrine tumors (PNETs) that arise from the glucagon-secreting alpha islet cells of the pancreas. They are very rare with an estimated incidence of 1/20,000,000 individuals.[1] Most are sporadic but 10% are associated with multiple endocrine neoplasia type 1 (MEN-1) syndrome.[2] Most glucagonomas are large (>5 cm) at diagnosis, with 70% to 90% of patients presenting with metastatic disease.[3] Operative treatment of a glucagonoma involves resection of the primary tumor as well as metastatic disease for cure when possible or to palliate hormonal or local symptoms.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Glucagonoma is classically associated with the 4 "Ds": dermatitis, diabetes, depression, and deep vein thrombosis.
- The skin lesions associated with a glucagonoma are termed necrolytic migratory erythema and are pathognomonic for glucagonoma. It is a pruritic rash that occurs in the lower abdomen, lower extremities, perineum, perioral area, and feet (**FIGS 1** and **2**). It is seen in approximately 70% of patients and may be the initial presentation of the tumor.[4]
- Glucose intolerance is often mild and insulin administration usually is not required.
- Weight loss is often out of proportion to the amount of tumor burden and is due to the catabolic effect of excess glucagon.
- Stomatitis, glossitis, and diarrhea are other frequent findings.
- Psychiatric manifestations may include depression, anxiety, and psychoses.
- Glucagonoma creates a hypercoagulable state, and 30% of patients will experience a thromboembolic event.[5]
- A thorough personal and family history should be taken, with particular interest in other endocrinopathies because glucagonomas may be associated with MEN-1. Glucagonomas may also secrete secondary hormones, which may lead to Zollinger-Ellison syndrome in up to 10% of patients. Less commonly, they may secrete vasoactive intestinal polypeptide (VIP), pancreatic polypeptide, somatostatin, or adrenocorticotropic hormone (ACTH).[6]

DIAGNOSIS

- Diagnosis is confirmed by high levels of fasting serum glucagon (>1,000 pg/mL; normal, <150 pg/mL). Other conditions that cause hyperglucagonemia include hepatic insufficiency, stress, sepsis, and starvation, but levels rarely reach beyond 500 pg/mL.

IMAGING

- Glucagonomas are typically greater than 5 cm at time of diagnosis and are easier to localize preoperatively than most PNETs. Most glucagonomas are located in the body or tail of the pancreas. Rarely, they may be located outside the pancreas in the duodenal wall, accessory pancreatic tissue, or the kidney.
- Triple-phase computed tomography (CT) scan is the first-line localization study. Somatostatin receptor scintigraphy (SRS) can also be used and can identify extraabdominal spread to lymph nodes and liver.
- Endoscopic ultrasound (EUS), visceral angiography, and portal venous sampling may be required for glucagonomas that are difficult to identify, but this is very unusual.

FIG 1 ● Necrolytic migratory erythema of the lower extremity.

FIG 2 ● Necrolytic migratory erythema of the lower extremity.

SURGICAL MANAGEMENT

- The goal of operative management of glucagonoma is an R0 resection including the primary tumor and all metastases. Patients who cannot undergo R0 resection benefit from tumor debulking because it can palliate symptoms due to excess glucagon by decreasing the levels of circulating hormone.
- If the tumor is limited to the pancreas, surgical resection can completely reverse all clinical manifestations of a glucagonoma. This demands a formal pancreatic resection due to the large size of the tumors, usually a distal pancreatectomy with or without splenectomy. Pancreaticoduodenectomy is required for tumors in the head of the gland. Resection should include peripancreatic lymph node dissection. Although smaller tumors may be technically amenable to enucleation, the high malignant potential of these tumors suggests caution with this approach (**FIG 3**).
- All nodal and hepatic metastases that can be safely removed should be excised. Hepatic metastases may be managed by either wedge resection or formal hepatic resection.
- Tumor debulking leads to a dramatic improvement in symptoms and the hormonal manifestations of glucagonoma may be diminished for years. Repeat debulking of recurrent disease may also prolong survival.
- In patients with MEN-1, consideration must be given to the presence of other functional and nonfunctional PNETs. If hyperparathyroidism is present as a component of the MEN-1 syndrome, it should be treated before addressing the pancreatic tumor to avoid problems with postoperative hypercalcemia.

Preoperative Planning

- Preoperative management is focused on treating the metabolic effects of excess glucagon and preventing or treating venous thromboembolism.

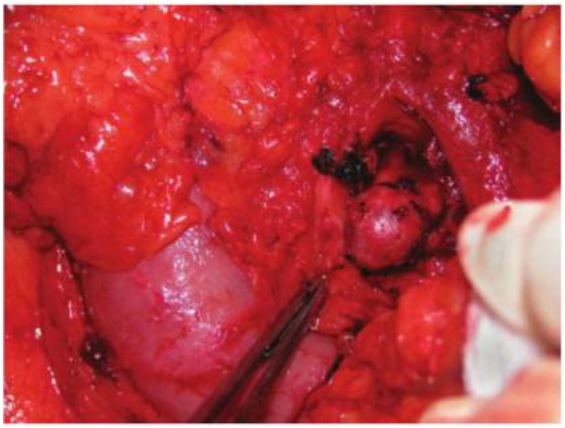

FIG 3 ● Small glucagonomas (<2 cm) with no malignant features can be enucleated from the pancreas using cautery or an energy device to control bleeding. Intraoperative ultrasound should be used to avoid injury to the pancreatic duct.

- Somatostatin analogue therapy with octreotide is titrated to symptomatic improvement. Total parenteral nutrition (TPN) may be needed if marked cachexia is present and may also help ameliorate necrolytic migratory erythema.
- Hyperglycemia and diabetes, when present, should be controlled.
- Patients should receive anticoagulation with Coumadin or low-molecular-weight heparin at the time of diagnosis. Preoperative placement of an inferior vena cava (IVC) filter may be necessary in patients with a history of thrombosis.

TECHNIQUES

POSITIONING

- As most patients present with metastatic disease and may require both pancreatic and hepatic resection, an open approach is preferred. For tumors confined to the pancreas, a laparoscopic approach may be possible. The open approach will be first described here.
- The patient is placed supine with arms either extended laterally or tucked according to surgeon preference.

INCISION

- Midline laparotomy, extended left subcostal, chevron, or a combination of these are all acceptable approaches to the abdomen and should be chosen based on surgeon preference and experience, the body habitus of the patient, and the possible need for hepatic or other organ resection.

DISTAL PANCREATECTOMY WITHOUT SPLENECTOMY

- After the abdomen has been explored, the lesser sac is entered by separating the greater omentum from the transverse colon. The short gastric vessels must be preserved to provide blood flow to the spleen.
- Mobilize the posterior wall of the stomach off the anterior surface of the pancreas and retract the stomach cephalad. The stomach may be held in place with retractors or stay sutures. The anterior body and tail of the pancreas should now be fully exposed (**FIG 4**).
- Incise the peritoneum along the inferior border of the pancreas along the length of the body and tail.

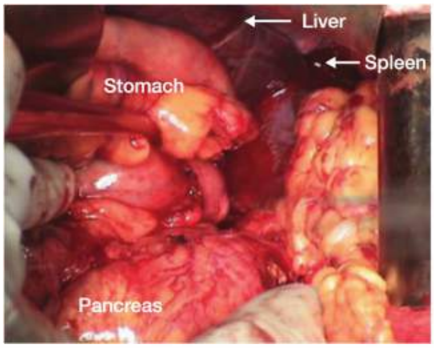

FIG 4 ● The anterior surface of the body and tail of the pancreas is exposed by entering the lesser sac thru the gastrocolic omentum and retracting the stomach cephalad.

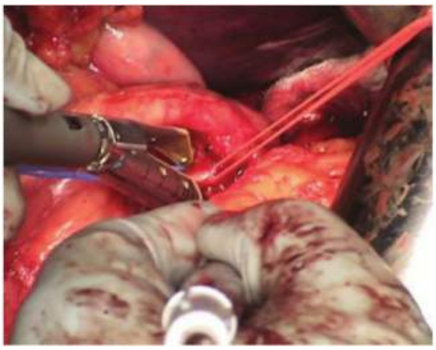

FIG 6 ● The splenic artery and vein are ligated with a vascular stapler as shown. Ligatures or suture ligatures may also be used according to surgeon preference.

Gently elevate the pancreas off the retroperitoneum using blunt dissection along the avascular plane.

- The splenic artery and vein, which run along the superior border of the pancreas (the vein runs posterior to the artery), will be elevated along with the rest of the pancreas.
- Determine the point of transection for the pancreas. This should be just to the left of the superior mesenteric vein in the pancreatic neck.
- Bluntly develop a plane between the splenic vessels and the pancreas at the point of transection. Place vessel loops around the splenic vessels to facilitate retraction and provide vascular control (**FIG 5**).
- Ligate the splenic artery and vein individually—ligatures, suture ligatures, or a vascular stapler (as shown) can be used according to surgeon preference (**FIG 6**).
- Divide the pancreas using a stapler with a vascular load. Multiple firings may be required (**FIG 7**). If there is bleeding from the staple line, place 2-0 sutures in a figure-of-eight pattern at the superior and inferior borders of the pancreas to secure the gastropancreatic arteries.
- Ligate, clip, or use an energy device to control the numerous small, short vessels connecting the splenic vessels to the pancreas along the entire body and tail. Control any bleeding that occurs on the splenic artery or vein with fine Prolene sutures.
- As the splenic vessels approach the hilum, they will branch into multiple tributaries. Care must be taken to avoid injury to these branches along the tail of the pancreas. The hilum of the spleen may be directly abutting or within 1 cm of the tail of the pancreas. Once fully dissected off the vessels, the specimen may be removed.
- Check the surgical bed for hemostasis. Omentum may be placed over the pancreatic stump. Placement of a closed suction drain is our preference.

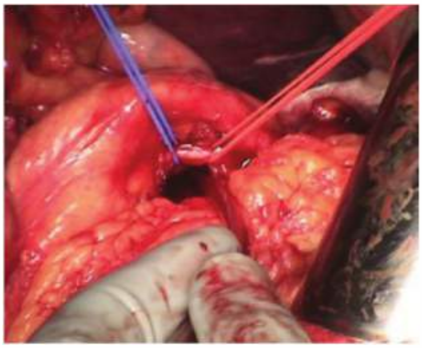

FIG 5 ● A plane is developed between the superior border of the pancreas and the splenic flexure at the point of transaction. Vessel loops are placed around the splenic vessels for retraction and vascular control.

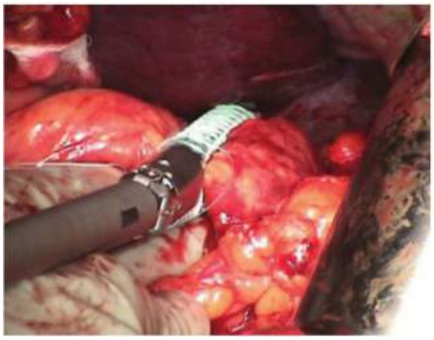

FIG 7 ● The pancreas is divided using a stapler with a vascular load.

DISTAL PANCREATECTOMY WITH SPLENECTOMY

- The exposure and mobilization of the pancreas proceed as described earlier.
- Divide the short gastric vessels.
- Mobilize the splenic flexure of the colon and retract it inferiorly.
- Divide the splenophrenic and splenocolic ligaments, and reflect the spleen and pancreatic body and tail up from the retroperitoneum.
- Once the point of transection of the pancreas has been determined, carefully isolate the splenic artery and vein and ligate them individually.
- Mobilize the splenic vessels along with the superior border of the pancreas.
- Divide the pancreas using a stapler with a vascular load. Multiple firings may be required. If there is bleeding from the staple line, place 2-0 sutures in a figure-of-eight pattern at the superior and inferior borders of the pancreas to secure the gastropancreatic arteries.
- The pancreas and spleen are then removed as specimen (**FIG 8**).
- Check the surgical bed for hemostasis. Omentum may be placed over the pancreatic stump. Placement of a closed suction drain is our preference.

FIG 8 ● The body and tail of the pancreas have been removed en bloc. The instrument points to the tumor.

LAPAROSCOPIC DISTAL PANCREATECTOMY

Positioning and Port Placement

- Laparoscopic distal pancreatectomy is a suitable approach for patients with localized disease confined to the pancreas.
- The patient is placed supine.
- A 5- to 12-mm port is placed infraumbilically.
- A diagnostic laparoscopy is performed and so is a laparoscopic ultrasound of the liver.
- Any suspicious lesions are biopsied and sent for frozen section analysis. If metastatic disease or invasion into surrounding organs is identified, conversion to an open operation should be considered.
- Additional trocars are as shown in the figure (**FIG 9**).
- The anterior wall of the stomach is elevated and the lesser sac is entered through the gastrocolic ligament using an energy device.

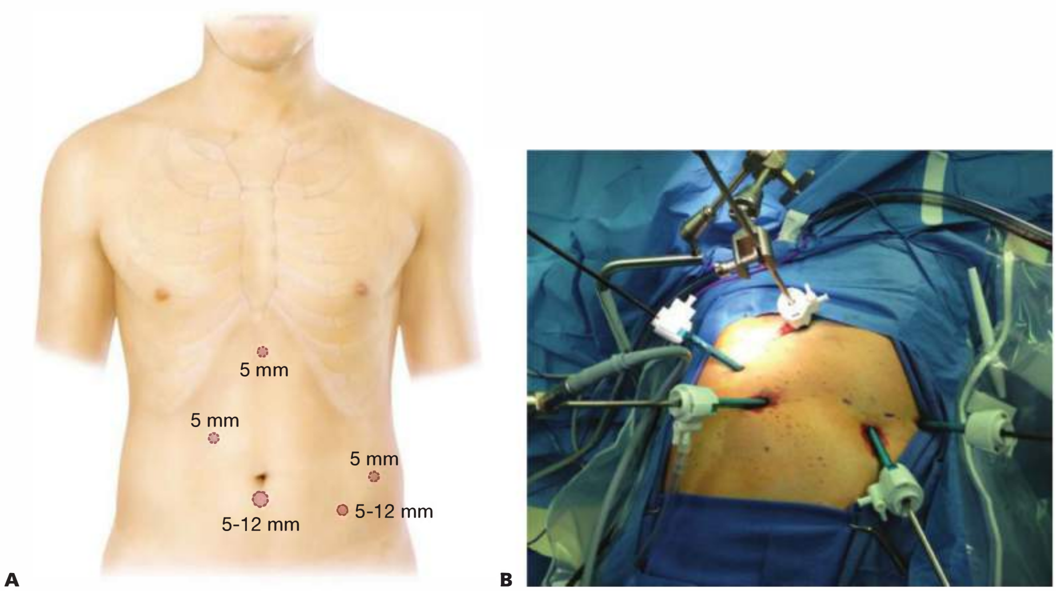

FIG 9 ● **A,B.** The position of the trocars for laparoscopic distal pancreatectomy is shown. A 5- to 12-mm trocar is placed at the umbilicus. A 5-mm trocar is placed subxiphoid for retraction. An optional assistant working port (5 mm) is placed in the right upper quadrant. Two working trocars, a 5- to 12-mm and another 5-mm, are placed in the left abdomen as shown. Trocar placement may be individualized for the patient.

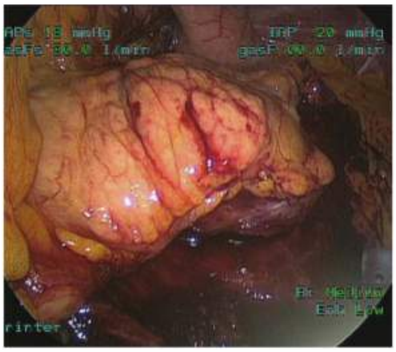

FIG 10 ● After entering the lesser sac through the gastrocolic ligament, the stomach is retracted superiorly and the transverse colon is mobilized inferiorly to expose the anterior surface of the pancreas.

FIG 12 ● When the specimen has been completely dissected free, it is elevated and placed in a plastic retrieval bag.

- The splenic flexure of the colon is mobilized inferiorly and the transverse mesocolon is dissected away from the inferior border of the pancreas, allowing visualization of the anterior surface of the pancreas and the splenic artery (**FIG 10**).
- Laparoscopic ultrasound is used to delineate the extent of the tumor and the proximal position for transecting the pancreas. In the medial to lateral technique, the splenic vessels are isolated and circumferentially dissected at the proposed transaction site.
- The splenic artery and splenic vein are individually divided using an endoscopic stapler with a 2- to 2.5-mm cartridge as determined by the vessel size. The splenic vein may need to be transected with the pancreatic parenchyma.
- The peritoneum on the inferior edge of the pancreas is incised and dorsal dissection of the pancreas is done to create a window for placement of the stapler.
- The pancreas is then divided with a linear stapler cutter with a vascular cartridge sized to the thickness of the pancreas (**FIG 11**). The pancreas and spleen are then mobilized in a retrograde fashion from left to right.
- The specimen is placed in a plastic retrieval bag and the umbilical port incision is extended to allow its removal (**FIG 12**).
- This incision is closed and the abdominal cavity is reinsufflated and irrigated and hemostasis confirmed.
- A closed suction drain is placed through the most lateral port in the left upper quadrant down to the pancreatic sump and fixed to the skin with sutures.
- The trocars are removed under direct vision and all port sites are closed with absorbable sutures.

Management of Hepatic Metastases

- Both curative intent resection and palliative intent resection are recommended for malignant glucagonoma (**FIG 13**). Other treatment options include hepatic artery occlusion or embolization, radiofrequency ablation, and cryoablation.
- Regional lymphadenectomy should be done because lymph node metastases are common.

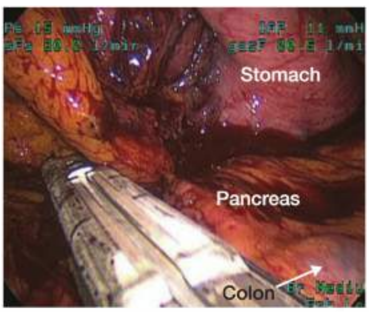

FIG 11 ● The pancreas is then divided with a linear stapler cutter with a vascular cartridge sized to the thickness of the pancreas. If the splenic vein could not be separated from the pancreas and individually ligated, it can be included with the pancreas transection.

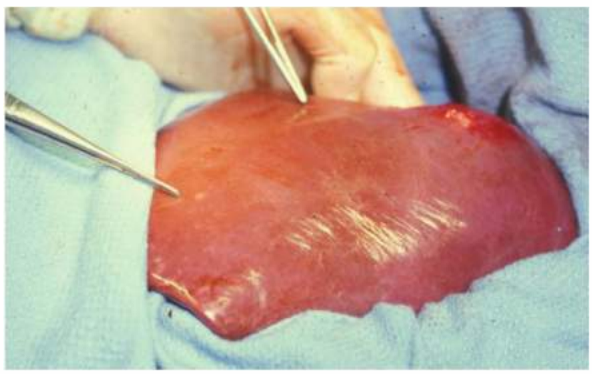

FIG 13 ● Glucagonoma metastases to the liver.

PEARLS AND PITFALLS

- MEN-1 patients with glucagonomas should have hyperparathyroidism addressed before surgical treatment for glucagonoma. Failure to do so may lead to uncontrolled hypercalcemia postoperatively.
- Although some tumors may be amenable to enucleation, formal pancreatic resection is preferred due to the high malignant potential of glucagonomas.
- Glucagonomas are associated with hypercoagulability and 30% of patients will have a deep vein thrombosis (DVT). Anticoagulation is recommended and serious consideration should be given to IVC filter placement preoperatively.
- Even if an R0 resection is not possible, patients may benefit tremendously from extensive debulking for palliation of symptoms.
- When performing a spleen-preserving distal pancreatectomy, care must be taken to avoid trauma to branches off the splenic vessels as you approach the tail of the pancreas. Remember, if extensive bleeding is encountered, the procedure can be changed to a distal pancreatectomy with splenectomy.
- Large tumors in the body of the pancreas may involve the splenic vein. In this situation, it may be helpful to divide the pancreatic neck early to better visualize the splenoportal confluence. If necessary, the splenic vein may be ligated flush with the superior mesenteric vein (SMV).
- The left adrenal may be located more superiorly than expected and may be injured by excessive medial retraction of the pancreas and spleen.
- Laparoscopic pancreatectomy without laparoscopic ultrasound is not recommended. Failure to use a laparoscopic ultrasound may result in a specimen that lacks part or all of the tumor.
- Pancreatic stump leak/fistula is one of the most common postoperative complications and may occur in up to 30% of patients. Consider octreotide for patients who do not respond to closed suction drainage or have high-output fistula. However, routine use of perioperative octreotide will not reduce the rate of fistula.

POSTOPERATIVE CARE

- Admission to the intensive care unit (ICU) is not mandatory and should be decided on a patient-by-patient basis. Management of pain, nasogastric intubation, and diet is similar to most major abdominal resections.
- Closed suction drain output should be tested for amylase and lipase before removal.
- Streptozocin is somewhat effective chemotherapy for both malignant tumors that are incompletely removed and their biochemical effects. Tumor regression is seen in 50% of patients and reduction in serum glucagon levels in over 60% of patients. Dacarbazine (DTIC) has also been used with some efficacy.
- Continued symptoms of excess glucagon after the operation should be treated with a somatostatin analog. However, routine perioperative use of octreotide therapy is not necessary and will not reduce the rate of pancreatic fistula.

OUTCOMES

- There is a paucity of outcomes data for glucagonoma. According to one study of MEN-1 patients, 10-year survival is approximately 50%.[7] In another, 5-year survival is approximately 50% following operative resection and adjuvant chemotherapy.[8]

COMPLICATIONS

- Patients may experience any postoperative complication associated with laparotomy such as superficial or deep wound infection, urinary tract infection, pneumonia, and cardiac dysrhythmia or ischemia.
- The risk of venous thromboembolism is elevated in patients with glucagonoma and the physician should remain vigilant about detection and treatment of thromboembolic events.
- Pancreatic leakage and fistula occur in up to 30% of patients undergoing distal pancreatectomy. This is managed by continued closed suction drainage in the stable patient. In a patient showing signs of infection, a CT scan should be obtained to look for abscess or inadequately controlled fistula. This can usually be treated with an additional percutaneous drain placed with image guidance. Consider octreotide therapy for persistent high-output fistulas. Operative drainage, endoscopic sphincterotomy, or stent placement may be necessary in patients not responding to percutaneous drainage.

Part 6 Operative Techniques in Vascular Surgery

Chapter 1

Arch and Great Vessel Reconstruction with Debranching Techniques

W. Anthony Lee Alexander Kulik

DEFINITION

- An aortic arch aneurysm is defined as dilation of the aortic arch to greater than 5 cm in diameter. Rarely occurring in isolation, aneurysms of the aortic arch are often extensions of aneurysms present in the ascending or descending aorta. Causes of aortic arch aneurysms included atherosclerotic degeneration, cystic medial degeneration, aortic dissection, congenital aortopathy (i.e., bicuspid aortic valve), penetrating aortic ulcer, previous traumatic transection (chronic pseudoaneurysm), and previously repaired aortic coarctation (postsurgical pseudoaneurysm). Aortic arch aneurysms have traditionally been repaired with graft replacement of the aorta, with or without an elephant trunk, using cardiopulmonary bypass and deep hypothermic circulatory arrest. With the advent of thoracic endovascular aortic repair (TEVAR), debranching of the brachiocephalic vessels is a recently developed technique that takes advantage of the reduced surgical trauma associated with stent grafting.[1] Debranching functionally extends the proximal landing zone by repositioning the inflow of the brachiocephalic arteries toward the proximal ascending aorta. This facilitates endovascular stent graft repair of the aortic aneurysm by allowing stent coverage across the ostia of the arch vessels, producing a stable and fixed proximal landing zone in the ascending aorta.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Aortic arch aneurysms are usually diagnosed as incidental findings noted on imaging studies, such as a chest x-ray or computed tomography (CT) scan, to evaluate other concurrent medical conditions.
- Most patients have no symptoms from their aneurysms. Symptoms, if they exist, may include chest or back pain from aneurysmal growth or those associated with compression of adjacent structures (i.e., trachea, esophagus). Hoarseness may develop from stretching of the left recurrent laryngeal nerve (Ortner's syndrome). Acute chest or back pain, with or without signs of shock, should raise the suspicion of impending aortic rupture and/or acute aortic dissection. Additional details regarding a patient's past medical history should be gathered, including a history of previous coronary intervention, previous cardiac surgery, known valvular heart disease, previous aneurysm surgery, or a family history of aortopathy.
- The physical examination is often unremarkable. However, attention should be directed to the presence of aortic valve insufficiency (diastolic murmur, widened pulse pressure), previous surgical incisions, and the presence of concomitant peripheral vascular disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Although a routine chest x-ray may be the first imaging test to note an aortic arch abnormality, further imaging is necessary, including a CT scan of the aorta (**FIG 1**) and an echocardiogram.
- An arterial phase CT angiogram should evaluate the entire length of the aorta, from the level of the skull base proximally to the femoral heads distally, to ensure visualization of the vertebral and iliofemoral arteries, respectively. The CT images are then processed using 3D imaging software for case planning and device selection. A magnetic resonance imaging (MRI) or a noncontrast CT scan will not suffice.
- A transthoracic (2D) echocardiogram should be performed to assess left and right ventricular function and to exclude the presence of significant valvular heart disease.
- Strong consideration should be given to evaluating the anatomy of the coronary arteries in the preoperative period. A CT coronary angiogram may be an option for younger patients or those with complex proximal aortic dissection. However, if there is a strong suspicion of coronary disease, then a preoperative conventional coronary angiogram should be performed, including those patients older than 40 years of age and those with a history of smoking.

SURGICAL MANAGEMENT

Preoperative Planning

- Indications for repair of an aortic arch aneurysm include large aneurysmal size (>5.5 cm), rapid growth (>0.5 cm per year), the presence of chest pain or back pain unexplained by other causes, and compression of adjacent organs (esophagus, trachea, or left main bronchus).[2]
- More aggressive size criteria may be applied for patients with Marfan's syndrome (repair at 4.5 to 5 cm). However, stent graft outcomes appear less favorable in patients with

FIG 1 ● Preoperative computed tomography (CT) angiogram of an aortic arch aneurysm.

connective tissue disease, and therefore, alternative surgical techniques (such as conventional aortic replacement surgery) should be considered.[2]

- The presence of significant concurrent cardiac disease may alter the surgical approach. Should significant coronary artery or valvular heart disease be identified in the preoperative period, consideration may be given to performing concomitant coronary artery bypass grafting (CABG) or valve replacement at the time of the aortic debranching procedure.
- During the second stage of the arch repair, stent graft deployment in the distal ascending aorta may require the placement of a guidewire across the aortic valve into the left ventricular cavity. The presence of a mechanical aortic prosthetic valve, through which a guidewire and the delivery system cannot safely be placed, may require a single-stage approach with deployment of the stent graft at the time of debranching (see endovascular second stage). A bioprosthetic valve in the aortic position may allow for careful transvalvular introduction of devices, with preference to bovine pericardial valves over porcine valves.
- Selection of the ideal treatment strategy for repair of an aortic arch aneurysm remains controversial and is dictated by surgical experience and local area expertise. Aortic arch debranching and stent graft completion is an appealing repair option that avoids a thoracotomy incision and may avert the use of cardiopulmonary bypass and circulatory arrest. These types of hybrid procedures may be performed either as single- or two-stage repairs. However, conventional open replacement of the entire aortic arch,[3,4] or replacement of the ascending aorta and proximal arch with the creation of an elephant trunk followed by stent graft completion,[1,5] should be considered as clinically indicated.
- Debranching of the aortic arch off the ascending aorta may not be applicable for a patient with an aortic arch aneurysm who has previously undergone cardiac surgery and who is too high-risk for consideration of redo sternotomy. In this case, an alternative option would include extra-anatomic debranching of the aortic arch (carotid–carotid, carotid–subclavian) followed by stent graft repair of the arch, with or without innominate artery chimney (snorkel) stenting.[6]
- The preoperative CT scan requires careful review before undertaking an aortic arch debranching operation. Arch branch anatomy and appropriate landing zones need to be identified proximal and distal to the arch aneurysm, with criteria similar to those that apply for stent graft repair of a descending thoracic aortic aneurysm. Anatomic variations of the aortic arch anatomy may require modification of the debranching procedure. These include a bovine aortic arch (common trunk of the innominate and left common carotid), arch origin of left vertebral artery, and an aberrant right subclavian artery.
- The ascending aorta is typically 6 to 7 cm in length from the sinotubular junction to the innominate artery. Placement of the proximal inflow anastomosis as low as possible on the ascending aorta (just distal to the sinotubular junction) will result in an optimal 3- to 4-cm proximal landing zone for the stent graft repair. The largest currently available thoracic stent grafts are 42 to 46 mm in diameter. To provide a safe and durable proximal landing zone and avoid a proximal type I endoleak, we recommend replacement of an ascending aorta that is extremely short or if its diameter is 36 mm or larger. Open replacement of the ascending aorta would be performed at the time of the arch debranching procedure, with implantation of an aortic graft 34 mm or smaller.
- The size of the iliofemoral arteries is worth noting on the preoperative CT study. The external iliac arteries need to be larger than 7 mm in diameter to provide adequate vascular access to deliver the stent graft devices during the second stage. An iliac artery conduit may be needed if the iliofemoral arteries are extremely small or in the presence of severe calcification and occlusive disease. Alternatively, a single-stage antegrade introduction of the stent graft from the ascending aorta may be performed (see endovascular second stage) to avoid access problems from a retrograde iliofemoral approach.
- The diameters of the brachiocephalic arteries are measured on the preoperative CT scan to determine the interposition graft sizes for the debranching procedure. Most frequently, the size of the graft chosen for the innominate artery branch is 10 to 14 mm, with 6- to 8-mm grafts usually used for the left carotid and left subclavian arteries.
- Cerebral oximetry monitoring may be helpful for the aortic debranching procedure to monitor brain perfusion before and after clamping of the brachiocephalic arteries. For the second-stage endovascular procedure, cerebrospinal fluid (CSF) drains are placed preoperatively to reduce the risk of spinal cord ischemia if a significant length of the descending thoracic aorta is to be covered.

Positioning

- For the arch debranching procedure, patients are positioned supine just as they are during standard cardiac surgical operations. Prepping is performed from the neck to the knees, with draping higher than usual to strategically provide access to the lower neck. The head may be turned slightly to the right to facilitate extension of the sternotomy incision proximally along the left sternocleidomastoid muscle.

AORTIC ARCH DEBRANCHING

- Although some advocate the use of a right thoracotomy incision or upper hemisternotomy, we prefer to expose the ascending aorta through a conventional sternotomy incision. This provides optimal visualization and control. The pericardium is incised and retracted.
- The ascending aorta is carefully mobilized to facilitate later placement of a proximally positioned side-biting clamp. The space between the left side of the aorta and the pulmonary artery is dissected, with small vessels cauterized or clipped and divided. The ascending aorta is mobilized proximally down to the level of the aortic root (sinotubular junction) to enable identification (and avoid injury) to the right coronary artery.
- The brachiocephalic arteries are circumferentially exposed. The innominate vein is mobilized and retracted

with an umbilical tape to facilitate exposure of the arch vessels (**FIG 2**). Uncommonly, the innominate vein requires ligation and division to aid in arch exposure. The left subclavian artery is often more posterior than expected, and exposure of this artery may be difficult. In these circumstances, the sternotomy incision may be extended superiorly and leftward along the sternocleidomastoid muscle. Alternatively, innominate and left carotid debranching may be combined with a left carotid-subclavian bypass/transposition procedure, through a standard supraclavicular approach, obviating the need to expose the left subclavian artery through the sternotomy.

- Although a preformed bifurcated or multilimb graft may be used, these occupy a large footprint and reduce the length available for the ascending aortic landing zone. Instead, we prefer to construct a Y-graft by sewing a beveled smaller Dacron graft end-to-side to larger Dacron graft (**FIG 3**). The graft sizes are selected based on the measured diameters from the preoperative CT scan. Typically, a 10- or 12-mm graft is used for the innominate artery, and a 6- or 8-mm graft is used for the left carotid artery.
- Heparin is administered to achieve an activated clotting time (ACT) of 200 seconds. The blood pressure is lowered to 90 mmHg systolic, and an aortic side-biting clamp is placed on the right anterolateral side (convexity) of the ascending aorta, as low as possible, with care not to compromise the right coronary artery.

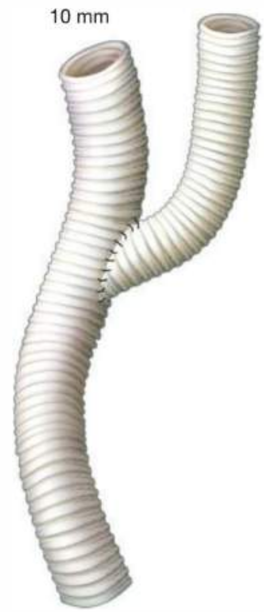

FIG 3 ● A Y-graft is constructed by sewing a beveled smaller Dacron graft (6 to 8 mm) end-to-side to larger Dacron graft (10 to 12 mm).

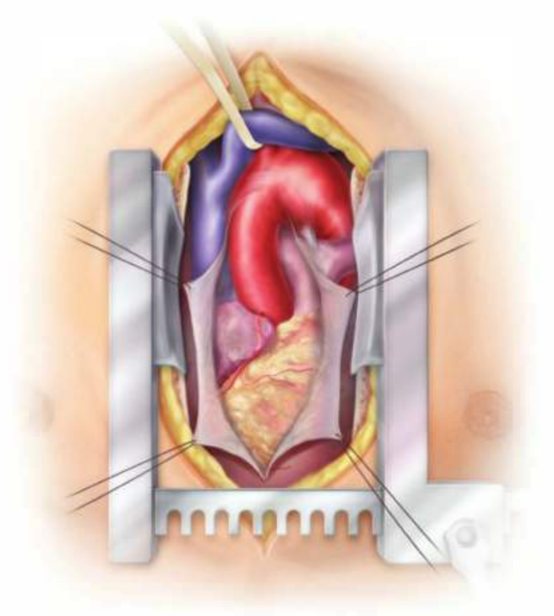

FIG 2 ● After sternotomy, the pericardium is incised and retracted. The ascending aorta is mobilized, and the brachiocephalic arteries are circumferentially exposed. The innominate vein is mobilized and retracted with an umbilical tape to facilitate exposure of the arch vessels.

A retraction suture in the right atrial appendage may be needed to facilitate proximal aortic exposure. Consideration may be given to performing this and subsequent steps in the operation with cardiopulmonary bypass to provide optimal hemodynamic control during clamp application and removal and to improve brain protection with systemic cooling in the range of 32°C to 34°C.

- The proximal end of the larger (10 or 12 mm) graft is cut to the appropriate length so the Y-graft easily reaches the arch vessels. The graft is beveled and sewn end-to-side to the ascending aorta with a running 3-0 or 4-0 polypropylene suture (**FIG 4**). BioGlue may be applied to further support the anastomosis. The aortic clamp is gently released. A large clip may be placed across the heel of the anastomosis. This will help visualize the origin of the debranching graft from the ascending aorta and precisely define the proximal landing zone without the need for contrast during the second-stage endovascular procedure.
- The innominate artery is transected, and the proximal end is oversewn with two layers of 4-0 polypropylene. The distal large end of the Y-graft is then tunneled underneath the innominate vein and sewn end-to-end to the innominate artery with running 5-0 polypropylene (**FIG 5**).
- Next, the left common carotid artery is transected, and the proximal end of the carotid artery is oversewn with 4-0 polypropylene. The distal smaller end of the Y-graft is tunneled underneath the innominate vein and sewn

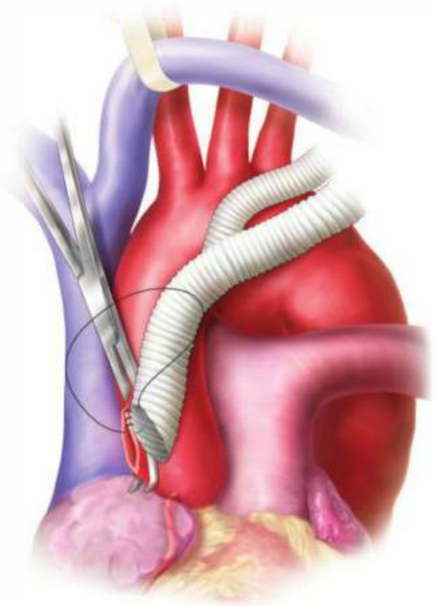

FIG 4 ● An aortic side-biting clamp is placed on the right anterolateral side (convexity) of the ascending aorta, as low as possible. The proximal end of the larger (10 or 12 mm) graft is beveled and sewn end-to-side to the ascending aorta with a running 3-0 or 4-0 polypropylene suture.

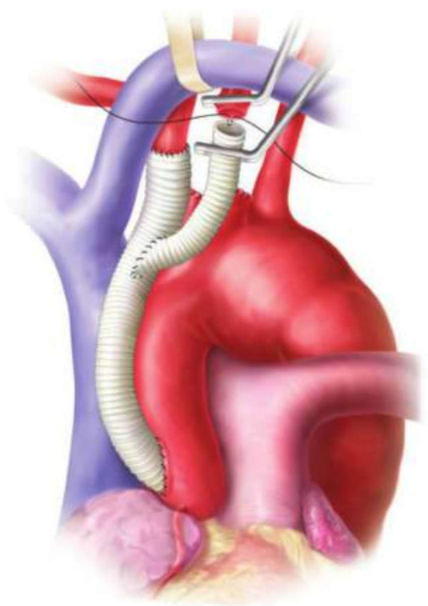

FIG 6 ● The left common carotid artery is transected, and the proximal end of the carotid artery is oversewn with 4-0 polypropylene. The distal smaller end of the Y-graft is tunneled underneath the innominate vein and sewn end-to-end to the carotid artery with running 5-0 polypropylene.

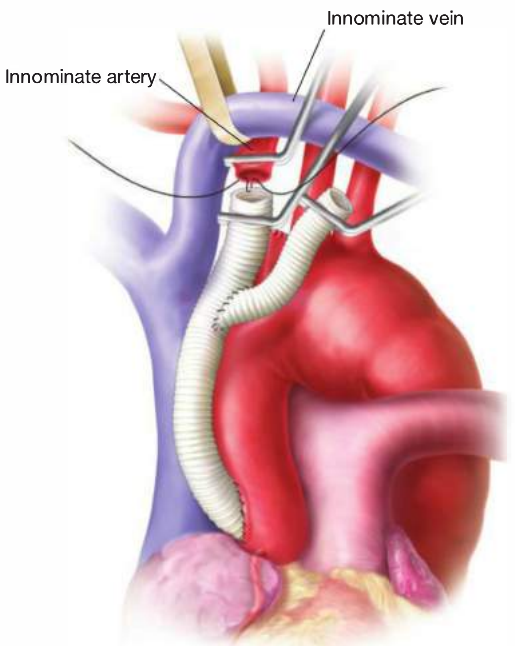

FIG 5 ● The innominate artery is transected, and the proximal end is oversewn 4-0 polypropylene. The distal large end of the Y-graft is then tunneled underneath the innominate vein and sewn end-to-end to the innominate artery with running 5-0 polypropylene.

end-to-end to the carotid artery with running 5-0 polypropylene (**FIG 6**).

- At this point, a decision needs to be made regarding the debranching strategy for the left subclavian artery. Indications for left subclavian revascularization are controversial. Routine versus selective strategies may be adopted.[7] If the left subclavian artery needs to be revascularized but cannot safely be exposed, a carotid–subclavian bypass can be performed as previously mentioned. If the subclavian artery can be exposed, the distal anastomosis is created first using a 6- or 8-mm Dacron graft anastomosed either end-to-end to the transected artery or end-to-side (functional end-to-end) followed by ligation of the proximal artery in continuity. A side-biting clamp is then placed along the carotid graft, and the subclavian graft is sutured end-to-side to the carotid graft with 5-0 polypropylene suture (**FIG 7**).
- Protamine is administered to reverse the heparin, and hemostasis is ensured. The grafts should lie tension free within the mediastinum. The pericardium may be partially closed over the grafts, with care to avoid compression of the graft branches. Chest tubes are positioned, and the sternum is closed routinely. After the sternum is closed, the blood pressure should be assessed in each arm and cerebral oximetry monitored to confirm adequate perfusion through the graft branches and the absence of graft compression.

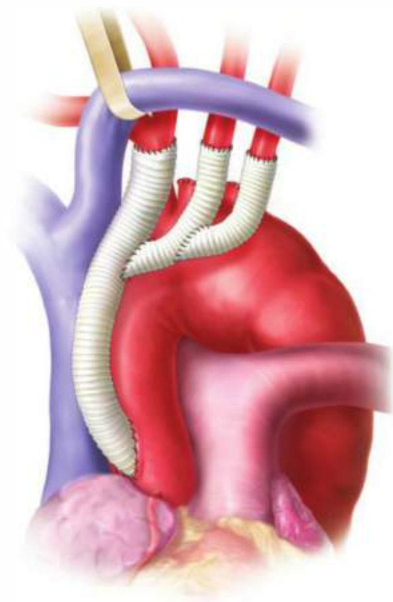

FIG 7 ● If the subclavian artery can be exposed, the distal anastomosis is created first using a 6- or 8-mm Dacron graft anastomosed end-to-end to the transected artery. The subclavian graft is then sutured end-to-side to the carotid graft with 5-0 polypropylene suture.

ENDOVASCULAR SECOND STAGE

- The endovascular second stage of the arch repair is conducted in a fairly similar manner to that of stent graft repair of a descending thoracic aortic aneurysm, as described in Part 6, Chapter 13 (Thoracic Endografting).
- The timing of the endovascular repair as a single versus staged approach remains controversial. We prefer to delay the second stage depending on the clinical scenario. It can range from a few days (same hospitalization) to several weeks (separate admission) to allow the patient to recover from the first procedure. This reduces the overall physiologic stress on the patient.
- Although we favor delivery of the stent graft in a retrograde manner from the iliofemoral arteries, in cases of a mechanical aortic valve or severe iliofemoral occlusive disease, single-stage antegrade deployment should be considered. The technical variations for these less common situations are beyond the scope of the present chapter.
- The site of insertion of the endovascular graft delivery system is decided based on the size and quality of the access vessels. In general, the grafts are delivered through the common femoral artery, whereas an iliac conduit may be required for very small or diseased iliofemoral arteries.
- The delivery guidewire is placed in the left ventricle during the endovascular procedure to provide sufficient proximal rail support for the endovascular graft.
- The proximal stent graft is deployed in the ascending aorta just distal to the origin of the debranching graft. During deployment, it is useful to lower the blood pressure using one of a variety of pharmacologic, ventricular pacing or atrial inflow occlusion techniques.[8]

PEARLS AND PITFALLS

Indications	■ The preoperative CT angiogram should be reviewed in detail to ensure the patient is a suitable candidate for aortic arch repair with debranching and stent grafting, including appropriate landing zones proximally and distally and adequate vascular access.
Proximal type I endoleak	■ To optimize the length of the proximal landing zone and prevent a type I endoleak, the debranching graft should be placed as low as possible on the ascending aorta. Preemptive replacement of the ascending aorta should be performed if it is extremely short or its diameter is $>$34 mm.
Mechanical aortic prosthesis	■ After aortic debranching, the endovascular graft delivery system may have to cross the aortic valve. Although transvalvular placement of a large sheath is relatively safe for native and bioprosthetic valves, it is contraindicated for a mechanical aortic valve. Antegrade stent graft deployment at the time of debranching should be considered in the presence of a mechanical prosthesis.
Injury to right coronary artery	■ Care should be taken when applying the side-biting clamp low on the ascending aorta to avoid occlusion or injury to the right coronary artery.

Ascending aortic dissection	■ The systolic blood pressure should be lowered to <90 mmHg when applying the side-biting clamp on the ascending aorta to prevent injury and dissection of an already fragile and diseased aorta.
Left subclavian artery	■ If the left subclavian artery is not easily accessible via the sternotomy incision (large rotated aortic arch aneurysm), then debranching of this artery can be performed via carotid–subclavian bypass.
Compression and kinking of debranching grafts	■ Ideally, the main debranching graft should lie along the right side of the ascending aorta to avoid compression by the sternum after chest closure. The graft branches should lie tension free, with care taken to avoid kinking at the time of pericardial and chest wall closure.

POSTOPERATIVE CARE

- Following the debranching procedure, patients are monitored in a cardiovascular surgical intensive care unit for 48 hours, with a focus on neurologic status, applying standard postoperative cardiac surgery protocols.
- Chest tubes are typically removed 2 days after the debranching operation.
- If a patient is recovering well after debranching without complication and has stable renal function, then the stent graft completion can be performed 3 to 5 days postoperatively. In the event of a major complication requiring extended recovery, the patient may be discharged to a rehabilitation center. The stent graft procedure can be delayed for a few weeks. However, up to 25% of patients may not return for their second stage.
- Following the second-stage stent graft procedure, the blood pressure is augmented with fluid and vasopressor support to achieve a target systolic blood pressure of 140 to 160 mmHg for 48 hours to optimize spinal cord perfusion.
- CSF drains are left open for 24 hours following stent grafting. Drainage is limited to less than 15 mL per hour or less than 350 mL per day to avoid the potential risk of subdural hemorrhage. In the absence of spinal cord injury, CSF drains are then clamped for 12 hours and subsequently removed.
- Follow-up CT angiograms of the aorta are performed at 1 and 6 months after the stent graft procedure, and then yearly thereafter.

OUTCOMES

- In the authors' experience of 37 aortic arch debranching procedures,[1] rates of spinal cord injury, stroke, and 30-day mortality were 0%, 10.8%, and 16.2%, respectively. The incidence of proximal type I endoleak was 3.7% at 1 and 12 months. Survival at 1 and 12 months was 86.5±5.6% and 71.6±8.5%, respectively. Freedom from undergoing any secondary surgical procedure after stent graft completion at 1 and 12 months was 71.0±7.8% and 52.8±10%, respectively.
- A recent systematic review of aortic arch debranching summarized the clinical outcomes of 27 published studies including a total of 642 patients.[9] Reporting results similar to those of the authors' experience[1]; the review noted rates of spinal cord injury, stroke, and 30-day mortality of 4.3%, 7.3%, and 11.9%, respectively. In this review, a trend existed between higher surgical volume and lower neurologic complications, with stroke rates of 9.6% and 6.5% in low-volume and high-volume case series, respectively.[9]
- In another review article that included 18 studies and data from 195 patients, the technical success rate following aortic arch debranching and stent graft repair was reported at 86%. The most common reason for technical failure was endoleak (9%).[10]

COMPLICATIONS

- Reopening for bleeding
- Stroke or transient ischemic attack (TIA)
- Spinal cord ischemic injury
- Ascending aortic dissection
- Endoleak
- Iliofemoral artery injury
- Mortality

Chapter 2

Extrathoracic Revascularization (Carotid–Carotid, Carotid–Subclavian Bypass and Transposition)

Edward Y. Woo Scott M. Damrauer

DEFINITION

- Extrathoracic revascularization, including carotid–subclavian and carotid–carotid bypass, involves the bypass of the proximal great vessels outside of the chest. Initially described for treatment of cerebrovascular and upper extremity occlusive disease, these procedures are commonly now employed to create a proximal seal zone for endovascular treatment of thoracic aortic disease by "debranching" the aortic arch.
- Carotid–subclavian bypass is accomplished by inserting a graft conduit between the mid-common carotid artery to the ipsilateral subclavian artery.
- Subclavian artery transposition is a potential alternative to carotid–subclavian bypass requiring division of the subclavian artery proximal to the vertebral artery and transposing it to the ipsilateral common carotid artery. It is an efficient way to revascularize the subclavian artery without the use of prosthetic conduit.[1]
- Carotid–carotid bypass provides flow from one common carotid artery to the contralateral common carotid artery.
- When carotid–carotid bypass is performed in a right-to-left manner and in conjunction with carotid–subclavian bypass, the blood flow to the left brain can be preserved while allowing for extension of the proximal thoracic endovascular aortic repair (TEVAR) seal zone to cover the left common carotid artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history should focus on neurologic symptoms that may indicate the presence of symptomatic cerebrovascular disease. Previous head and neck or carotid surgery should be noted, as well as a history of head, neck, or upper chest region external beam radiation therapy, as these may significantly increase the complexity of the procedure.
- The directed physical exam should be focused on detection of underlying vascular disease that may complicate planned intervention. Bilateral upper extremity blood pressures should be obtained; a difference of greater than 10 mmHg indicates the potential presence of preexisting occlusive disease. Likewise, the presence of carotid bruits, delayed carotid upstrokes, or abnormal upper extremity pulses suggests arterial occlusive disease that should be delineated prior to extrathoracic reconstruction or bypass of the great vessels.
- Special attention should be directed toward the cranial nerves and voice, especially in patients with prior cervical surgical procedures. Indirect laryngoscopy should be performed preoperatively in patients with hoarseness or in whom a preexisting vocal cord or cranial nerve deficit has been noted.
- Neck mobility and the presence of cervical spinal disease should be assessed, as neck extension and rotation is essential for adequate operative exposure. Patients with relative neck immobility may be poorly suited for these procedures.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Carotid duplex scanning should be used to identify patients with carotid artery stenosis prior to planned bypass procedures. Failure to identify and address stenoses at the carotid bifurcation may lead to postoperative steal phenomenon and neurologic sequelae. Manipulation of the diseased carotid artery may also increase the risk of periprocedural stroke. In these circumstances, concomitant or staged carotid intervention may be warranted.
- Computed tomographic (CT) angiography of the aortic arch and proximal carotid arteries provides the anatomic detail necessary to safely perform carotid–subclavian bypass, subclavian artery transposition, or carotid–carotid bypass. This study is complementary to duplex scanning, as it provides anatomic rather than hemodynamic assessment and images vessels equally well inside and outside the chest. CT scanning also visualizes the course of the subclavian artery in relationship to the clavicle, as its course may also be distorted by a large arch aneurysm.

SURGICAL MANAGEMENT

Preoperative Planning

- Neuromonitoring is a useful adjunct to ensure adequacy of cerebral perfusion from the contralateral cerebral circulation when the ipsilateral common carotid artery is clamped. Numerous modalities exist for neuromonitoring, including electroencephalography (EEG), transcranial Doppler, near-infrared spectroscopy, and stump pressure measurement. An indwelling carotid shunt may be placed to improve ipsilateral blood flow when monitoring indicates cerebral perfusion is inadequate. This problem occurs infrequently, as only the common carotid is occluded, but preparations should be made for shunting procedures when indicated. Alternatively, as with carotid endarterectomy (CEA), in the absence of neuromonitoring, shunts may be placed prophylactically to preserve carotid flow in all cases.
- Invasive continuous arterial pressure monitoring is routinely employed, with line placement dictated by the laterality of the procedure. Keeping in mind the potential need to occlude the subclavian artery for the reconstruction, the arterial line should be placed in the contralateral limb or in a femoral artery.

Positioning

- The patient is positioned supine with the head rotated away from the operative side. A pneumatic pillow is placed under the shoulders to allow for neck extension. Careful attention must be paid to achieve maximum neck extension while still supporting the occiput. The bed is placed in a semi-Fowler's position to reduce venous pressure and minimize bleeding.
- For carotid–carotid bypass, the head is positioned midline to facilitate bilateral dissection.

CAROTID–SUBCLAVIAN BYPASS

Exposure of the Subclavian Artery

- The incision is extended from the lateral aspect of the clavicular head of the sternocleidomastoid (SCM) muscle laterally across the supraclavicular fossa. This is further developed through the subcutaneous tissue and platysma with electrocautery. If the external jugular vein is encountered, it should be ligated and divided.
- Sufficient clavicular head of the SCM is divided to allow for adequate medial exposure. Up to one-half of the sternal head of the SCM can also be divided if also needed, but this is rarely necessary. The scalene fat pad is then visualized and divided. It is preferable to divide this near its inferior border so that most of the fat pad can be preserved and reclosed to cover the reconstruction. Care must be taken to identify and preserve the phrenic nerve as it courses over the anterior scalene muscle deep to the fat pad. The thoracic duct is easily identified. If it is injured or in the way, it should be ligated to prevent significant morbidity from a postoperative lymphatic leak.
- Once the fat pad has been mobilized, the anterior scalene muscle is divided to reveal the underlying subclavian artery (**FIG 1**). It is best to divide the muscle slowly and in layers to prevent injury to the underlying vessel. The subclavian artery is dissected circumferentially and controlled with vessel loops. Care must be taken when manipulating this vessel, as the subclavian artery is significantly more fragile and prone to injury than lower extremity arteries of comparable diameter (e.g., femoral or popliteal). Depending on the method of reconstruction and location of the planned anastomosis, the thyrocervical trunk, inferior mammary, and vertebral arteries may need to be controlled separately (**FIG 2**).

FIG 2 ● The subclavian artery and its branches are circumferentially dissected and controlled with vessel loops.

Exposure of Carotid Artery

- In the medial aspect of the wound, the lateral border of the internal jugular vein is identified and sharply defined. The vein is retracted posteriorly and the carotid sheath is entered from the lateral posterior margin. Care must be taken to identify the vagus nerve early, as its usual posterior position places it immediately in the field of dissection as the sheath is opened from this approach.

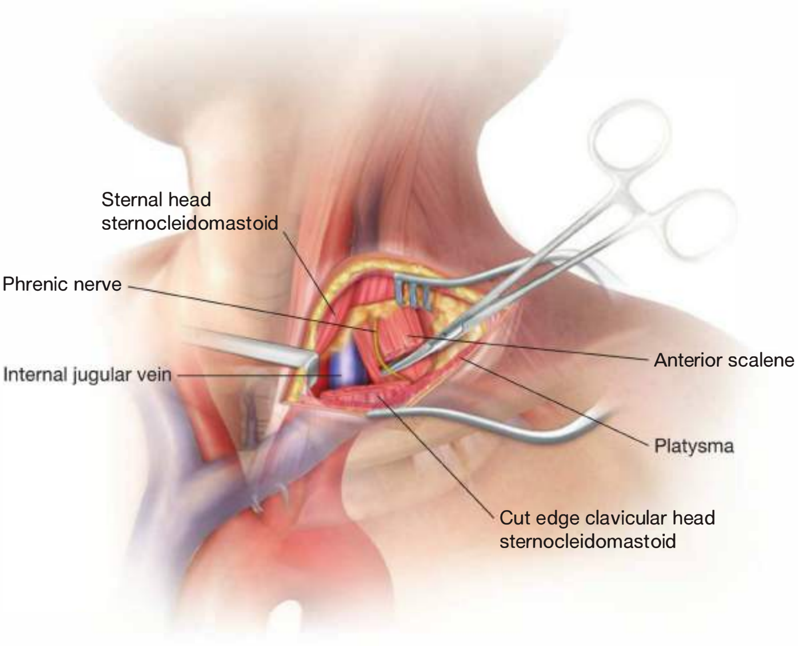

FIG 1 ● The skin incision is placed in the supraclavicular fossa over the clavicular head of the SCM muscle. The subclavian artery lies directly beneath the anterior scalene muscle. Care must be taken to identify and preserve the phrenic nerve when dividing the anterior scalene muscle.

FIG 3 ● The carotid artery is dissected circumferentially after entering the carotid sheath from its posterior lateral margin. The internal jugular vein can be seen retracted out of the way. The vagus nerve is running parallel to the artery between it and the nerve.

- The common carotid artery is dissected circumferentially (**FIG 3**). Only 5 cm of artery needs to be isolated in order to obtain control and perform the anastomosis. The dissection should stay proximal to the carotid bulb, which minimizes risk of cerebral embolization and injury to more proximal nerves.

Bypass

- Either Dacron or polytetrafluoroethylene (PTFE) can be used as conduits for extrathoracic bypass with no difference in outcomes.[2] Autogenous vein grafts should be avoided, however, as their long-term patency is inferior to prosthetic in this location.[3] We favor Dacron given the size ranges available and the relative resistance of the graft to kinking over the short distance of the reconstruction.
- Prior to arterial clamping, systemic anticoagulation is achieved with intravenous heparin administration. The activated clotting time (ACT) should be monitored and additional heparin administered throughout the procedure to maintain adequate anticoagulation.
- The subclavian anastomosis is performed first. Arterial control (vessel loops or clamps) is obtained and the vessel is opened with a longitudinal arteriotomy. The anastomosis should be fashioned in the position most favorable to the planned graft. The graft is beveled and trimmed so that the graft lies at an approximately 60-degree angle to the artery. A running Prolene suture is used to perform the anastomosis with completion of the back wall first. Once the anastomosis is complete, the graft is clamped and flow restored to the arm by unclamping the subclavian artery. It is useful to flush through the graft to remove any debris prior to opening to the arm. The graft should also be flushed with heparinized saline and clamped near the anastomosis to avoid any thrombosis of the stagnant blood column within the graft. If repairs are needed, control is restored and pledgeted sutures are used to avoid injury to the fragile artery.
- The graft is tailored to the appropriate length to prevent redundancy and kinking, and beveled so that the heel of the anastomosis will lie proximally on the carotid artery. As the common carotid artery is clamped, special attention must be directed to neuromonitoring; significantly diminished cerebral perfusion, although very uncommon, mandates shunt placement at this stage of the procedure. A longitudinal arteriotomy is performed and the proximal anastomosis completed with running Prolene suture, again starting with the back wall (**FIGS 4 and 5**).

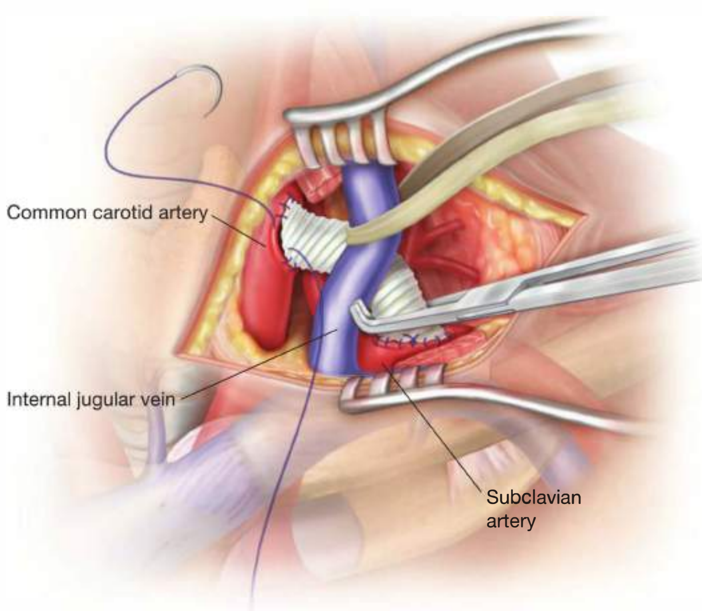

FIG 4 ● After completing the distal anastomosis, the graft and the subclavian artery are all controlled and the proximal anastomosis is performed in a running fashion. The graft can be tunneled superficial or deep to the internal jugular vein depending on patient anatomy and surgeon preference.

FIG 5 ● The completed bypass graft can course anterior or posterior to the internal jugular vein. The phrenic nerve is seen in the lower field.

- The final sequence of clamp removal is important to prevent embolism to the brain. Proximal subclavian artery control is again obtained, and the clamp is removed from the graft. The proximal carotid clamp is then removed to allow "flushing" down the arm rather than to the brain. After a few cardiac cycles, the distal carotid clamp is also removed. The proximal subclavian artery is then released as well.
- When performed in anticipation of thoracic aortic stent grafting, the subclavian artery must be ligated proximal to the origin of the vertebral artery. This can involve dissection deep into the mediastinum and carries an inherent risk of catastrophic bleeding. Alternatively, the proximal subclavian artery can be controlled by placement of an intraarterial occlusion device (e.g., Amplatzer), either during the carotid–subclavian bypass or at the time of subsequent stent graft placement via a left brachial approach.[4]

Closure

- If a pneumatic pillow was used to provide exposure, it is deflated prior to wound closure in order to reduce neck extension and assist in allowing the wound to be closed without tension.
- A closed suction drain is left in the deep wound and brought out through a separate stab incision.
- In order to provide coverage for the graft, the scalene fat pad is returned to its anatomic location and sutured in place. The SCM is reapproximated with running absorbable sutures.
- The platysma and subcutaneous tissues are closed in separate layers in a running fashion and the skin is reapproximated with a running dermal suture.

SUBCLAVIAN ARTERY TRANSPOSITION

Exposure

- The subclavian artery is exposed, as described in the previous section, for carotid–subclavian bypass. The dissection must be carried proximal to the vertebral artery and enough artery must be exposed proximally to allow sufficient length for the anastomosis as well as control the proximal stump. This can often be difficult as an aortic aneurysm can occupy a significant portion of the mediastinum limiting vessel manipulation.
- The carotid artery is exposed in the same manner as described in the previous section.

Division of the Subclavian Artery

- Systemic heparin is administered, and maximum arterial length is obtained by advancing a Cooley clamp as deeply as possible into the mediastinum along the subclavian artery. A distal atraumatic clamp is then applied, typically in the midsubclavian artery, with the more proximal branches individually controlled with vessel loops. There must be adequate distance between the proximal clamp and the vertebral artery to allow for proximal control, transposition, and anastomosis. Prior to transection, pledgeted 5-0 Prolene stay sutures are placed on each side of the proximal artery to ensure that if clamp control is lost for any reason, the open artery does not retract into the mediastinum (FIG 6).
- The proximal subclavian artery is oversewn by extending the stay sutures across the stump. Hemostasis is confirmed by slowly releasing clamp control while maintaining traction on the stay sutures. Only once hemostasis is rigorously ensured are the sutures divided and the proximal subclavian artery allowed to retract into the mediastinum.

Carotid–Subclavian Anastomosis

- The subclavian artery, having been freed circumferentially, is then mobilized toward the carotid artery. It may be tunneled anterior or posterior to the internal jugular vein depending on the length of the artery and patient-specific anatomy. The carotid artery is then clamped proximally and distally and the anastomosis performed in the standard running fashion. Prior control of the subclavian artery is maintained (FIG 7). As the anastomosis is completed, the unclamping sequence should be repeated as described in the preceding section to prevent inadvertent air or particulate embolization to the brain.

Closure

- As described in the section on carotid–subclavian bypass, the wound is closed in multiple layers over a closed suction drain placed through a separate stab incision.

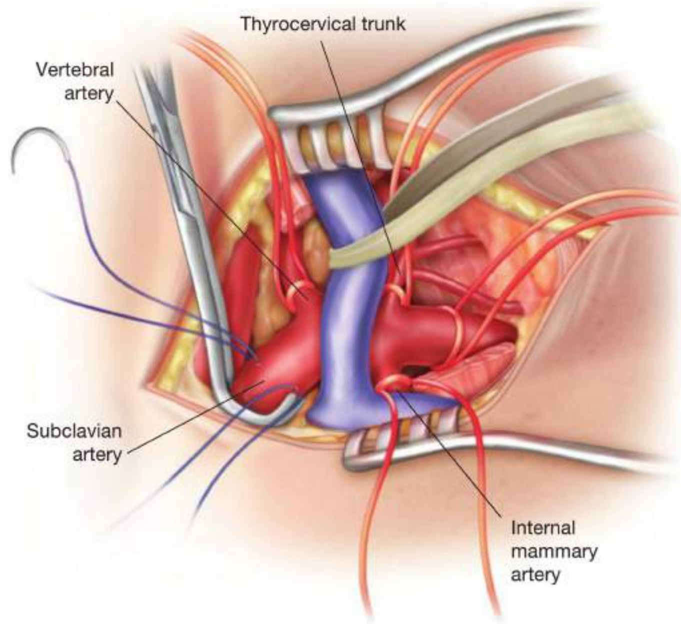

FIG 6 ● The subclavian artery and its branches are controlled individually with vessel loops and clamps. A Cooley clamp is used proximally on the subclavian artery. Stay sutures of 5-0 Prolene are placed in both ends of the subclavian artery proximal to the transection line.

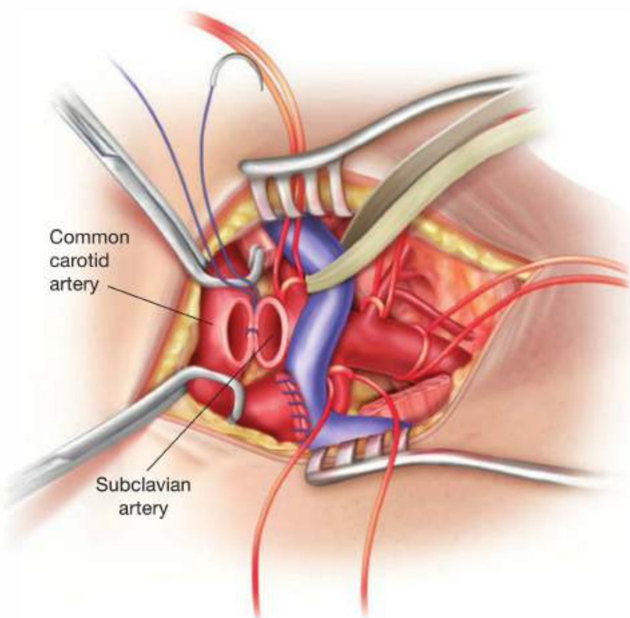

FIG 7 ● The subclavian artery is mobilized so that it may reach to the carotid artery and the end-to-side anastomosis is performed in the standard running fashion, starting along the back wall. The thyrocervical trunk may be divided if necessary to facilitate mobilization.

CAROTID–CAROTID BYPASS

Exposure of the Bilateral Carotid Arteries

- Bilateral incisions are made over the anterior border of the SCM at the base of the neck. The subcutaneous tissues and platysma are divided and the anterior border of the SCM is identified.
- The SCM is mobilized laterally by carrying the dissection down toward the internal jugular vein; this exposes the carotid sheath. Any bridging veins encountered can be divided; however, the entire dissection should be below the level of the facial vein, as this marks the carotid bifurcation. For this procedure, there is no need to risk injury to adjacent structures by

exposing the carotid bifurcation. To obtain sufficient proximal exposure, the omohyoid muscle may need to be divided bilaterally.

- The carotid sheath is entered sharply on its anterior surface. The vagus nerve must be identified within the carotid sheath and protected as the common carotid artery is exposed and controlled.

Graft Tunneling and Anastomosis

- Once the bilateral common carotid arteries are sufficiently exposed and controlled, the appropriate graft tunnel can be created. Tunneling is achieved via blunt finger dissection from both sides of the neck. The graft may be tunneled either between the trachea and esophagus or behind the esophagus, depending on patient habitus and surgeon preference (**FIG 8**). Care must obviously be taken to avoid injuries to these critical structures. Placement of an orogastric or nasogastric tube prior to creation of the dissection plane can be helpful for identifying the esophagus.
- Once the tunnel has been developed, the graft is passed and patient systemically anticoagulated with intravenous heparin administration.
- The anastomoses are performed in the standard running fashion; either one may be performed first. Careful attention must be paid to neuromonitoring as the carotid artery is clamped.
- Once the first anastomosis is complete, the graft is clamped and carotid artery flow restored on that side. Prior to removing the distal carotid artery clamp, the distal artery can be back-bled and the proximal artery flushed out the open graft. As with the subclavian artery, the graft should be flushed with heparinized saline and clamped close to the anastomosis to avoid a long stagnant column of blood within the prosthetic graft.
- The contralateral anastomosis is then performed in the same fashion (**FIG 9**). The graft should be flushed with heparinized saline and the graft, proximal carotid artery, and distal carotid artery should be vigorously flushed prior to completion.

Closure

- Hemostasis is obtained. The neck wounds are closed in layers, first taking care to reapproximate the SCM in its anatomic position with interrupted absorbable sutures.
- A closed suction drain is left in each wound.
- The platysma and subcutaneous tissues are closed with running absorbable sutures and the skin reapproximated with a running deep dermal suture.

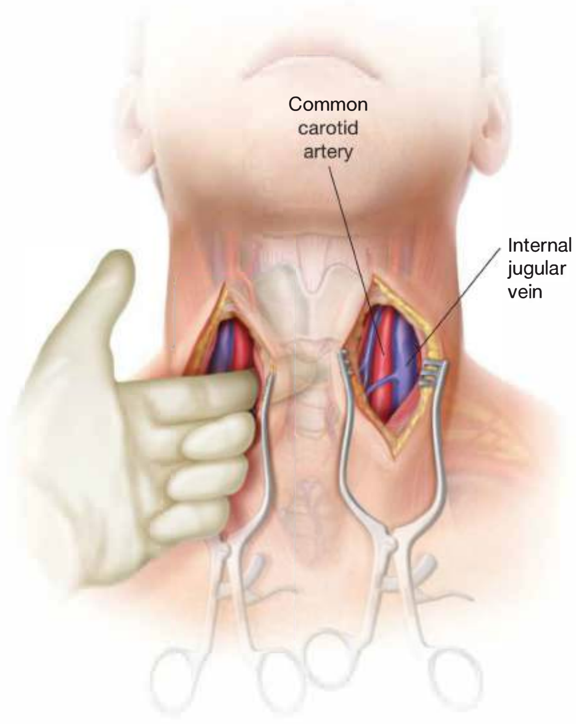

FIG 8 ● After isolating both common carotid arteries, a retropharyngeal tunnel is fashioned using blunt finger dissection. The placement of a nasogastric or orogastric tube allows for easy identification and protection of the esophagus.

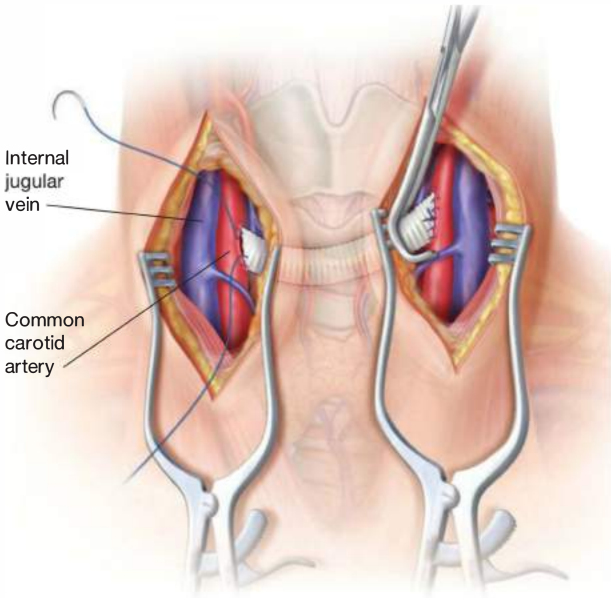

FIG 9 ● The distal anastomosis is performed in the standard running fashion starting with the back wall. Prior to completing the anastomosis, the carotid arteries and graft should be back-bled and flushed with heparinized saline.

PEARLS AND PITFALLS

Positioning	■ When inflating the pneumatic pillow, care must be taken to ensure that the occiput is adequately supported. Failure to adequately support the head may result in cervical spine and neurologic injuries.
Thoracic duct	■ Great care must be taken to avoid injuring the thoracic duct when exposing the subclavian artery. All lymphatic tissue encountered should be ligated before being divided as the ensuing lymphatic leak can be quite troublesome for the patient and the surgeon.
Subclavian artery control	■ The subclavian artery can be controlled either with vessel loops or with atraumatic vascular clamps, depending on which helps to better deliver the artery into the wound without undue tension.
Subclavian artery anastomosis	■ The subclavian artery is exceedingly friable and should be handled carefully. Given the exposure, it may be easier to parachute the anastomosis rather than fix the suture line at the heel of the anastomosis.
Positioning vis-à-vis the internal jugular vein	■ Depending on the habitus of the individual patient, the graft may lie better tunneled either above or below the internal jugular vein. It is prudent to explore both options prior to creating and completing the carotid anastomosis.
Proximal subclavian control during transposition	■ The use of stay sutures on the proximal subclavian artery in subclavian artery transposition is crucial. Once the stay suture on the proximal end of the artery is released, the artery retracts deep into the mediastinum and is not retrievable. Uncontrolled bleeding may be disastrous and lead to fatal complications. As such, the proximal oversewed subclavian artery must be hemostatic prior to release of the stay sutures. Stay suture safety is ensured by placement of pledgeted sutures at either end of the subclavian closure.
Common carotid artery exposure	■ It is not necessary and not advisable to expose or manipulate the carotid bulb or bifurcation in performing any of these reconstructions unless a concomitant CEA is necessary or the bifurcation is situated low in the neck. These procedures are performed on the common carotid artery, and exposing the bifurcation only increases the risk of cranial nerve injury and stroke.
Closure	■ The pneumatic pillow should be deflated prior to closure to assist in bringing the tissue together without tension.

POSTOPERATIVE CARE

- Careful attention should be paid to both systolic and mean arterial blood pressure in the postoperative period. Invasive arterial monitoring is usually maintained for the first 24 hours. When carotid–subclavian bypass or subclavian artery transposition is performed, blood pressure should be monitored in the contralateral arm.
- Neurologic status and distal pulses should be followed closely in the postoperative period. Any pulse changes need to be rigorously investigated as they may indicate the presence of either graft occlusion or distal embolization.
- When carotid–subclavian bypass, where the proximal subclavian artery is not ligated, is performed as a debranching procedure prior to thoracic aortic stent grafting, the timing of the endovascular procedure is important. In these patients who tend not to have concomitant occlusive disease, there is competitive flow via the native circulation, putting the newly placed graft at risk of thrombosis. In the absence of complications or other mitigating circumstances, the endovascular aortic procedure should be performed within 3 to 5 days of the debranching bypass.
- Patients should be placed on aspirin therapy and followed at regular intervals with duplex ultrasonography.

OUTCOMES

- Recent review of the American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) database from 2005 to 2010 demonstrates that extrathoracic revascularization carries a 3.5% risk of stroke and 3.3% risk of death in the immediate perioperative period.[5] Over this time period, 918 procedures were performed, with 10% of them as part of a staged approach to thoracic aortic stent grafting.
- Carotid–subclavian bypass has excellent durability. In a series of 284 consecutive patients, Takach and colleagues[2] reported 5-, 10-, and 15-year primary patency rates of 94%, 88%, and 86%, respectively. These results have subsequently been replicated by other large, multiple-decade series.[6] Subclavian artery transposition has similarly outstanding long-term patency, with rates as high as 99% reported at 5 years.[6,7]
- Symptom-free survival following revascularization is likewise excellent, with long-term results approaching 88% to 99% at 5 years.[6,7]

COMPLICATIONS

- The thoracic duct lies at the medial aspect of the field of dissection when dissecting in the supraclavicular fossa. This can be easily injured and remain undetected during the course of the operation. Continued or milky drainage is a clear sign of duct injury. The oral administration of cream can be used to promote chyle flow, and if a leak is present, will promptly increase drain output. When this occurs, the closed suction drain should be left in place, the patient kept fasting, and parenteral nutrition instituted. With conservative management, some of these injuries may close without further intervention. The complete management of this complication is beyond the scope of this text; however, it should be mentioned that reexploration of the wound in the early period is relatively straightforward and may represent the best way to resolve the problem. Late reexploration can be fraught with difficulty finding the leak as the tissue becomes fixed. A muscle flap may then be needed to close the space. The main concern with a persistent leak is the potential for graft infection. Unfortunately, early wound reexploration significantly increases the risk of prosthetic graft infection as well.
- The vagus, phrenic, and recurrent laryngeal nerves, as well as the brachial plexus, can all be injured as a result of carotid and subclavian artery exposure. Most injuries are due to traction rather than transection, and conservative therapy will generally resolve symptoms over the course of months to a year. In the case of a staged bilateral subclavian revascularization, it is important to ensure that any vagus or phrenic nerve injury has resolved prior to contralateral intervention, as bilateral injuries can lead to tracheal obstruction and acute respiratory failure.
- Although uncommon, significant bleeding from the wound should mandate reexploration. More commonly, minor wound hematomas may develop that can be observed. Judgment regarding the need for reexploration of a neck hematoma is similar to that required during any other neck procedure.
- Infection of the wound can be devastating if prosthetic is involved. Local cellulitis should be treated aggressively with early institution of antibiotics in order to prevent deeper infection. Upon removal of the drain, it is important that the drain site does not continue to leak, as continued leakage may act as an entry point for bacterial contamination. Simple suture closure should resolve this. Prosthetic graft infection necessitates graft removal, which is extremely difficult and beyond the scope of this chapter.
- Although uncommon, stroke is a complication of any carotid procedure. Taking the precautions outlined previously in this chapter should minimize these risks.

Chapter 3

Carotid Surgery: Interposition/Endarterectomy (Including Eversion)/Ligation

Vinit N. Varu Wei Zhou

DEFINITION

- Stroke is the leading cause of disability in the United States and Western Europe and the third leading cause of death behind coronary artery disease and cancer.
- Pivotal studies have shown the efficacy of carotid endarterectomy (CEA) in stroke prevention in both symptomatic and asymptomatic patients with internal carotid artery (ICA) stenosis versus medical therapy alone.[1,2]
- CEA is defined as the surgical excision of atherosclerotic lesions of the intima and tunica media of the carotid artery.
- Occasionally, ICA ligation and/or interposition bypass may be indicated for stroke prevention.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients may be entirely asymptomatic and still benefit from carotid intervention to prevent long-term stroke. In the United States, most CEA procedures are performed on asymptomatic patients. Symptoms of cerebroembolic disease originating from the carotid bifurcation, when present, may include dysarthria, dysphasia, aphasia, hemiparesis, or hemisensory deficit or amaurosis fugax. Symptoms that resolve within 24 hours are defined as transient ischemic attacks (TIAs) regardless of severity; symptoms that persist past the first day constitute a stroke.
- For patients at risk for cerebroembolic disease, a thorough vascular history is obtained including modifiable risk factors such as smoking, hyperlipidemia, hypertension, and diabetes management. Prior to surgery, single-agent antiplatelet therapy is initiated and continued indefinitely following intervention. Blood pressure control at or below 140 mmHg systolic and 90 mmHg diastolic is the single most important medical intervention to reduce stroke risk.[3] Sufficient β-blockade to stabilize resting heart rate at 60 bpm is also instituted prior to surgery to limit perioperative myocardial oxygen demand unless contraindicated.[4]
- Cervical auscultation is performed in both the supraclavicular and mandibular regions. Bruits appreciated at the mandibular angle usually indicate ICA or bifurcation disease. More proximal bruits may indicate common carotid artery (CCA) disease or radiating heart sounds.
- A full neurologic assessment including mental status, speech, facial symmetry, and extremity strength must be obtained and documented prior to surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients exhibiting symptoms of carotid territory ischemia need appropriate vascular imaging studies. Screening is not recommended to detect asymptomatic disease in the general population; patients with appropriate risk factors, or those with a bruit on physical exam should be evaluated when clinical circumstances warrant.
- Carotid duplex ultrasound provides a reliable and accurate noninvasive tool to identify predicted stenosis and is the initial diagnostic study of choice. Peak systolic velocity (PSV) higher than 125 cm per second predicts angiographic stenosis more than 50% and higher than 230 cm per second predicts more than 70% stenosis. However, a combination of PSV, end diastolic velocity, and the PSV ratio of ICA to CCA is more accurate in estimating significant carotid stenosis. In general, end diastolic velocity higher than100 cm per second correlates to more than 80% carotid stenosis.
- When duplex imaging is not definitive, as is the case in the setting of extensive carotid bifurcation calcification, additional cross-sectional imaging (computed tomography angiography [CTA] or magnetic resonance angiography [MRA]) may be necessary to quantify the degree of stenosis. When accurate velocity information is obtainable, duplex imaging provides the most accurate and physiologically relevant estimates of percent diameter reduction.

SURGICAL MANAGEMENT

Indications

Endarterectomy

- The Society for Vascular Surgery recommends that neurologically symptomatic patients with greater than 50% stenosis or asymptomatic patients with greater than 60% stenosis should be offered CEA to reduce risk of recurrent or initial stroke, respectively. Endarterectomy is appropriate for patients with at least a 3- to 5-year life expectancy with perioperative stroke/death rates less than 3%. In all other circumstances, optimal medical therapy is preferred.[5]
- Surgical endarterectomy is the procedure of choice for good-risk surgical patients with normal cervical anatomy. For selected high-risk patients, such as those with tracheal stoma, previously radiated neck, prior cranial nerve injury, or lesions proximal to the clavicle or distal to C2 vertebral body, transcatheter angioplasty and stenting is generally the preferred approach.[5] Indications and technical guidelines for carotid angioplasty and stenting procedures are discussed in Part 6, Chapter 4.

Carotid Artery Interposition Bypass

- Reconstruction for extensive bifurcation disease, injury to the bifurcation during endarterectomy, or aggressive restenosis following previous intervention (endarterectomy or stent placement) is best accomplished by carotid resection and interposition grafting. Other indications include the following:

- Significant diffuse CCA and ICA disease
- Radiation-induced stenosis or other forms of arteritis involving long arterial segments
- Aneurysms (degenerative or traumatic) and invasive carotid body tumors.

Ligation

- Ligation and resection of the proximal ICA may be indicated in the setting of carotid stump syndrome, when persistent distal embolization from the "cul-de-sac" of the occluded ICA may reflux into collateral pathways, such as through the ophthalmic artery into the distal ICA.

Preoperative Planning

- Similar outcomes are achieved with general anesthesia or regional anesthesia.
- Use of shunt during CEA is dependent on operator preference. Most surgeons either shunt selectively or use a shunt for all cases. Some surgeons never shunt.[6] Surgeons should develop the methods they feel most comfortable with to optimize outcome. Objective measures that may influence shunt usage include stump pressure measurement, electroencephalographic monitoring, and transcranial Doppler assessment. Data supporting use of these adjuvants is inconsistent, and none is considered standard of care nationally.
- Optimal neck extension is obtained by placing a towel or gel roll behind the scapula. The head is rotated contralateral to the operative side. In older patients, often with limited neck movement or prior cervical fusions, padding and shay positioning must be sufficient to support the neck to prevent hyperextension injury. The chin, angle of the mandible, lower earlobe, and sternal angle are prepped and preliminarily draped within the operative field. The bed itself can be flexed with the head in relative extension to aid in positioning (**FIG 1**).

FIG 1 ● Recommended patient position for a CEA procedure.

- Arterial blood pressure monitoring is necessary for optimal anesthetic management. Bladder catheterization is performed if the procedure is expected to extend beyond 2 hours. If endarterectomy is performed with regional anesthesia, an audible squeeze device is placed in the patient's contralateral hand for indirect neurologic monitoring. Preoperative antibiotics are administered routinely.
- Aspirin therapy is initiated well in advance of surgery and continued throughout the perioperative period. Evidence suggests that statin therapy, initiated preoperatively, reduces postoperative neurologic events and mortality.[7]

CAROTID ENDARTERECTOMY—PATCH ANGIOPLASTY

Incision

- The skin incision is optimally placed along the anterior border of the sternocleidomastoid muscle. This should be curved posterolaterally near the angle of the mandible to avoid dissection into the parotid gland.
- Alternatively, a more transverse incision can be made at the level of the carotid bifurcation. Although providing an improved cosmetic result, exposure of the distal ICA may be compromised with this approach (**FIG 2**).

Carotid Exposure and Control

- As the incision is extended through the platysma muscle, the anterior border of the sternocleidomastoid muscle is visualized and retracted posterolaterally. The greater auricular nerve should be identified and protected at the superior extent of the incision.
- Following fascial incision, the facial vein is identified and securely ligated. This vein usually transverses the CCA near the bifurcation. Failure to adequately secure this vein may lead to bleeding and airway compromise during postoperative cough spells or Valsalva maneuvers.
- Within the carotid sheath, the vagus nerve usually extends posterior to, and parallel with, the artery and vein. However, this position relative to the other contents of the carotid sheath may vary, and the vagus should always be identified and protected in the course of the dissection. The ansa cervicalis nerve is commonly much smaller than the vagus and runs anterior to the carotid bifurcation. When completely isolated, the proximal ansa arises from the ipsilateral hypoglossal (XII) cranial nerve. The ansa cervicalis can be divided to improve exposure if necessary or mobilized sufficiently to be gently retracted out of the operative field.
- The CCA is circumferentially dissected from surrounding structures in sufficient length to provide adequate exposure for proximal clamping and control. The CCA is

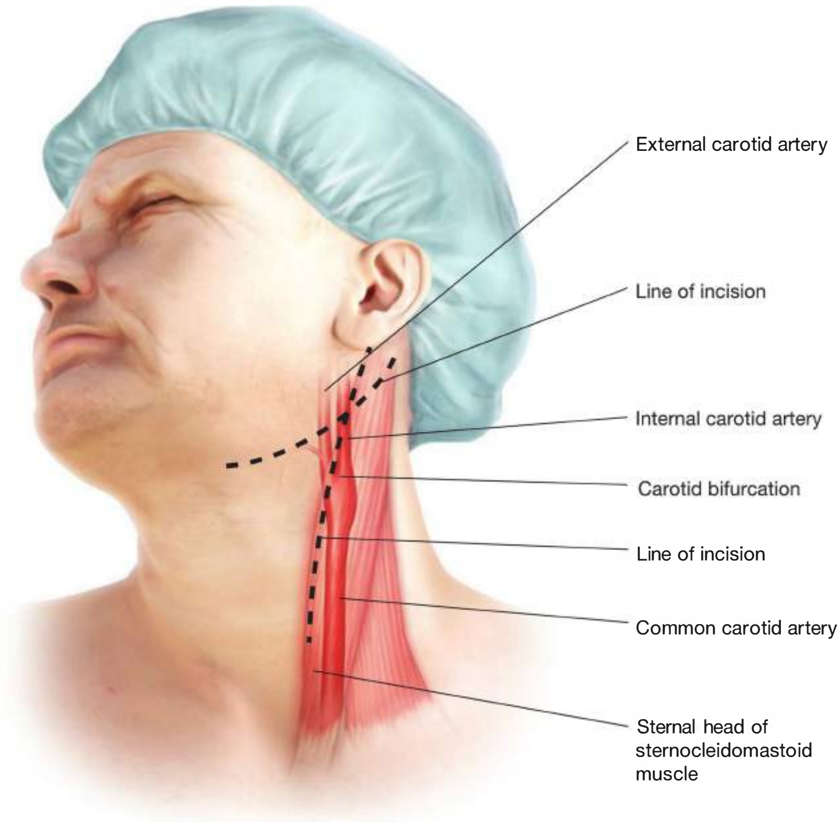

FIG 2 ● The incision along the anterior border of sternocleidomastoid (SCM) muscle is the most commonly used incision for a CEA procedure. A transverse incision along a skin crease in the vicinity of the carotid bifurcation is an alternative incision for a better cosmetic result. CCA, common carotid artery; ICA, internal carotid artery; ECA, external carotid artery.

optimally controlled by placement of an appropriately sized, atraumatic vascular clamp such as a Gregory profunda clamp. The ratchet should be engaged only to the minimal amount necessary to control bleeding to prevent intimal injury and dissection at the site of clamp placement.

- Following common carotid control, the dissection is extended cranially and posteriorly along the posterolateral border of the ICA. Development of the dissection plane posterolaterally along the proximal ICA minimizes risk of hypoglossal nerve injury. This dissection is also performed with minimal displacement and instrumentation of the ICA to reduce intraoperative embolization risk (**FIG 3**).
- To complete the necessary exposure, the external carotid artery (ECA) is dissected and mobilized to at least the level of the superior thyroidal artery. The superior laryngeal nerve may also be encountered posterior to the carotid bifurcation in this area.
- Following dissection, and prior to clamp placement, sufficient unfractionated heparin is administered intravenously to obtain an activated clotting time (ACT) of more than 200 seconds. With normal circulation times, this is usually accomplished within 2 or 3 minutes of injection.
- Clamping of ICA is performed first, followed by control of the external and common carotid arteries. This sequence is followed to minimize embolization risk associated with clamping. When necessary, measurement of ICA stump pressure is obtained at this juncture by cannulation of the carotid bifurcation and selective removal of the internal carotid clamp.

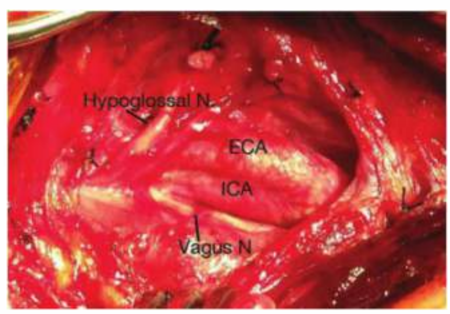

FIG 3 ● Exposure of carotid bifurcation. Vagus nerve and hypoglossal nerve are most commonly encountered nerves during carotid dissection.

Conventional Endarterectomy

- The arteriotomy is initiated in a soft, uninvolved proximal segment of the CCA and extended cephalad with Potts scissors. It should be positioned on the anterior-lateral surface of the ICA to avoid the flow divider. (**FIG 4A**).
- When an indwelling shunt is indicated or required, the distal tapered end is carefully inserted into the ICA under direct vision. We prefer the Pruitt-Inahara shunt, which has pilot balloons at both ends to maintain shunt position and hemostasis. Once the distal end is inserted, the distal balloon is inflated with less than 1 mL of air until the "pop-off" balloon inflates on the pilot tube. Familiarity with this shunt prior to insertion is essential; if the inflation override cuff covers the "pop-off" balloon on the pilot tube, overinflation may injure or rupture the distal ICA. Following distal ICA cannulation and balloon inflation, the shunt is back-bled to confirm luminal placement and decant air. With the shunt actively back-bleeding, the proximal end is inserted into the CCA followed by proximal clamp removal into the unobstructed lumen. The proximal pilot tube is inflated with the provided syringe until the cuff is palpable in the CCA, after which a prepositioned Rumel tourniquet is gently cinched around the artery. When performed quickly, with concurrent digital control of the CCA following clamp removal and prior to shunt insertion, minimal bleeding ensues. When saline is applied to the shunt tubing, pulsatile flow is appreciable with handheld Doppler insonation.
- At the site of maximal atherosclerotic disease in the CCA, the Penfield knife is employed to identify and develop the appropriate endarterectomy plane within the medial layer. When the correct plane is identified, the plaque is easily and rapidly elevated from the underlying adventitia. In areas containing intraplaque hemorrhage, inflammation may increase adherence of the plaque to the adventitia, and care should be taken not to extend the dissection plane into the adventitia itself.
- At the distal extent plaque, sufficient exposure should be present to create a defined endpoint, allowing placement of tacking sutures if necessary, ensuring that no further potentially mobile plaque remains. It is essential to "feather" the plaque at the distal endpoint to minimize risk for distal dissection or thrombus accumulation. If the plaque extends past the point where feathering is feasible, a distal endpoint should be determined and created sharply with scissors or a no. 15 blade (**FIG 4B**). Tacking sutures, placed circumferentially, can control distal plaque at the transection site. Care should be taken, however, to place the minimal number of sutures necessary to prevent dissection, or consider extending the arteriotomy and endarterectomy to identify a more suitable termination site. Successful suture placement requires circumferential dissection and optimal visualization.
- Once the distal endpoint is determined, residual plaque is removed from the ECA by eversion into the CCA and circumferential dissection and traction. Sufficient back-bleeding is performed to remove any luminal debris within the ECA.
- Direct visualization of the endarterectomy bed following plaque removal commonly identifies loosely attached residual medial elements. These are best removed with fine forceps under magnification. Complete removal is facilitated by continuous irrigation to identify mobile medial elements. Integrity of the distal and proximal endpoints is also verified using this technique.

Patch Placement

- An appropriately sized bovine pericardial or Finesse Dacron knitted polyester patch is selected and trimmed as necessary for closure-assisted angioplasty. Both bovine pericardial and polyester patches have chirality considerations; one surface is preferred for luminal apposition. Please consult the accompanying instructions for use prior to implantation. Closure is secured with running 6-0 polypropylene suture initiated at the cephalad extent of the arteriotomy and continued proximally along the long axis of the patch.
- After 90% or more of the circumference of the patch is secured, flushing is accomplished by sequential clamp removal and luminal irrigation with heparinized saline. Closure is then completed prior to restoration of flow.
- The declamping sequence is of critical importance. The CCA is released first, followed by the ECA clamp. After several cardiac cycles have ensued, the distal ICA is released (**FIG 4C**).
- We perform intraoperative completion duplex imaging of the endarterectomy site as well as the proximal and distal carotid arteries, with purpose-designed, miniaturized 7 MHz probes. Completion duplex scanning is quick, efficient, highly reproducible, and effective at identifying significant residual luminal defects. Detailed description of the characteristics of significant luminal defects identified by completion ultrasonography are beyond the scope of this chapter. Intraoperative insonation is not possible through extruded polytetrafluoroethylene (ePTFE) patches and should not be attempted.

Closure

- Following adequate duplex imaging and endpoint determination, anticoagulation is reversed with protamine sulfate. Some practitioners are reluctant to reverse anticoagulation due to uncertainty regarding thrombogenicity at the endarterectomy site. In our experience, technical issues at the endarterectomy site are most predictive of postoperative neurologic events, and these are efficiently identified and corrected, when present, with completion ultrasonography. Following reversal, the entire wound is inspected for venous or arterial bleeding. The entirety of the patch angioplasty suture line is reinspected for periodicity of suture placement and potential leaks. Reinforcing sutures are applied liberally as needed to ensure hemostasis, but with experience and even suture spacing, the need for additional sutures should be rare. Bleeding lymph nodes should be sutured and removed from the operative field. Confirmation of hemostasis, the platysma is reapproximated with running absorbable suture followed by skin closure. We usually also perform a Valsalva maneuver to identify occult venous injuries that may not be apparent with positive pressure ventilation prior to closure.

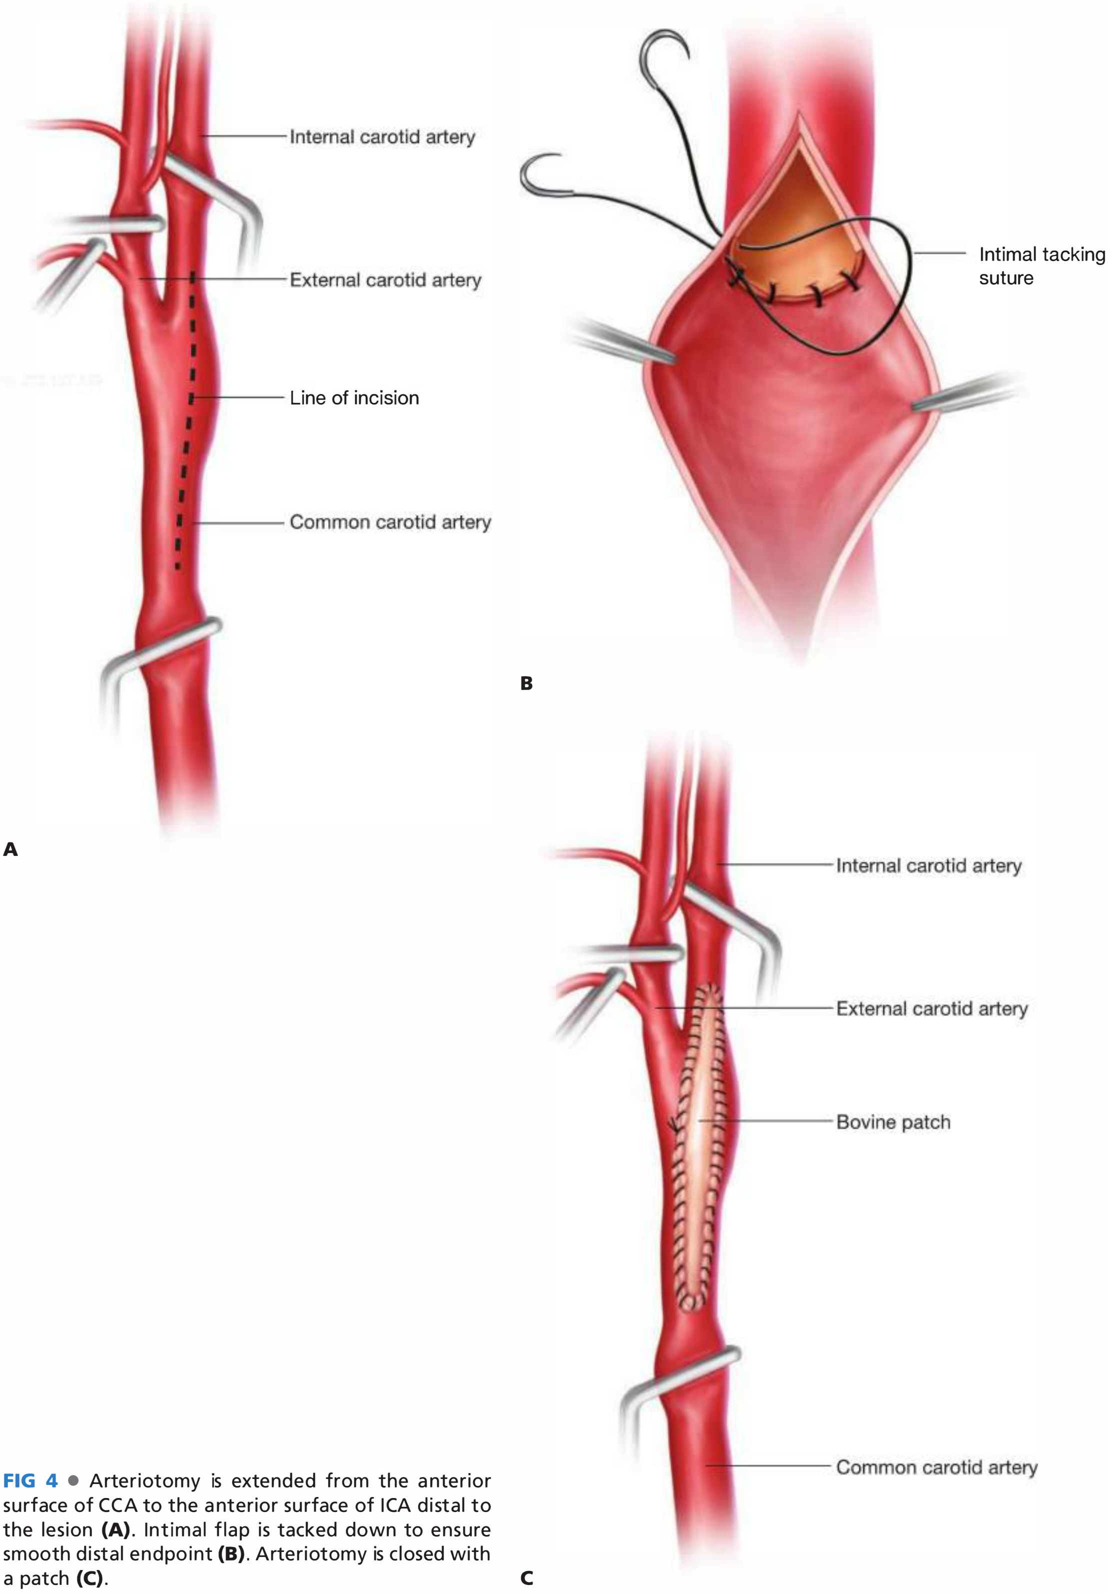

FIG 4 ● Arteriotomy is extended from the anterior surface of CCA to the anterior surface of ICA distal to the lesion **(A)**. Intimal flap is tacked down to ensure smooth distal endpoint **(B)**. Arteriotomy is closed with a patch **(C)**.

CAROTID ENDARTERECTOMY—EVERSION

Incision

- See section under Carotid Endarterectomy—Patch Angioplasty.

Dissection and Control of the Carotid Artery

- See section under Carotid Endarterectomy—Patch Angioplasty.

Eversion endarterectomy

- An oblique or circumferential incision is made at the junction of the bulbous portion of the ICA and CCA (**FIG 5A**).
- The ICA adventitia is grasped with fine forceps and everted away, as gentle traction is placed on the plaque within the artery. This maneuver is extended distally until the feathered endpoint identifies itself. Tacking sutures are not possible using this approach, which can be a deterrent to adoption by surgeons trained with conventional endarterectomy. Common and external carotid plaque is subsequently removed by the Penfield knife as indicated. The proximal CCA arteriotomy may be extended as needed to ensure complete removal.
- Common and external carotid plaque is subsequently removed by the Penfield knife as indicated. The proximal CCA arteriotomy may be extended as possible to ensure complete removal (**FIG 5B**).

Anastomosis

- The ICA is reverted and anastomosed end-to-end to the proximal CCA (**FIG 5C**).
- If redundant residual ICA is present following plaque removal, the ICA spatulation is extended, as is the CCA arteriotomy, and the two ends are further advanced over each other prior to closure. Alternatively, a portion of the redundant ICA may also be excised.

Closure

- See section under Carotid Endarterectomy—Patch Angioplasty.

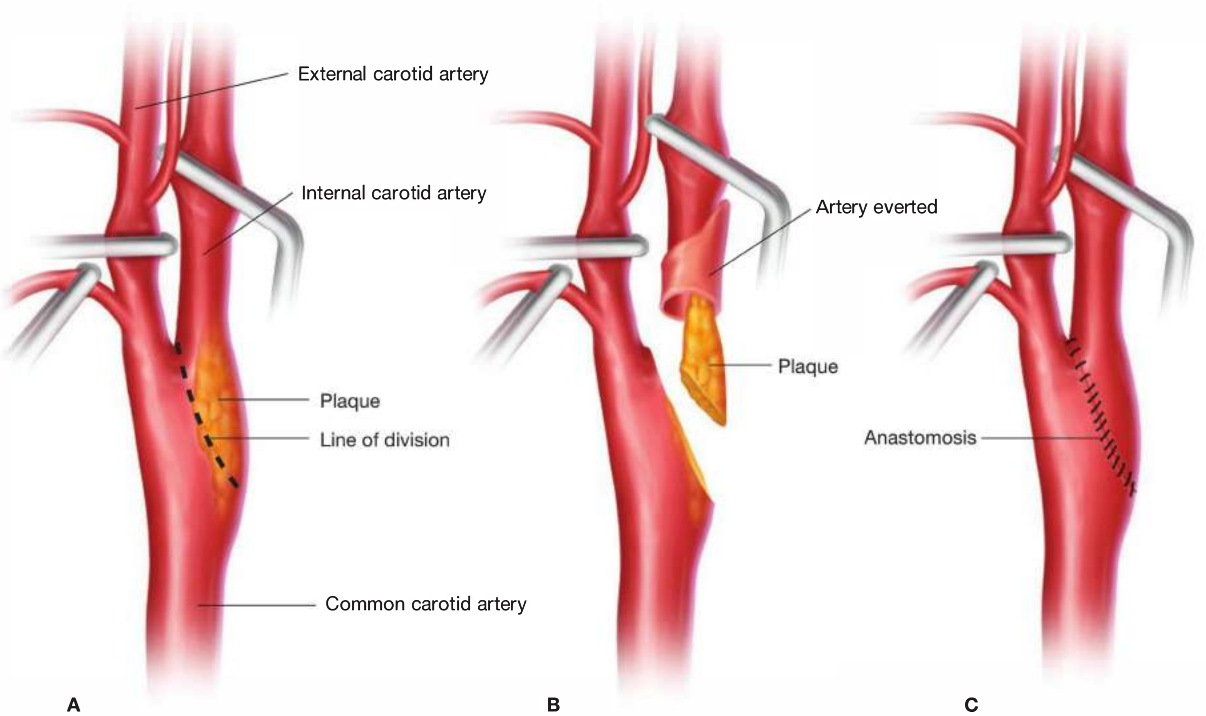

FIG 5 ● Carotid eversion endarterectomy. The ICA is divided from the CCA in an oblique line **(A)**. The divided ICA is everted on itself until the plaque endpoint is encountered and the plaque is removed from the ICA **(B)**. Following endarterectomy, the ICA is reverted and reattached to the CCA **(C)**.

CAROTID ARTERY INTERPOSITION BYPASS

Incision

- See section under Carotid Endarterectomy—Patch Angioplasty.

Dissection and Control of the Carotid Artery

- See section under Carotid Endarterectomy—Patch Angioplasty.
- Although reversed autogenous vein is the preferred conduit, when available, ePTFE provides a suitable alternative when necessary.[8]

Anastomosis

- The diseased segment of the carotid artery is resected. Commonly, the ECA is oversewn as well.
- End-to-end anastomoses are performed in standard fashion. Prior to completion, flushing maneuvers are done to evacuate particular matter or residual air (**FIG 6**).

Closure

- See section under Carotid Endarterectomy—Patch Angioplasty.

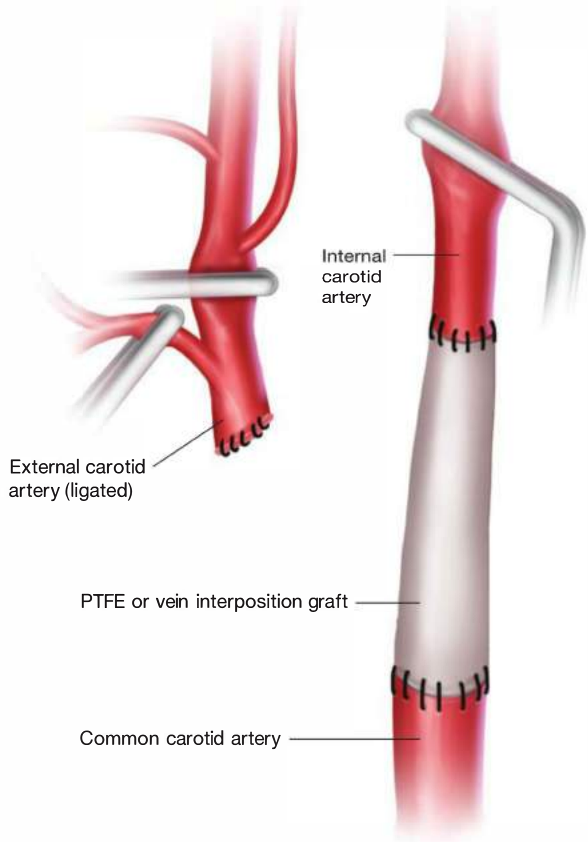

FIG 6 ● Carotid interposition graft. Following resection of the diseased segment, a prosthetic graft or a segment of reversed greater saphenous vein is used to bridge the CCA and ICA in an end-to-end fashion.

CAROTID ARTERY LIGATION (CAROTID STUMP SYNDROME)

Incision

- See section under Carotid Endarterectomy—Patch Angioplasty.

Dissection and Control of the Carotid Artery

- See section under Carotid Endarterectomy—Patch Angioplasty.

Endarterectomy

- The technique is similar to that for standard ICA endarterectomy, the difference being the arteriotomy being carried out on the distal CCA into the ECA (**FIG 7A**).
- The thrombosed ICA is resected, ideally in line with the common and external carotid arteriotomies. Closure is accomplished via patch angioplasty (**FIG 7B,C**).

Closure

- See section under Carotid Endarterectomy—Patch Angioplasty.

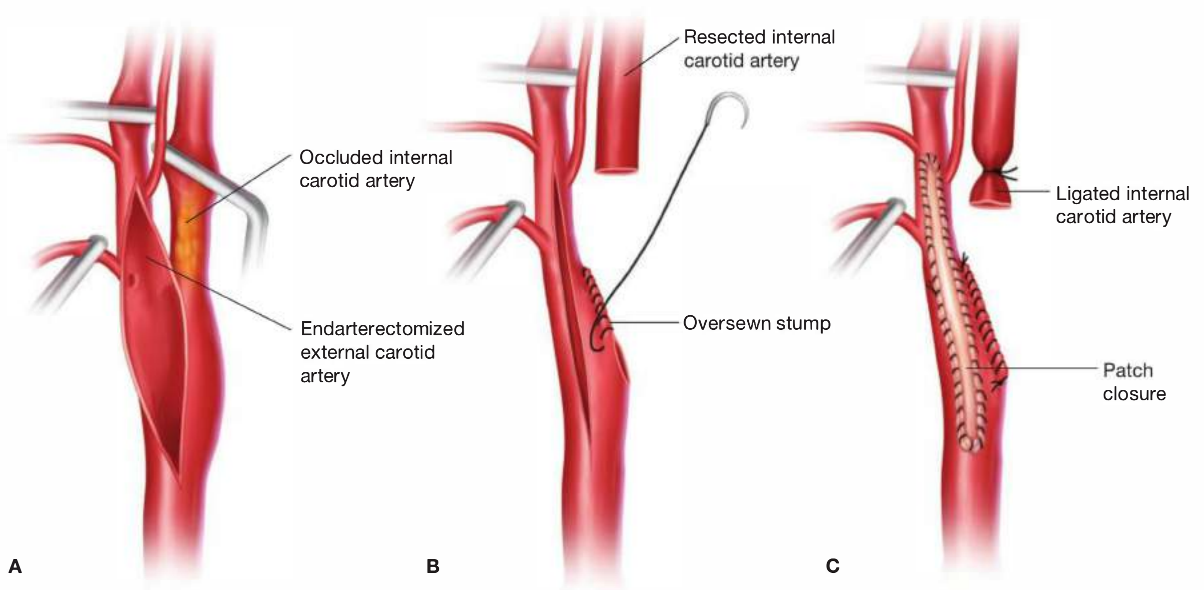

FIG 7 ● Carotid ligation. The occluded ICA is amputated and removed **(A)**, and the ICA stump is oversewn **(B)**. The plaque in the CCA and ECA is removed, and the arteriotomy is closed with a patch **(C)**.

PEARLS AND PITFALLS

Incision	▪ On table duplex scanning optimizes incision placement, particularly for transverse exposure.
Identifying the vagus nerve and hypoglossal nerve	▪ Vagus nerve is located posterolateral to the carotid artery, within the carotid sheath and between carotid artery and internal jugular vein. Hypoglossal nerve typically crosses ICA anteroinferiorly to posterosuperiorly. Following the ansa cervicalis will lead to hypoglossal nerve.
Clamping	▪ A "robin blue" hue is often seen in the distal ICA, which signifies a soft area for safe clamp placement.
Shunting	▪ Be prepared in all cases for potential shunt placement. This should be flushed and prepared on the back table prior to performing the arteriotomy.
Conventional endarterectomy	▪ Lavage the arterial lumen with heparinized saline to identify and remove luminal debris.
Eversion endarterectomy	▪ Use caution in patients with high bifurcation (difficulty visualizing and securing distal endpoint), those who require a shunt, or those with a small ICA. These procedures are best suited for patients with redundant ICAs.
Interposition bypass	▪ Use the anastomotic suture line to tack down distal residual plaque as necessary to prevent antegrade dissection.
Ensuring technical perfection	▪ A completion imaging study, either an on-table angiogram or a carotid duplex study, can help to ensure technical perfection prior to skin closure.
Closure	▪ If a closed suction drain is placed, it should be removed on postoperative day 1.

POSTOPERATIVE CARE

- Patients should be placed on continuous monitoring to assess for blood pressure lability. Patients generally are discharged on postoperative day 1 or 2.
- A postoperative duplex should be obtained within 30 days of intervention to assess the reconstruction, provide a new baseline for long-term surveillance, and monitor wound healing and plaque incorporation. Serial ultrasounds should be obtained to identify and manage restenosis, which most commonly occurs in the first 2 years following endarterectomy.

OUTCOMES

- The North American Symptomatic Carotid Endarterectomy Trial (NASCET) demonstrated the 30-day CEA stroke and death rate of 5.5% for symptomatic patients.[1]

- The Asymptomatic Carotid Atherosclerosis Study (ACAS) demonstrated a combined 30-day CEA stroke and death rate of 2.3%.[2]
- More recently, the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) demonstrated the 30-day stroke, death, or rate of myocardial infarction (MI) to be 5.4% in symptomatic patients and 3.6% in asymptomatic patients, and the 30-day death and stroke rates were found to be 3.2% in symptomatic patients and 1.4% in asymptomatic patients undergoing CEA. In the periprocedural period, there is a lower rate of stroke with CEA versus stenting (2.3% vs. 4.1%) but a higher rate of MI (2.3% vs. 1.1%). Mortality rates are similar.[9]

COMPLICATIONS

- Cervical hematoma
- Hemodynamic instability
- Cerebral hyperperfusion syndrome manifested by severe headache
- Cranial nerve palsy
- Stroke/MI
- Thrombosis (early)
- Recurrent stenosis (late)

Chapter 4

Carotid Surgery: Bifurcation Stenting with Distal Protection

Zhen S. Huang   Darren B. Schneider

DEFINITION

- Carotid artery stenosis was first successfully treated via percutaneous balloon angioplasty in 1977 by Mathias and colleagues.[1,2] This technique has evolved over time to include use of self-expanding nitinol stents and distal embolic protection devices (EPD). Carotid angioplasty and stenting (CAS) is indicated as an alternative to open carotid endarterectomy (CEA) in certain clinical scenarios where the patient's anatomy and/or physiology pose a greater risk for complications with CEA. However, these specific clinical conditions are not absolute and must be weighed against risks for endovascular intervention.
- Distal EPD
  - According to the 2011 ASA/ACCF/AHA/AANN/AANS/ACR/ASNR/CNS/SAIP/SCAI/SIR/SNIS/SVM/SVS guideline on the management of patients with extracranial carotid and vertebral artery disease, "EPD deployment during CAS can be beneficial to reduce the risk of stroke when the risk of vascular injury is low."[3]
  - A distal filter is placed in the internal carotid artery (ICA) distal to the lesion but below the skull base, with the purpose of capturing debris to prevent distal embolization during CAS (**FIG 1**). The target lesion must be crossed by the filter before deployment but this system allows for cerebral protection with maintenance of blood flow to the brain during subsequent steps of the procedure. The filter is mounted on the same wire used to perform CAS and after successful CAS, the filter is retrieved along with any captured debris.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be obtained prior to intervention and should include a detailed description of, if present, symptoms (quality, duration, etc.) that may be indicative of transient ischemic attacks (TIA) or prior stroke, past medical/surgical history (e.g., prior cerebrovascular disease/interventions), current medications (e.g., antiplatelet or anticoagulation medications), and social history (e.g., tobacco use).
- A comprehensive physical exam is mandatory and should include a complete vascular and neurologic/stroke evaluation. Vascular exam should note the presence of palpable femoral and distal lower extremity pulses and carotid bruits.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Initial carotid duplex ultrasound is obtained to evaluate the degree of stenosis and plaque morphology. Studies have highlighted a higher potential for embolism during CAS with hypoechoic lipid-containing plaque.[4]
- Angiographic imaging of the aortic arch and carotid and cerebral arterial vasculature must be obtained to aid in proper patient selection and procedural planning. This is accomplished through computed tomographic arteriography (CTA) (**FIG 2**), magnetic resonance arteriography (MRA), or catheter-based contrast arteriography.
  - Arch anatomy
    - Aortic arch morphology is variable and can change with advancing age. The arch anatomy can be divided into three types, dictated by the position of the innominate artery origin relative to two horizontal lines drawn across the apices of the outer and inner aortic arch curvatures (**FIG 3**).
    - Type I—the innominate origin arises at or above the horizontal plane of the outer arch curvature (**FIG 3A**)
    - Type II—the innominate origin arises in between the two horizontal planes of the outer and inner arch curvatures (**FIG 3B**)
    - Type III—the innominate origin lies below the horizontal plane of the inner arch curvature (**FIG 3C**)
    - The difficulty in gaining access to the carotid arteries increases from types I to III. There is an increase in angle acuity of the great vessel origins off the arch with increasing arch types that make wire/catheter guidance/exchange more difficult.
    - Bovine arch—congenital arch variations where the left common carotid artery (CCA) shares a common origin with the innominate artery (more frequent) or the left CCA branches off the innominate artery. In a pure bovine arch (extremely rare), the right subclavian, common carotid—both right and left—and left subclavian all derive from one common arterial trunk off the aortic arch.

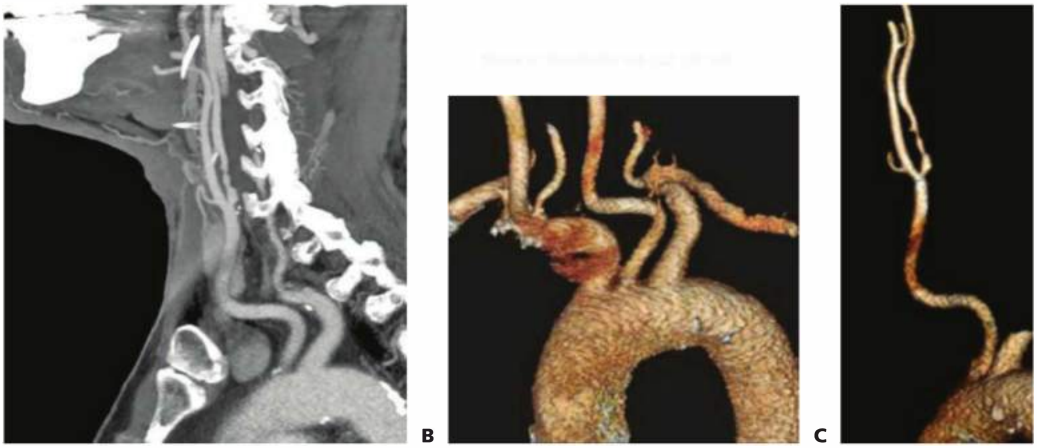

FIG 2 • CTA imaging of aortic arch and great vessels demonstrating a left ICA stenosis. **A.** Sagittal image. 3-D image reconstructions from the CTA images of the aortic arch **(B)** and cervical left carotid artery, demonstrating the left ICA stenosis **(C)**.

  - Shaggy aorta—when extensive aortic wall irregularities exist, there is a high risk for significant atheroembolism and thus, this may be a contraindication to CAS.
  - Eggshell aorta—with severe aortic wall calcification, there is increased risk of intimal disruption and difficulty of wire/catheter manipulation/advancement.
- Cerebral flow to both hemispheres is assessed to determine cerebral reserve.
- Carotid vessel size, tortuosity, and calcification—carotid artery diameter should be assessed to aid in determining device sizes. In addition, severe carotid circumferential calcification and vessel tortuosity may negatively impact procedural success (e.g., difficulty with inserting stent, placement of EPD in distal ICA) and may represent a contraindication to CAS.
- Preoperative brain imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is needed for symptomatic patients to document prior infarcts and to rule out preexisting hemorrhagic stroke prior to the initiation of the procedure.

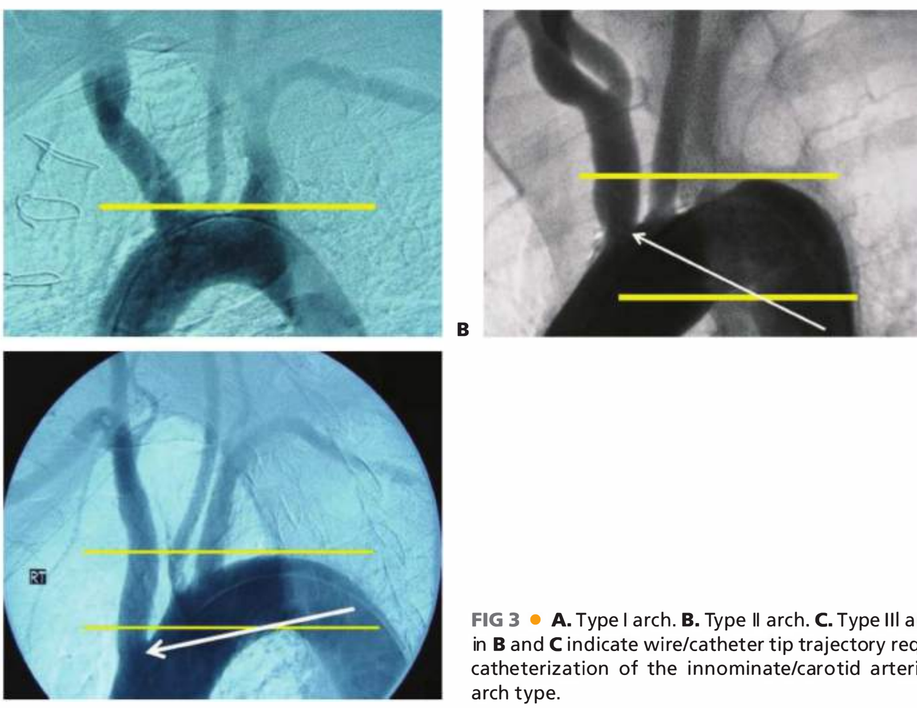

FIG 3 • **A.** Type I arch. **B.** Type II arch. **C.** Type III arch. (*White arrows* in **B** and **C** indicate wire/catheter tip trajectory required for selective catheterization of the innominate/carotid arteries within specific arch type.

SURGICAL MANAGEMENT

- The indications for any surgical intervention for carotid disease depend on the patient's clinical status (i.e., symptomatic or asymptomatic) and the characteristics of the carotid lesion.
- It has been widely accepted that appropriate candidates for CEA are symptomatic patients with carotid stenosis of 70% to 99% on noninvasive imaging and an anticipated perioperative risk of stroke or mortality of less than 6%. Benefit of intervention for symptomatic patients with lesser degrees of stenosis (50% to 69%) has also been shown but not for symptomatic patients with less than 50% carotid stenosis. CAS is an alternative to CEA for symptomatic patients meeting similar criteria along with anatomic and/or physiologic factors unfavorable for CEA (Table 1).[3,5]
- The recommendations/indications for CAS in asymptomatic patients are still issues for debate and no consensus exists. CAS may be considered for patients with asymptomatic ICA stenosis between 70% and 99%, but there are insufficient data to recommend CAS for primary therapy in asymptomatic patients. Therefore, these patients need to be addressed on a case-by-case basis with consideration of patient comorbidities and risks of CAS.
- The contraindications for CAS are predominantly related to aortic arch and carotid artery anatomic factors (Table 2).

Table 1: Anatomic and Physiologic Factors Favoring Carotid Angioplasty and Stenting

Anatomic Factor	Physiologic Factor
Reoperative neck (e.g., prior CEA, prior radical neck dissection)	Unstable angina
History of cervical radiation	Recent MI (<30 days)
High carotid lesion (above C2)	CHF with EF less than 30%
History of contralateral CEA with associated cranial nerve injury	Severe COPD (FEV_1 <30%)
Tracheostomy	
Contralateral carotid occlusion	

CEA, carotid endarterectomy; CHF, congestive heart failure; EF, ejection fraction; COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in 1 second.

Preoperative Planning

- Patients are initiated on antiplatelet therapy with aspirin 325 mg per day and clopidogrel 75 mg per day for 5 days prior to intervention. Alternatively, a clopidogrel loading dose of 300 mg can be administered 4 to 6 hours prior to the intervention.
- Antihypertensive medications can be held off the day of intervention to prevent contribution to the possible periprocedural hypotension.

Positioning

- The patient is placed in the supine position with adequate monitoring throughout the peri- and postprocedural period. Minimal monitoring includes continuous electrocardiogram (EKG), intraarterial blood pressure, and pulse oximetry. The patient's neurologic status must be frequently evaluated during the procedure via answering of simple questions and squeezing a plastic sound toy (e.g., rubber duck squeaky toy) in the contralateral hand.
- Intraarterial blood pressure monitoring is established usually via a radial arterial line.
- In order to maintain patient cooperation/comfort and frequent neurologic monitoring, minimal or no sedation is administered and only local anesthesia is infiltrated for the access site.

Table 2: Anatomic and Physiologic Factors Unfavorable for Carotid Angioplasty and Stenting

Anatomic Factor	Physiologic Factor
Severely angulated aortic arch (type III)	Ages 80 years and older
Shaggy/eggshell aorta	Contraindication to antiplatelet therapy
Severe aortoiliac occlusive disease	Severe renal dysfunction
Severe ICA calcification/tortuosity	
Severe carotid stenosis/string sign	
Unstable carotid plaque	
Fresh carotid thrombus	
Decreased cerebral reserve	

ICA, internal carotid artery.

PERCUTANEOUS RETROGRADE FEMORAL ARTERY ACCESS

- Obtain retrograde access via the common femoral artery (CFA) using a percutaneous micropuncture (21-gauge needle) system under ultrasound guidance. The CFA should be accessed immediately proximal to the femoral bifurcation in an area with minimal disease. The right CFA is the most convenient site for right-handed operators. The left CFA and brachial and radial arteries are alternative access sites. Ultimately, the safest and simplest access site to the target lesion should be employed.
- The micropuncture sheath is then exchanged for a 5-Fr introducer sheath over the 0.035-in access wire.

ARCH AORTOGRAPHY

- A guidewire is advanced into the aortic arch followed by a pigtail catheter. The pigtail catheter is positioned in the mid-ascending aorta and arch aortography is performed in a 45- to 60-degree left anterior oblique projection in order to adequately visualize the origin of the great vessels (**FIG 4**).

FIG 4 ● Arch aortography with pigtail catheter in midascending aorta.

SELECTIVE COMMON CAROTID CATHETERIZATION

- Before further manipulation of wires/catheters in the arch and great vessel origins, the patient is administered systemic heparin at 70 to 100 U/kg intravenously (IV) with a goal activated clotting time of 250 to 300 seconds.
- While maintaining the left anterior oblique (LAO) projection that allows for optimal visualization of the great vessels origins, a road map image is used to assist in selective catheterization of the CCA. The pigtail catheter is exchanged for the operator's catheter of choice.
- Multiple curved catheters are available (**FIG 5**), each with unique features that may be beneficial in different anatomies. However, frequently, selective common carotid catheterization can be accomplished with a combination of an angled or simple curved catheter and a floppy angled Glidewire™.

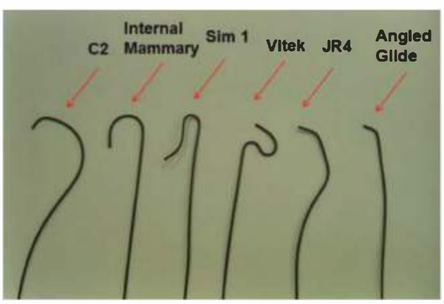

FIG 5 ● Various catheters can be used for selective catheterization of the common carotid.

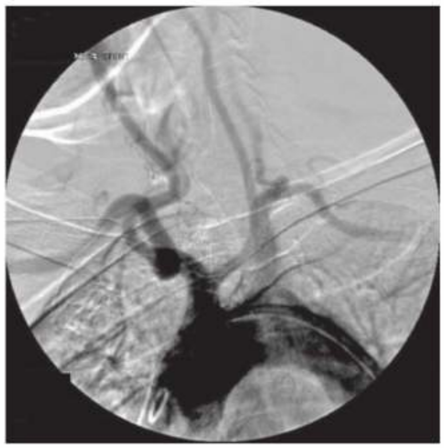

FIG 6 ● Type I arch with bovine configuration.

- However, a retroflexed or complex curved catheter (e.g., SIM or Vitek) may be necessary with a difficult arch anatomy such as type III arch or bovine configuration (**FIG 6**).
- After the Glidewire™ has accessed the common carotid (but taking extreme care not to advance past the bifurcation), the selective catheter is advanced over the Glidewire™ into the common carotid. Common carotid–selective angiograms are then performed typically in the anteroposterior, lateral, and oblique projections (more views are performed as needed) (**FIG 7**). Contralateral carotid arteriogram can be performed as well if necessary, but this usually is not performed during CAS of a unilateral lesion.
- Cerebral vessel angiography is then performed, typically in anteroposterior and lateral views (**FIG 8**). Additional views can be done if necessary.

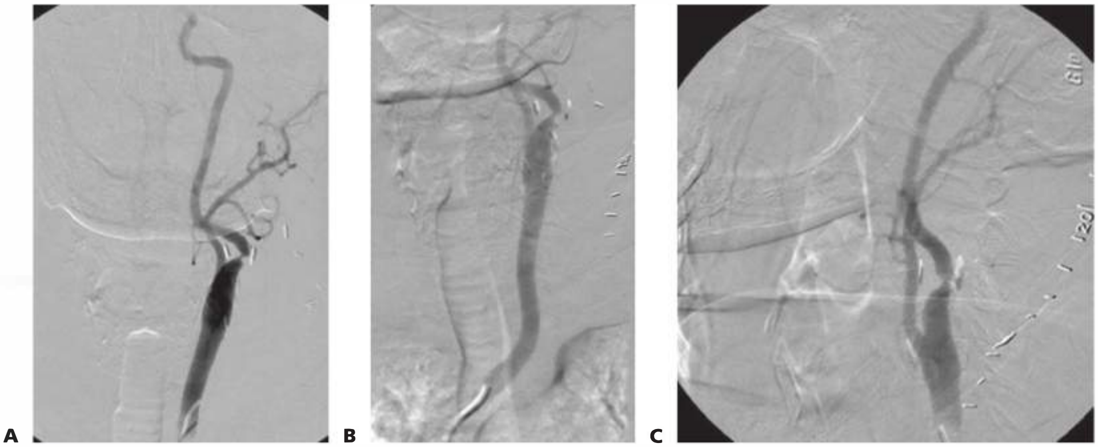

FIG 7 ● **A.** Selective left common carotid angiography, craniocaudal anteroposterior projection. **B.** Selective left common carotid angiography, oblique projection. **C.** Selective left common carotid angiography, lateral projection.

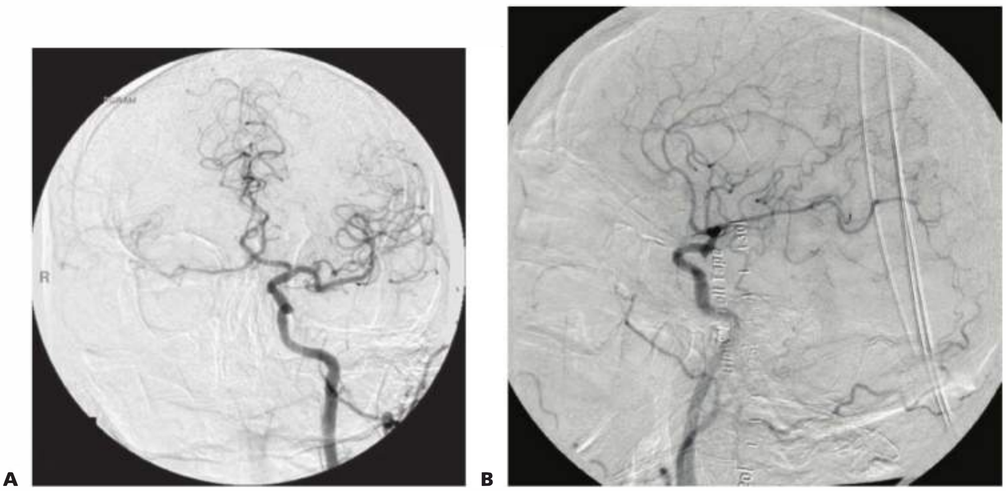

FIG 8 ● **A.** Cerebral vessel angiography via left CCA, craniocaudal anteroposterior (AP) projection. **B.** Cerebral vessel angiography via left CCA, lateral projection.

PLACEMENT OF GUIDING SHEATH

- After common carotid angiography is complete, it is recommended that the appropriate necessary equipment to complete the procedure is selected prior to further selective cannulation of the carotid vessels (e.g., access sheaths, wires, catheters, filter and filter retrieval system, pre- and postdilatation balloons, stent).
- In order to advance a sheath into the proximal common carotid, adequate exchange support is needed with a stiff guidewire. To achieve this, the selective catheter is carefully advanced over the floppy Glidewire™ into a branch of the external carotid artery (ECA). The floppy Glidewire™ is then exchanged for a stiff guidewire (e.g., long Amplatz™ Superstiff wire with floppy tip). Caution needs to be exercised to ensure the stiff wire tip does not inadvertently advance and potentially perforate the ECA branch. The catheter is then removed leaving the stiff wire in place in the ECA (FIG 9). If there is significant atherosclerotic stenosis involving the carotid bifurcation, or if the ECA is severely stenotic/occluded that prevents safe ECA access, an Amplatz™ wire with a 1-cm floppy tip may be left in the distal CCA.
- Once the supportive wire is in place, the groin introducer sheath is exchanged for a 6-Fr 90-cm sheath. The sheath is tracked over the stiff wire and placed into the distal CCA proximal to the bifurcation. It is imperative that sheath advancement is performed on live fluoroscopy, especially when negotiating the turn at the common carotid origin, to ensure the sheath is advancing appropriately.

FIG 9 ● Stiff wire within ECA to allow guiding sheath advancement into common carotid.

CROSSING THE LESION WITH DISTAL EMBOLIC PROTECTION DEVICES

- With the sheath in place and using a road map image, the ICA lesion is crossed with the 0.014-in wire component of the distal EPD. The distal EPD should be deployed in a straight portion of the distal ICA proximal to the petrous portion at skull base (**FIG 10**). It is important not to allow inadvertent migration of the EPD further distally for risk of injury to the intracranial ICA.

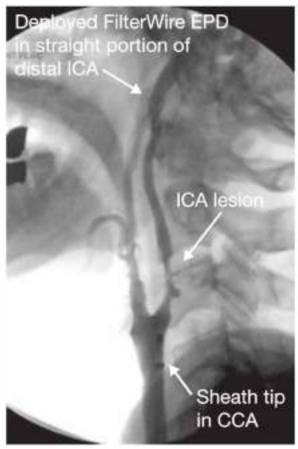

FIG 10 ● Distal EPD deployed in the distal ICA proximal to the petrous portion at skull base.

PREDILATATION WITH ANGIOPLASTY BALLOON

- After the distal EPD is in position, the carotid lesion is predilated with a 3- or 4-mm coronary angioplasty balloon up to nominal pressure (**FIG 11**). A higher inflation pressure may be required for heavily calcified lesions. Using a balloon length of 4 cm should help to minimize the risk of the balloon slipping ("watermelon seeding") during inflation. In addition, it is important to be extra vigilant in monitoring the patient's heart rate for possible bradycardia (or even asystole) during lesion predilatation and atropine must be readily available for administration before predilatation.

FIG 11 ● Left ICA lesion predilatation with 3-mm coronary balloon.

STENTING AND POSTDILATATION

- Following predilatation, a channel is created that will accommodate the advancement of the stent system. A self-expanding stent compatible with the distal EPD system is advanced over the wire and deployed under a road map. The distal and proximal stent landing zones must be at areas of normal vessel wall and this will frequently necessitate stenting across the ECA origin with the proximal landing zone in the distal CCA (**FIG 13**). After stent deployment, it is postdilated (usually using a 5 to 6 mm × 2 cm balloon), treating only the stented portions of the ICA to minimize injury to the native vessel wall (**FIG 12**) and over postdilatation is strictly avoided to reduce risks of embolization. During postdilatation, the patient's heart rate must be closely monitored for any changes and atropine should still be readily available.

FIG 12 ● Stent postdilatation with a 5 mm × 2 cm balloon.

EMBOLIC PROTECTION DEVICE RETRIEVAL AND COMPLETION ANGIOGRAM

- Completion angiography is performed to assess stent placement and poststent carotid antegrade flow before the distal EPD is removed (**FIG 13**). With normal flow through the stent and no filling defects present, the filter is retrieved. Slow flow and/or filling defects at the filter can be secondary to significant debris and this must be aspirated prior to retrieval. The EPD retrieval system is advanced carefully past the stent without engaging/catching on the stent. With extensive debris present in the filter, it is important not to fully recapture the filter in the retrieval catheter as this can extrude debris from the filter and cause distal embolization. Distal ICA vasospasm can be present as well and it is usually secondary to migration of EPD during the procedure. Typically, this is managed conservatively but with significant ICA spasm, nitroglycerin (50 to 200 μg) can be administered in small doses directly intraarterially in the ICA.

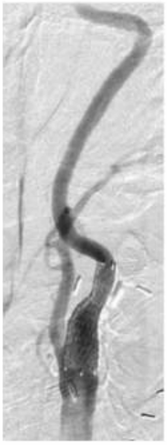

FIG 13 ● Completion angiography is performed to assess stent placement and poststent carotid antegrade flow. Note that this stent is placed across the ECA origin.

ACCESS HEMOSTASIS

- The femoral access arterial puncture can be closed using standard techniques either with a closure device or by direct manual compression. We prefer to use a closure device and do not routinely reverse heparin anticoagulation with protamine. For brachial artery access, direct manual compression is the preferred method for achieving hemostasis.

PEARLS AND PITFALLS

Selective common carotid catherization	■ Tortuous aortic arch/great vessel anatomy may require additional manipulation with various retroflexed catheters in order to select the common carotid. However, with increasing manipulation, there is a greater risk of embolization/aortic injury. Therefore, aortic arch/great vessel anatomy should be analyzed preoperatively and, when indicated, suitable alternative plans should be prepared if the initial method proves unsuccessful. ■ An extremely diseased aortic arch may be a relative contraindication to CAS.
Placement of guiding sheath	■ When the ECA is occluded, a supportive guidewire cannot be placed to allow tracking of the sheath and an alternative method is needed. Alternatively, an Amplatz guidewire with a 1-cm floppy tip in the distal CCA may provide sufficient support for sheath placement. Shuttle systems that permit telescoping the sheath into the CCA over a guidewire and catheter assembly are another alternative.
Crossing the lesion with EPD	■ Difficulty crossing the lesion can be addressed by changing the shape of the crossing wire tip or using a directional catheter. Additionally, changing the patient's head/neck position may make a vessel less angulated. ■ Certain EPD such as the Nav-6 (Abbott Vascular, Abbott Park, IL) and Spider (Covidien, Plymouth, MN) are introduced over a wire that is introduced independently before the filter. Introduction of the independent wire may facilitate subsequent introduction of the filter across a tightly stenotic lesion or a lesion with an acute entry angle. ■ A "buddy wire" (additional 0.014-in wire) can also be used to provide extra support and facilitate crossing a difficult lesion. ■ If the crossing profile of the EPD is too large to cross the stenotic lesion, the stenotic lesion can also be predilated with a 2.5-mm balloon in order to create a channel large enough for EPD. However, dilating the lesion without an EPD in place increases the risk of distal embolization.
Distal ICA spasm	■ Usually caused by distal EPD and resolves after EPD and wire are removed. ■ Small doses of nitroglycerin administered directly to carotid may aid in resolution.
Occlusion of flow proximal to EPD after stent placement	■ Distal ICA filter may be full of debris causing slow flow or ICA occlusion. The debris should be aspirated from the filter using an aspiration catheter and repeat angiogram is performed after to confirm return of flow prior to EPD retrieval. ■ If it is determined that occlusion is due to acute stent thrombosis then immediate conversion to open exploration, stent removal, and formal CEA may be necessary. Preparations for carotid stenting should always include this possibility.
Distal embolization with neurologic symptoms and/or intracranial arterial occlusion	■ Neurorescue techniques are used to treat distal embolization or thrombosis, including the following: ■ Catheter-directed thrombolysis with tissue plasminogen activator (tPA) ■ Mechanical thrombolysis with aspiration ■ Glycoprotein (GP) IIa/IIIb inhibitor administration ■ Direct removal with snare (intraarterial) ■ Direct balloon angioplasty to restore a lumen Note: Intracranial neurorescue techniques should be performed by physicians with appropriate experience and training.

POSTOPERATIVE CARE

- Neurologic status is immediately evaluated after completion of the procedure and continuous invasive blood pressure monitoring and pulse oximetry are maintained. Typically, CAS patients are observed in a monitored step-down unit overnight.
- Goal systolic blood pressures should be based on preoperative measurements. Vasopressor and/or inotropic support may be required to compensate for hypotension and/or bradycardia likely due to carotid sinus distension related to the procedure until the carotid sinus adapts to the presence of the stent. Other causes of hypotension need to be excluded prior to attributing the cause to angioplasty/stenting alone. Conversely, antihypertensives should be used as needed to prevent hypertension and potential cerebral hyperperfusion.
- The patient needs to remain on bed rest in the supine position for 4 to 6 hours after access site hemostasis is achieved. The head of the bed can be inclined to a maximum 30 degrees to promote patient comfort and respiratory function. Afterward, the patient can ambulate as tolerated.
- Immediate head and neck imaging along with neurology consultation are mandatory if the patient experiences a postoperative neurologic event.
- Antiplatelet therapy with clopidogrel should be continued for at least 1 month post-CAS, whereas aspirin is continued indefinitely.

OUTCOMES

- Studies prior to year 2000 failed to define the role of CAS in treating carotid artery disease due to numerous factors. More recent randomized controlled trials (RCTs) were performed in order to elucidate CAS' role in carotid disease, namely as a noninferior alternative to CEA.

- The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial[6] randomized symptomatic patients with 50% or greater carotid stenosis or asymptomatic patients with 80% or greater stenosis with comorbidities that increased their risk of surgery to receive either CEA or CAS. For the CAS patients, they all had self-expandable nitinol stents (S.M.A.R.T. or PRECISE; Cordis, Miami Lakes, FL) placed with EPD (Angioguard or Angioguard XP; Cordis, Miami Lakes, FL). The primary endpoint was composite incidence of death, stroke, or myocardial infarction (MI) within 30 days postprocedure or death or ipsilateral stroke between 31 days and 1 year. Only 334 patients were randomized—167 to CEA and 167 to CAS (trial stopped early due to poor enrollment). No significant difference in the primary composite endpoint rate was detected in the periprocedural period (30 days) for CAS compared to CEA. However, 1-year primary composite endpoint rate was lower in CAS compared to CEA (12.2% vs. 20.1%; *P* = .004) with a more pronounced difference in asymptomatic (9.9% in CAS vs. 21.5% in CEA; *P* = .02) than in symptomatic patients (16.8% in CAS versus 16.5% in CEA; *P* = .95). This difference vanished in long-term follow-up and at 3 years, the major secondary endpoint (primary endpoint plus death or ipsilateral stroke 1 to 3 years) cumulative incidences were 24.6% for CAS vs. 26.9% for CEA; *P* = .71.[7] Thus, the SAPPHIRE authors concluded that CAS with EPD was not inferior to CEA in patients with severe carotid artery stenosis and increased surgical risk.
- However, these results were not mirrored in two large European multicenter RCTs—Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE)[8] and Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis (EVA-3S)[9] trials. Both of these studies failed to show noninferiority of CAS compared to CEA in their respective study populations. In SPACE, the primary endpoint (rate of death or ipsilateral ischemic stroke 30 days postprocedure) was 6.84% in CAS and 6.34% in CEA (absolute difference 0.51%, 90% CI −1.89% to 2.91%; noninferiority *P* = .09). In EVA-3S, the results demonstrated greater rates of stroke and death in the CAS group as compared to the CEA group: 30-day incidence of stroke or death was 9.6% in CAS (95% CI, 6.4 to 14.0) and 3.9% in CEA (95% CI, 2.0 to 7.2); the relative risk of any stroke or death after CAS as compared with CEA was 2.5 (95% CI, 1.2 to 5.1). At 6 months, the incidence of any stroke or death was 11.7% after CAS and 6.1% after CEA (*P* = .02). However, long-term data at 4 years from EVA-3S did not demonstrate significant differences in the risk of any stroke or death in between both CAS and CEA; the hazard ratio (HR) was 1.39 (0.96 to 2.00; *P* = .08).[10] The authors interpreted these results to "suggest that carotid stenting is as effective as carotid endarterectomy for middle-term prevention of ipsilateral stroke, but the safety of carotid stenting needs to be improved before it can be used as an alternative to carotid endarterectomy in patients with symptomatic carotid stenosis."
- A more recent international multicenter RCT, the International Carotid Stenting Study (ICSS), demonstrated that CEA was safer than CAS as treatment for patients with symptomatic carotid stenosis of 50% or greater (enrolled 1,713 patients; CAS, n = 855; CEA, n = 858).[11] The primary composite endpoint, 120-day incidence of stroke, death, or MI was higher in CAS compared to CEA (8.5% vs. 5.2%; HR, 1.69; 95% CI, 0.16 to 2.45; *P* = .006). The adverse events occurring with the 30-day postprocedure period accounted for the majority observed at 120 days where the cumulative incidence of stroke, death, and MI was 7.4% in CAS compared to 4.0% in CEA (*P* = .003). The authors concluded that CEA should remain the treatment of choice for symptomatic carotid stenosis patients that are suitable for surgery while awaiting the long-term follow-up data of ICSS.
- The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) is a U.S. trial that is the most recent and largest RCT to compare the efficacy between CAS and CEA in standard-risk patients.[12] Two thousand and five hundred two patients with asymptomatic carotid stenosis of 70% or greater (based on ultrasound criteria) or symptomatic carotid stenosis of 50% or greater (based on angiographic North American Symptomatic Carotid Endarterectomy Trial criteria) were randomized to either CAS (n = 1,262; RX Acculink stent; Carotid Stent System, Abbott Vascular, Abbott Park, IL) and a distal EPD (RX Accunet Embolic Protection System, Abbott Vascular, Abbott Park, IL) or CEA (n = 1,240). The primary composite endpoint was stroke, death, or MI during the periprocedural period or any ipsilateral stroke within 4 years. During the periprocedural period, the primary endpoint incidence was similar with CAS and CEA (5.2% and 4.5%, respectively; HR for stenting 1.18; 95% CI, 0.82 to 1.68; *P* = .38). However, the rates of individual endpoints differed between CAS and CEA: greater risk of stroke in CAS (4.1% vs. 2.3%, respectively; *P* = .01), greater risk of MI in CEA (1.1% vs. 2.3%, respectively; *P* = .03), no difference in death (0.7% vs. 0.3%, respectively; *P* = .18). The periprocedural risk of stroke or death was higher after CAS for symptomatic patients (6.0% vs. 3.2%; *P* = .02). There was no significant difference in the estimated 4-year rate of the primary endpoint between CAS and CEA (7.2% vs. 6.8%, respectively; HR, 1.11; *P* = .51; 95% CI, 0.81 to 1.51). CREST also demonstrated an interaction between age and treatment efficacy (*P* = .02) where CAS tended to show greater efficacy at younger than 70 years of age and CEA at older than 70 years of age.
- Overall, CAS as a noninferior or equivalent alternative treatment compared to CEA has not been definitively established and further studies are needed.

COMPLICATIONS

- Postoperative complications
  - Stroke—the incidence of stroke is higher with CAS than CEA.[11] Risk factors include advanced age, symptomatic carotid stenosis, and complex anatomy. Postoperative stroke needs to be addressed immediately with full neurologic evaluation and potential intervention.
  - Hypotension—frequently observed post-CAS; however, it usually will resolve spontaneously. Patients may require transient blood pressure support with vasopressors/volume.

- Cerebral hyperperfusion syndrome—may occur within the first week post-CAS and is usually associated with poorly managed underlying hypertension. It presents as a unilateral headache and can progress to seizures, intracranial hemorrhage, and/or coma. Head CT is obtained and focal cerebral edema may be observed. The treatment is aggressive blood pressure management.
- MI—cardiac complications, namely MI, may occur during the periprocedural period for CAS. This is likely due to the typically high-risk patient population selected for CAS given that most are poor candidates for CEA.
- Access site complications—the most common access site complications that are inherent to endovascular procedures are hematoma, pseudoaneurysm, retroperitoneal hematoma, and arteriovenous fistula. To minimize the risk for these complications, we recommend direct visualization of the access vessel under ultrasound and using a micropuncture access system. In addition, proper use of vessel arteriotomy closure devices and/or manual vessel compression is mandatory to reduce the risk for these complications.
- Stent restenosis—restenosis will occur in any current stent placed in the body and can be managed with reintervention as needed.

Chapter 5

Carotid Surgery: Distal Exposure and Control Techniques and Complication Management

Cheong J. Lee

DEFINITION

- The carotid artery typically bifurcates at the level of the C3-C4 cervical spine. High carotid bifurcations and lesions that extend to the C1-C2 level pose technical challenges that may increase perioperative risk of stroke and cranial nerve injury. Ideally, the need for high access in carotid surgery should be anticipated preoperatively, with familiarity of the anatomy and exposure necessary for distal carotid control.

PATIENT HISTORY AND PHYSICAL FINDINGS

- As with any medical therapy, the clinician must first clearly define the goals of treatment and thoroughly review the operative risk with the patient.
- Optimal medical therapy must be instituted prior to intervention (e.g., antiplatelet agent, statin, beta-blocker).
- Patients with hostile neck anatomy, such as those with history of high-dose neck radiation or severe systemic comorbidities contraindicating general or cervical block anesthesia, should be offered carotid angioplasty and stenting (CAS) as an alternative procedure.
- Patients with prior contralateral carotid revascularization procedures should have laryngeal, hypoglossal, and glossopharyngeal nerve function documented prior to ipsilateral dissection and exposure. When evidence of prior injury to CN IX, X, or XII is evident, CAS should be considered as an alternative. If CAS is not feasible under these circumstances, the potential need for tracheostomy to manage postoperative airway obstruction should be reviewed with the patient.
- Although duplex scanning provides accurate and reproducible assessment of the presence and severity of carotid stenosis, precise anatomic detail required for surgical planning is optimally obtained from computed tomographic angiography (CTA) or magnetic resonance arteriography (MRA). Localization of the carotid bifurcation in regard to cervical landmarks, as well as the distal extent of internal carotid artery (ICA) disease, is best assessed by CTA or MRA (**FIG 1**).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Current indications for carotid endarterectomy were reviewed in Part 6, Chapter 3.[1–3]
- In recent years, CTA and MRA have assumed preeminent roles in carotid intervention planning. Improved resolution has enabled highly accurate characterization of plaque morphology, which may provide useful guidance regarding plaque vulnerability during operative manipulation.
- MRA and CTA also provide essential information regarding potential collateral arterial flow through the circle of Willis and the need for adjuvant maneuvers such as shunt placement during carotid revascularization (**FIG 2**).

SURGICAL MANAGEMENT

Preoperative Planning for Distal Cervical Carotid Exposure

- Knowledge of patient-specific cervical anatomy is essential to successful management of distal carotid disease. When recognized as necessary, specifying nasotracheal, rather than orotracheal, intubation for general endotracheal

FIG 1 ● Reformatted CTA of a carotid body tumor extending to the distal ICA at the C1 cervical spine level.

FIG 2 ● Rendered CTA demonstrating incompetency of the circle of Willis.

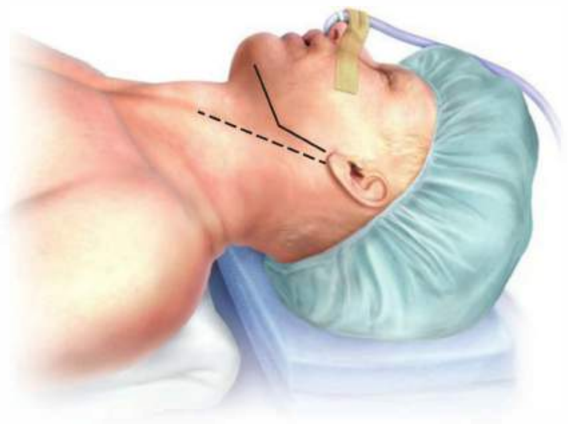

FIG 3 ● Nasotracheal intubation facilitates exposures of the distal ICA by opening the angle between the mastoid process and the mandible *(black lines)*.

anesthesia is a simple and highly effective maneuver to improve exposure. Nasotracheal intubation allows the mouth to stay closed during surgery, providing more room between the ramus of the mandible and mastoid process for distal dissection.

- Temporomandibular subluxation may further advantage carotid exposure cephalad to the C2 cervical spine. Subluxation of the ipsilateral mandibular condyle, performed via intraoral wiring, facilitates exposure from infratemporal ICA to the skull base. Subluxation is distinguished from dislocation, which is more injurious and can potentiate long-term temporomandibular joint pain syndromes.

Positioning

- The patient is positioned supine, with the head extended and rotated away from the operative site. Shoulder rolls and shays are placed to stabilize the neck and optimize extension. The nasotracheal tube is secured over the head (**FIG 3**).
- Arms are tucked to the patient's side to allow the operator and the assistant to maneuver and stand comfortably. This position also facilitates C-arm positioning when needed.
- The patient is placed in the "beach chair" position to limit venous hypertension (**FIG 4**).

FIG 4 ● Patient in the "beach chair" position.

TECHNIQUES

ANTERIOR APPROACH TO THE DISTAL INTERNAL CAROTID ARTERY

Incision

- A vertical, rather than transverse, cervical incision is recommended for optimal distal ICA access (**FIG 5**).
- Standard exposure of the carotid artery in the sheath was previously described in Part 6, Chapter 3.

FIG 5 ● Anatomic landmarks for carotid exposures include the mastoid process, the angle of the mandible, and the sternal notch. Skin incision for carotid exposures are placed anterior to the sternocleidomastoid muscle (SM) *(solid line)*. If distal exposure is anticipated, the incision can be carried in front of the ear *(dotted line)*.

Exposure of the Internal Carotid Artery Distal to the Bifurcation

- Key structures that lie superior to the carotid bifurcation are the posterior belly of the digastric muscle, the hypoglossal nerve, crossing veins from the sternocleidomastoid muscle to the internal jugular vein, and muscular arterioles of the posterior branches of the external carotid artery (ECA) (**FIG 6**).
- The hypoglossal nerve is identified safely using a posterolateral to anteromedial dissection of the ICA. Moving cephalad, the hypoglossal nerve is dissected free from the medial surface of the digastric muscle. Crossing artery and veins of the SCM often tether this nerve closer to the bifurcation. Meticulous identification and controlled division of these tethering vessels will enable mobilization of the nerve. Tracing the course of the descending branch of the ansa cervicalis back to the hypoglossal itself provides positive confirmation of the location and course of the nerve (**FIG 7**).
- The posterior digastric muscle belly may be retracted or divided as required for exposure, following release of the adherent hypoglossal nerve.
- Additional cephalad exposure at this juncture requires division of the occipital branch of the ECA. This further releases the hypoglossal nerve. This maneuver also requires division of the styloid musculature (styloglossus, stylopharyngeus).
- Continued cephalad dissection exposes the glossopharyngeal nerve, seen as a single or double trunk crossing the ICA anteriorly and coursing posterior to the external carotid. Care must be taken in separating the hypoglossal and glossopharyngeal nerves, as small motor

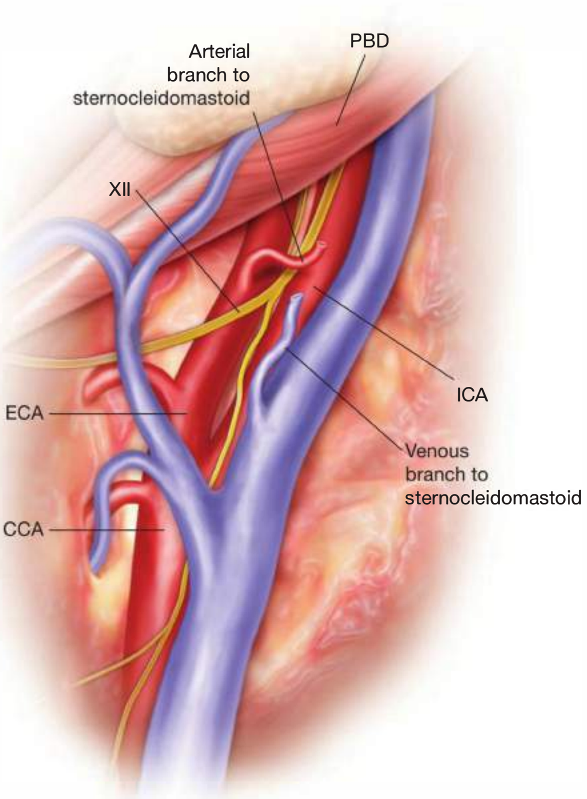

FIG 6 ● Once the carotid sheath is entered, exposure of the distal ICA from an anterior approach begins with identification and dissection of the hypoglossal nerve (XII), the posterior belly of the digastric muscle (PBD), and the crossing veins and arteries to the sternocleidomastoid muscle.

FIG 7 ● Following division of the digastric muscle and the crossing muscular vein and arteries to the sternocleidomastoid, the descending ansa cervicalis nerve (DAC) can be ligated to further mobilize the hypoglossal nerve (XII). To further facilitate hypoglossal mobilization, the occipital artery coming off the ECA has been ligated and divided.

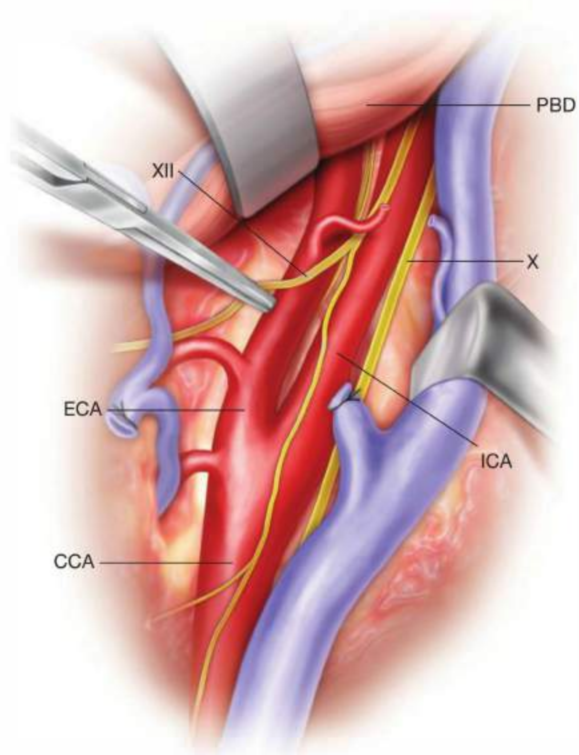

FIG 8 ● Mobilization of the hypoglossal nerve (XII) allows exposure of the distal ICA.

fibers exiting the vagus nerve also course in this plane. Damage to these nerves or the glossopharyngeal can cause swallowing dysfunction. Classically, injury to the glossopharyngeal nerve in this region may impair the ability of the soft palate to rise sufficiently with swallowing to prevent nasopharyngeal liquid reflux.

- When these steps are safely completed, the ICA may be adequately exposed for reconstruction up to the level of C2 (**FIG 8**). Further exposure to the level of C1 following this course requires styloidectomy and/or preoperative mandibular subluxation.
- Distal dissection may also be facilitated by mobilization of the parotid gland and facial nerve. This is most safely accomplished with assistance from otolaryngologists or craniomaxillofacial surgeon. To provide this method of exposure, the skin incision is carried cephalad anterior to the ear (**FIG 9**). This enables mobilization of the parotid gland superiorly and medially.
- The parotid fascia is entered and the branches of the facial nerve are dissected, identified, and protected before dividing the posterior belly of the digastric muscle.
- Care is again taken to identify the glossopharyngeal nerve and the motor fibers of the vagus nerve (**FIG 10**).
- Distal control of the ICA at high C1-C2 level may require specialized instrumentation. Small detachable occluding clamps (such as the Heifetz or Yasargil clips) may provide improved exposure compared to traditional "handled" vascular clamps in this region. When used, however,

FIG 9 ● If further exposure of the ICA is required and mandibular subluxation is not feasible, incision can be carried in front of the ear for mobilization of the parotid gland.

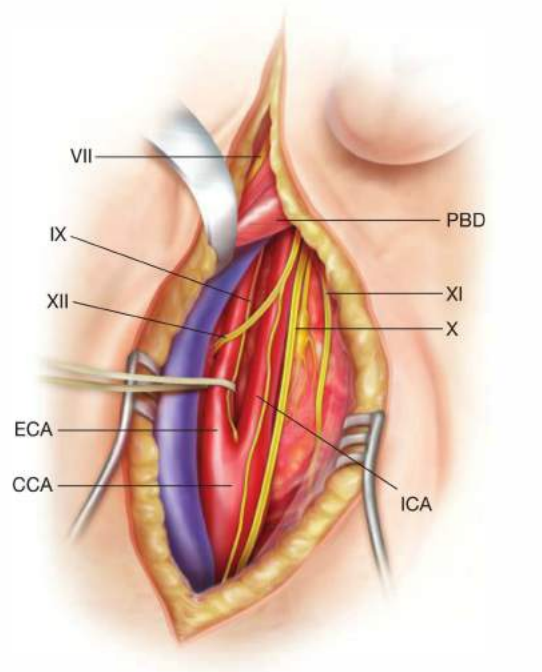

FIG 10 ● Once the parotid fascia is entered, the branches of the facial nerve (VII) are identified followed by the division of the posterior belly of the digastric muscle (PBD). Dissection is then carried anterior to the ICA from the hypoglossal nerve (XII) distally to identify the glossopharyngeal nerve (IX). Motor fibers from the vagus nerve (X) are carefully identified and preserved.

care must be taken to avoid clamp dislodgement in this crowded and moving field, which when it does happen usually does so at the maximally inconvenient time.

- As an alternative to distal clamp control, short occluding intraluminal catheters can be used, such as a #2 Fogarty embolectomy catheter with stopcock. Extreme care must be taken in positioning and deploying embolectomy balloons in this area, however, as inflation within the petrous portion or overinflation in any region may precipitate dissection, arterial rupture, or thrombosis. Only the lowest amount of inflation required to prevent back-bleeding should be used. The carotid artery is thin-walled at this level and easily traumatized by balloon inflation. Late complications also include pseudoaneurysm or arteriovenous fistula formation. The inflated catheter should be secured to prevent its migration. Stay sutures may be placed in the distal carotid to maintain access should control be lost due to reflux of the balloon from the distal artery or balloon puncture during suture closure of the anastomosis.

RETROJUGULAR APPROACH TO THE DISTAL INTERNAL CAROTID ARTERY

Retrojugular Dissection

- A third approach to the distal ICA is provided by retrojugular access. The internal jugular (IJ) vein angles anteriorly as it ascends from the base of the neck to the base of the skull and overlies the distal ICA as the artery approaches the transverse process of C1.
- Using the posterior approach, dissecting behind the IJ vein, obviates the need for hypoglossal exposure and relocation, as that nerve passes anteriorly over the ICA.

Identification of the Spinal Accessory Nerve

- The retrojugular dissection uses the same incisions as other approaches to the distal internal carotid, with the incision made vertically, anterior to the SCM muscle.
- Using this approach, it is essential to identify the spinal accessory nerve where it exits 2 to 3 cm below the edge of the mastoid process, anterior to the SCM. The SCM is fully mobilized to facilitate this exposure.
- Once the spinal accessory nerve is identified and isolated, the IJ vein is dissected along its posterior border. The vagus nerve is identified and reflected anteriorly. With the vein and vagus nerve mobilized anteriorly, the hypoglossal nerve remains anterior to the distal ICA (**FIG 11**).

Identification of the Superior Laryngeal Nerve

- In the retrojugular space, the ICA can be dissected along its posterior lateral wall superiorly whereupon the superior laryngeal nerve will be encountered exiting the vagus nerve and looping around the distal ICA. Often, the superior cervical ganglion can be identified just lateral to this looping point (**FIG 12**).
- For added exposure, the nerve is carefully lifted from the ICA adventitia.

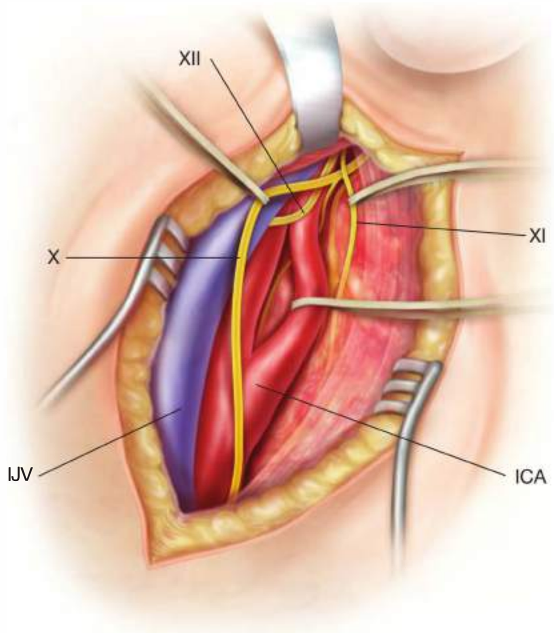

FIG 11 ● Retrojugular exposure of the ICA: Dissection is carried behind the IJ vein and the vagus nerve (X) mobilized anterior to the ICA. Care is taken in identifying the spinal accessory nerve (XI) at the superior aspect of the dissection. This approach avoids mobilization of the hypoglossal nerve (XII) as the plane of dissection remains posterior to the nerve.

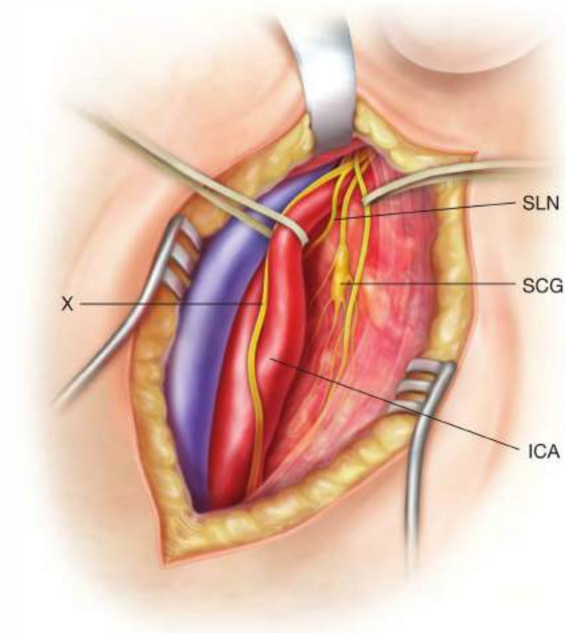

FIG 12 ● At the distal aspect of this retrojugular space, the ICA will be looped by the super laryngeal nerve (SLN) as it comes off the vagus nerve (X). Often, the superior cervical ganglion (SCG) serves as a landmark for where the SLN emanates.

PEARLS AND PITFALLS

Indications	■ Make note of significant radiation or surgery to the neck, which may inform the choice of procedure (surgery vs. stent). ■ Make certain the patient's cranial nerve status is documented, especially in the setting of prior neck operations.
Imaging	■ Although duplex imaging alone is sufficient to plan most routine carotid surgery, cross-sectional imaging (CTA/MRA) provides essential guidance for complex exposures and reconstructive techniques. ■ The status of the circle of Willis should be defined in the course of preoperative planning.
Technique	■ For lesions extending to the C1-C2 cervical spine, consider at a minimum nasotracheal intubation. ■ In extreme situations, mandibular subluxation may provide critical additional degrees of freedom. ■ Mandibular dislocation is not recommended and should not be performed to assist carotid surgery. ■ *Knowledge of cranial nerve anatomy is the most important determinant of success.* ■ Any neural tissue crossing anterior to the carotid bifurcation and the ICA should *not* be divided. ■ Mobilization of diseased arterial segments, including the carotid bifurcation, should be avoided or minimized prior to heparinization. ■ Anterior distal ICA exposure is dependent on the extent to which the hypoglossal nerve can be safely mobilized. ■ Posterior, retrojugular exposure requires early identification of the spinal accessory nerve and anterior reflection of the vagus nerves to visualize the superior laryngeal nerve encircling the distal internal carotid. ■ Balloon occlusion may facilitate far distal carotid control, but overadvancement and overinflation are real risks that must be considered. Placement of stay sutures will facilitate future control maneuvers should the catheter become dislodged.

POSTOPERATIVE CARE

- Following carotid revascularization, the immediate postoperative care is focused on close neurologic surveillance. Patients are recovered typically in an intensive care unit or monitored setting to facilitate ready identification of evolving neurologic deficits.
- Careful blood pressure monitoring and management is also essential. Following carotid revascularization, patients need to avoid the extremes of blood pressure, which may elicit hemodynamic stroke and intracerebral hemorrhage.
- Immediate postoperative (<24 hours) neurologic deficits should be assumed to be thromboembolic in nature, most commonly associated with a technical (surgical) error. Further imaging studies are unlikely to alter decision making and should not delay immediate reoperation. Neurologic deficits arising later in the postoperative period (>24 hours) may be due to intracranial hemorrhage; in these cases, computed tomography (CT) or magnetic resonance (MR) imaging may assist the decision-making process and should be considered when etiologic circumstances are less certain.
- Bleeding complications following carotid surgery are rare but potentially serious or fatal. These may occur during the first several hours after surgery or even later, particularly in patients resuming anticoagulation therapy for existing conditions early in the postoperative period. Recognition and expeditious control of the airway is of utmost importance as a wound hematoma develops, as cord and airway edema rapidly worsen in response to reduced venous and lymphatic drainage. Reopening a carotid incision prior to anesthetic induction may facilitate emergency endotracheal intubation; however, this dramatic maneuver is best performed in a controlled environment with resuscitation equipment available should complications ensue. Ideally, preparations are made for wound decompression as endotracheal intubation is being attempted, with the wound being opened as a last step maneuver prior to emergency cricothyroidotomy. Cord edema in these circumstances may be profound, however, and visualization may not improve sufficiently after hematoma evacuation to enable orotracheal or nasotracheal intubation. Therefore, cricothyroidotomy may become necessary in extreme circumstances, and all carotid surgeons should be facile in this maneuver as a matter of course.

OUTCOMES

- Although carotid endarterectomy is a well-established technique continually refined over several decades, good outcomes are not limited to regional centers of excellence. Data provided to the American Board of Surgery regarding surgical case experience in the 12 months preceding application for recertification in vascular surgery, carotid endarterectomy is recorded as one of the most common procedures performed by contemporary vascular surgeons. A recent query of the Nationwide Inpatient Sample (NIS) identified 259,080 carotid revascularization procedures performed during 2003 and 2004. Although the study examined and compared outcomes of both carotid endarterectomy and carotid artery stenting, endarterectomy outcomes alone demonstrated an impressive overall stroke rate of 0.88% and operative mortality rate of 0.39%.[4] Similarly, data prospectively obtained from National Surgical Quality Improvement Program (NSQIP) participation reviewed 13,622 carotid endarterectomies performed between 2000 and 2003 at 123 Veterans Affairs and 14 private sector academic medical centers demonstrated a combined stroke and death rate of 3.4%.[5]
- Data describing outcome of distal (base of skull) carotid revascularizations is based on more limited, institution-specific case series. In these circumstances, outcomes are more difficult to benchmark. One recent series reported that one of five patients requiring a distal ICA bypass for aneurysm repair suffered a stroke; 60% suffered varying degrees of cranial nerve deficit.[6] The largest experience reported to date is that of Sessa et al.,[7] who reported a 3% and 6% rate of perioperative stroke and restenosis at 1 year, respectively. When distal carotid/skull base exposure appears to be necessary to safely manage an occlusive lesion, consideration should again be given to CAS as a lower risk alternative technique to open endarterectomy or interposition grafting.

COMPLICATIONS

- Stroke
- Cranial nerve injury
- Horner's syndrome
- Seroma
- Infection

Chapter 6

Vertebral Transposition Techniques and Stenting

Mark D. Morasch

DEFINITION

- Treatment for occlusive lesions involving the origin of the vertebral artery (V1 segment) is undertaken to relieve posterior brain circulation ischemia, otherwise known as vertebrobasilar insufficiency. Revascularization options include open surgical and endovascular techniques. The most common operation is a proximal vertebral to common carotid transposition. Endoluminal treatment includes balloon angioplasty and (typically) stenting.

DIFFERENTIAL DIAGNOSIS

- Other medical conditions mimicking posterior circulation ischemia include postural hypotension, cardiac arrhythmias, anemia, brain tumors, and benign vertiginous states. A thorough investigation consists of ruling out (1) inner ear pathology, (2) cardiac arrhythmias, (3) internal carotid artery stenosis/occlusion, and (4) complications of excessive blood pressure control (Table 1).
- Evaluation of patients with posterior circulation ischemia requires defining the precise circumstances that elicit symptoms. Vertigo, instability, and occasional loss of consciousness often accompany positional changes and standing in older individuals due to reduced sympathetic venous tone. This is particularly common in patients with diabetes. The presence of orthostatic hypotension should be evaluated as a common alternative cause for vertebrobasilar symptoms. Any decreases in basilar artery perfusion pressure may precipitate hemodynamic symptomatology, with or without concomitant vertebral occlusive disease.
- The next most common cause of brainstem ischemia is reduced cardiac output. When suspected, evaluation includes 24-hour Holter monitoring and echocardiography. In patients with vertebrobasilar insufficiency, palpitations may be noted with the onset of symptoms. Transesophageal echocardiography may be necessary to rule out structure heart issues.
- Inner ear pathology, including rare cerebellopontine angle tumors, produces symptoms suggestive of vertebrobasilar insufficiency. Benign vertiginous states should also be considered. Physical examination can alert the physician to the possibility of subclavian steal in patients with differences in brachial blood pressure greater than 25 mmHg or with diminished left upper extremity pulses. Reversed flow in the ipsilateral vertebral artery demonstrated on duplex scanning is pathognomonic for subclavian steal physiology and subclavian steal syndrome in patients with appropriate symptoms at rest or following exercise in the ipsilateral upper extremity.
- Patients may relate symptoms of vertebrobasilar insufficiency to positional changes, including turning or extending their head. These dynamic symptoms usually appear when turning the head to one side. In this circumstance, symptoms may be elicited by extrinsic compression of the dominant or sole vertebral artery (in the case of unilateral occlusion) by adjacent arthritic bone spurs.[1]

Table 1: Nonvascular and Cardiac Conditions that Mimic Vertebrobasilar Ischemia

Cardiac arrhythmia
Pacemaker malfunction
Cardioemboli
Antihypertensive medications
Labyrinthine dysfunction
Cerebellopontine angle tumors
Cerebellar degeneration
Myxedema
Electrolyte imbalance
Hypoglycemia

PATIENT HISTORY AND PHYSICAL FINDINGS

- In general, ischemic mechanisms in vertebrobasilar insufficiency can be categorized as hemodynamic or embolic. Symptoms of vertebrobasilar insufficiency include dizziness, vertigo, drop attacks, diplopia, perioral numbness, alternating paresthesia, tinnitus, dysphasia, dysarthria, and ataxia. When two or more of these symptoms are present, vertebrobasilar ischemia is more likely to be the inciting cause. Unlike other regions of the brain, strokes in the posterior circulation territory occur due to large artery occlusive diseases.
- Patients with "hemodynamic" ischemia experience transient vertebrobasilar symptoms due to inadequate vertebral artery inflow or collateral circulation. Symptoms are typically short lived, repetitive, somewhat predictable, and rarely result in stroke. Postural hypotension may precipitate serious traumatic injury, however, when patients lose their balance with standing.
- Embolic events may also precipitate vertebrobasilar ischemia as well as cerebellar and brainstem infarction. Microemboli from the heart, aortic arch, or any arteries leading directly to the basilar artery may arise from atherosclerotic lesions, intimal defects, repetitive trauma, fibromuscular dysplasia lesions, aneurysms, or dissections. Although much less common than hemodynamic vertebrobasilar insufficiency, when present, microemboli are much more likely to cause fatal events or debilitating infarcts.[2–4]
- Timing of the onset of symptoms following positional changes may help differentiate vertebrobasilar insufficiency from labyrinthine disorders. In the latter circumstance, rapid head movement invokes immediate symptoms. In the case of vertebrobasilar insufficiency, however, a short delay usually precedes the onset of symptoms, including nystagmus.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Duplex ultrasound, an otherwise excellent tool for the assessment of extracranial cerebrovascular disease, has limitations in the diagnosis of vertebral artery pathology. Direct visualization of the second portion is obscured by the transverse processes of C2–C6. As previously mentioned, however, duplex imaging reliably identifies subclavian steal physiology, as well as detect proximal velocity increases consistent with orificial vertebral or proximal subclavian stenosis.[5]

- Magnetic resonance imaging (MRI) provides safe, noninvasive, and detailed evaluation of the aortic arch and great vessels, the extracranial and intracranial arterial vasculature, as well as the presence of mass lesions, fluid collections, or parenchymal defects in the posterior fossa. Contrast-enhanced magnetic resonance angiography (MRA), with three-dimensional reconstruction and maximum image intensity techniques, provides excellent image quality in high resolution (**FIG 1**). As in other applications, however, in low-flow circumstances, excessive signal dropout may result in overestimation of lesion severity based on signal intensity alone.
- In contrast to computed tomographic (CT) imaging, transaxial MRI readily diagnoses both acute and chronic brain infarctions in the posterior fossa. Brainstem infarctions are typically small and as such may be overlooked with noncontrast CT imaging. Brain MRI is performed in symptomatic patients prior to vertebral artery intervention to identify infarctions when they are present and provide baseline images for future comparison.
- Evaluation of vertebral anatomy via catheter-based, contrast arteriography requires acquisition of images in multiple projections to fully evaluate the entire extent of both vertebral arteries. Evaluation begins with the aortic arch to determine the origin of the bilateral vertebral arteries. Anomalous origin of the left vertebral artery, arising directly from the aorta proximal to the left subclavian, is present in 6% of patients. Much less frequently, the right vertebral artery originates from the innominate or right common carotid artery. This anomaly often accompanies an aberrant right subclavian artery, which itself may precipitate symptoms of dysphagia lusoria.
- Usually, right and left posterior oblique projections are sufficient to comprehensively evaluate the V1 (first) vertebral artery segment from the origin to the transverse process of C6. In most patients, the left artery is usually dominant, but a number of normal variants may be encountered, including congenital atresia of either vertebral artery.

FIG 1 ● Vertebral MRA (with the carotid image subtracted).

- The vertebral artery origin may not be visualized adequately with either duplex ultrasonography or MRA. Oblique projections are required during arteriography due to superimposition of the subclavian artery over the vertebral origin. Additional projections, including craniocaudal tube angulation, may also be required to optimize visualization. The presence of a poststenotic dilatation in the first centimeter of the vertebral artery is a clue that should prompt further projections to isolate the origin from the overlying subclavian artery.
- Dynamic arteriography, incorporating provocative positioning, may be required to assess the possibility of extrinsic vertebral artery compression. Finally, delayed imaging may demonstrate reconstitution of patent distal extracranial vertebral arteries through cervical collaterals when the origin initially appears occluded.

SURGICAL MANAGEMENT

- Some degree of vertebral artery orificial stenosis is present in 20% to 40% of patients with other manifestations of cerebrovascular disease.[2] A number of operative approaches will satisfactorily address V1 segment disease and orificial stenosis.[6,7] Vertebral transposition, or repositioning of the origin of the vertebral artery onto the adjacent common carotid artery is the most common. Endoluminal dilatation, with or without stenting, is also appropriate in selected circumstances.

Vertebral to Common Carotid Transposition

- General endotracheal anesthesia is preferred. Positioning supine, with the back of the table slightly elevated toward a chair position with the head rotated away from the planned incision site facilitates additional deep mediastinal exposure when required.
- Proximal vertebral artery exposure is similar to that required for subclavian-to-carotid transposition. One fingerbreadth above the clavicle, a transverse incision is created directly over the two heads of the sternocleidomastoid muscle (SCM). Between the SCM heads, the omohyoid muscle is identified and divided. Lateral retraction of the internal jugular vein and vagus nerve exposes the carotid sheath medially. Maximal proximal carotid artery exposure, facilitated by positioning of the primary operator at head of the patient, is necessary to ensure an optimal result (**FIG 2**).
- The sympathetic ganglia are identified running behind and parallel to the carotid artery. On the left side, the thoracic duct is divided between ligatures to minimize lymphatic leaks. The proximal end should be doubly ligated, avoiding transfixion sutures. Accessory lymph ducts—often seen on the right side—should also be ligated and divided when identified. The entire dissection is confined medial to the prescalene fat pad covering the scalenus anticus muscle and phrenic nerve. These latter structures are left unexposed lateral to the field. The inferior thyroid artery, running transversely across the field, is also ligated and divided.
- The vertebral vein is next identified emerging from the angle formed by the longus colli and scalenus anticus and

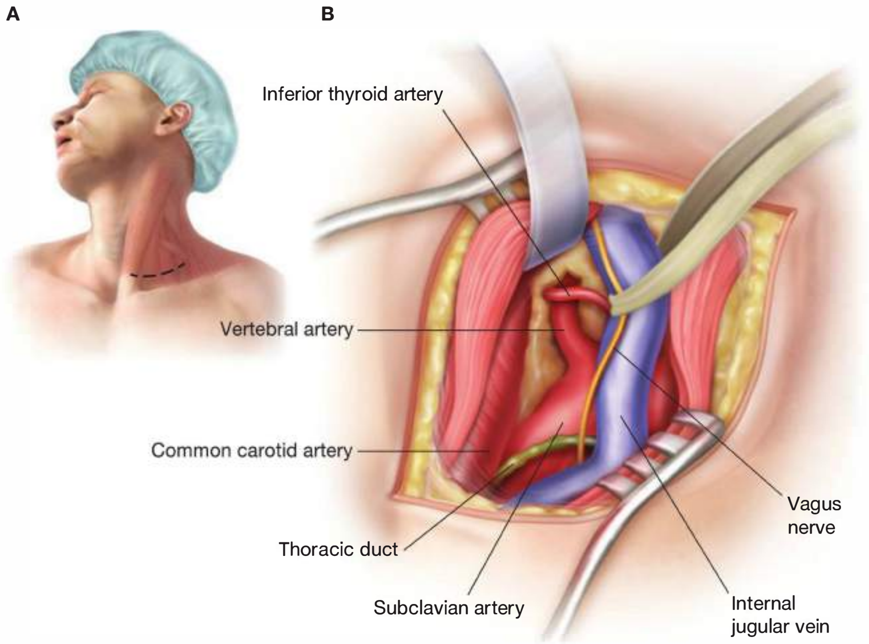

FIG 2 ● **A.** Access to the proximal vertebral artery between the sternocleidomastoid muscle bellies. **B.** Transposition of the proximal vertebral artery to the posterior wall of the common carotid artery.

overlying the vertebral artery and, at the bottom of the field, the subclavian artery. Unlike its sister artery, the vertebral vein has branches. It is ligated in continuity and divided. Below the vertebral vein lies the vertebral artery. It is important to identify and avoid injury to the adjacent sympathetic chain. The vertebral artery is dissected superiorly to the tendon of the longus colli and inferiorly to its origin in the subclavian artery. The vertebral artery is freed from the sympathetic trunk resting on its anterior surface without damaging the trunk or the ganglionic rami. Preserving the sympathetic trunks and the stellate or intermediate ganglia resting on the artery usually requires freeing the vertebral artery from these structures, and after dividing its origin, the latter is transposed anterior to the sympathetics.

- Once the artery is fully exposed, an appropriate site for reimplantation in the common carotid artery is selected. The patient is systemically anticoagulated with intravenous heparin. The distal portion of the V1 segment of the vertebral artery is clamped below the edge of the longus colli with a microclip placed vertically to indicate the orientation of the artery and to avoid axial twisting during its transposition. The proximal vertebral artery is closed by transfixion with 5-0 polypropylene suture immediately above the stenosis at its origin. The artery is divided at this level, and its proximal stump is further secured with a hemoclip. The artery is then brought to the common carotid artery and its free end is spatulated for anastomosis.
- The carotid artery is then cross-clamped. An elliptical 5- to 7-mm arteriotomy is created in the posterolateral wall of the common carotid artery with an aortic punch. The anastomosis is performed in open fashion with continuous 6-0 or 7-0 polypropylene suture while avoiding any tension on the vertebral artery, which tears easily. Before completion of the anastomosis, any slack in the suture is tightened appropriately with a nerve hook, standard flushing maneuvers are performed, and the suture is tied to reestablish flow (**FIG 3**).

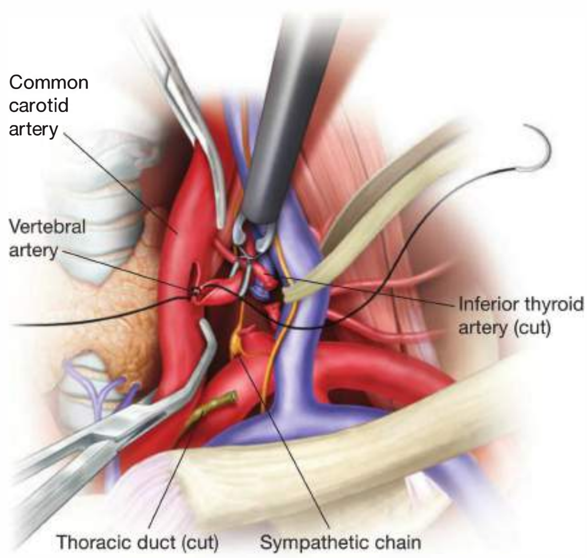

FIG 3 ● Proximal vertebral–to–common carotid transposition.

Vertebral Artery Angioplasty and Stent Placement

- In the past decade, endovascular treatment of vertebral artery disease has gained increasing acceptance. For endovascular intervention, patients are pretreated with dual antiplatelet therapy (aspirin and clopidogrel). The procedure is usually performed with local anesthesia and conscious sedation, enabling continuous neurologic monitoring of the patient. The patients are positioned supine and prepped to allow percutaneous entry into the chosen access vessel. Most cases are performed from a femoral approach (93%), although transbrachial (3%) and transradial (5%) access has also been used as noted in one recent review.[8] The stenotic lesions are crossed and then dilated with 0.014- or 0.018-in guidewires and small coronary-diameter balloons. If a stent is chosen, these are usually bare metal type, but drug elution has also been used. The same 0.014- or 0.018-in guidewires are used as platforms over which the stents are delivered and then deployed. Post-deployment angioplasty may be necessary in selected cases. Procedures can be performed with or without the assistance of embolic protection, although most vertebral arteries are too small to accommodate most distal protection devices.

PEARLS AND PITFALLS

Placement of incision	■ It is important to place the incision medially enough to dissect between the heads of the sternocleidomastoid. An approach lateral to this structure will make the transposition challenging, if not impossible, to complete.
Orientation	■ Enough of the V1 segment of the vertebral artery, up to near where it disappears into the transverse process of C6, needs to be mobilized. Also, plan ahead and see where on the carotid is best to reimplant the vertebral before creating the carotid arteriotomy.
Closure	■ A drain is usually helpful, especially on the left side where the thoracic duct crosses the exposure, just in case a tie comes off of a large lymphatic. The drain allows for early diagnosis of this complication.

POSTOPERATIVE CARE

- Following surgical transposition, absent significant lymphatic drainage from the wound, the patient may be safely discharged on the first or second postoperative day. Similarly, after endoluminal therapy, patients are kept overnight to ensure neurologic stability.

OUTCOMES

- After proximal vertebral–to–common carotid transposition, patency rates at 5 and 10 years equal or exceed 95% and 91%, respectively. When selected appropriately, more than 80% of patients will experience symptomatic relief following proximal surgical reconstruction.[9]
- Appropriate reconstruction and subsequent reperfusion of the brainstem in patients experiencing hemodynamic vertebrobasilar symptoms may also improve hypertension management.
- Overall, retrospective reviews suggest that endoluminal vertebral artery intervention is reasonably safe, although a selection bias exists. A 2005 Cochrane review identified 313 interventions for vertebral artery stenosis, with just over half using stent placement as part of the treatment. The technical success rate was 95%, and the 30-day stroke and death rate was 6.4%.[10]
- Despite high technical success rates, vertebral artery angioplasty alone, especially when used for the treatment of disease at the origin of the vessel, appears to have an unacceptably high rate of restenosis. Adjuvant stent placement adds to the clinical durability but adds potential morbidity such as malposition or potential fracture. In their series of 105 patients who underwent endovascular stenting for symptomatic vertebral artery disease, Jenkins et al.[11] achieved 100% radiographic improvement (residual stenosis ≤30%). The authors reported immediate (30-day) periprocedural risk of death of 1% and periprocedural complication rate of 4.8%. Complications included transient ischemic attack, flow-limiting dissection, hematoma, and catheter-access-site problems. At 1 year of follow-up, six patients had died and five had experienced a vertebrobasilar stroke, and at approximately 2.5 years of follow-up, 70% of patients remained symptom free, but 13% of patients had restenosis requiring retreatment.[11]
- A recent systematic review of the available literature noted a weighted mean technical success rate of 97%. The authors estimated mean periprocedural stroke and death rate from combined angioplasty and stenting to be around 1.1%. Transient ischemic events occurred in 1.5% of patients. Recurrent symptoms occurred in 8% of patients within a reported range of follow-up of 6 to 54 months and greater than 50% restenosis developed in 23% of the subset of patients who underwent follow-up imaging.[8]

COMPLICATIONS

- Proximal vertebral to common carotid transposition has been reported to have a combined stroke and death rate of 0.9%.[9] Among patients undergoing this operation, in one report, there were no deaths or strokes in those who underwent only a vertebral reconstruction. Berguer and coauthors reported four instances of immediate postoperative thrombosis (1.4%). Three of the four patients had vein grafts interposed between the vertebral artery and the common carotid because of a short V1 segment. The grafts kinked and thrombosed. Other complications that are particular to proximal reconstruction include vagus and recurrent laryngeal nerve palsy (2%), Horner's syndrome (8.4% to 28%), lymphocele (4%), and chylothorax (0.5%).
- Periprocedural risks for angioplasty and stenting include access complications, distal embolization and stroke, arterial rupture, stent malposition, and vessel thrombosis or dissection. Later, restenosis and stent fracture are not uncommon (**FIG 4**).

Chapter 7

Neurogenic Thoracic Outlet Syndrome Exposure and Decompression: Supraclavicular

Robert W. Thompson   Chandu Vemuri

DEFINITION

- Thoracic outlet syndrome (TOS) is a group of conditions caused by compression of one of the neurovascular structures that serve the upper extremity.[1–3] Neurogenic thoracic outlet syndrome (NTOS) is the most frequent of these, occurring in 85% to 90% of thoracic outlet patients. It is caused by compression and irritation of the brachial plexus nerves within the supraclavicular scalene triangle and/or underneath the pectoralis minor muscle tendon in the subcoracoid space (**FIG 1**). NTOS tends to occur in patients between the ages of 15 and 40 years, typically manifesting as neck and upper extremity pain, paresthesias, and functional limitations in the ipsilateral arm. Although relatively uncommon, clinical recognition and appropriate treatment are crucial to optimizing outcome in young active individuals with NTOS-related disability.[4]
- The causes of NTOS include anatomic variations (anomalous scalene musculature, aberrant fibrofascial bands, and/or cervical ribs) and previous neck or upper extremity injury, which promotes scalene/pectoralis muscle spasm, fibrosis, and other pathologic changes.[4] These muscular alterations, in turn, lead to compression and irritation of the adjacent brachial plexus nerves. The presence of a cervical rib is often cited as a risk factor for NTOS; however, few NTOS patients (approximately 10%) have a definable cervical rib, and development of NTOS symptoms are rare in cervical rib patients in the absence of predisposing injury.[5]
- NTOS often occurs in individuals involved in occupational or recreational activities requiring repetitive overhead activities with the arms and/or heavy lifting, occasionally aggravated by injury (e.g., motor vehicle collisions or falls upon the outstretched arm). Other predisposing conditions include low-grade repetitive strain injury (e.g., prolonged keyboard use), poor posture, and dysfunctional shoulder girdle mechanics.
- Surgical treatment for NTOS may be effectively accomplished by several different approaches, including transaxillary 1st rib resection and anterior (supraclavicular) decompression. The supraclavicular approach has long been a mainstay in the surgical

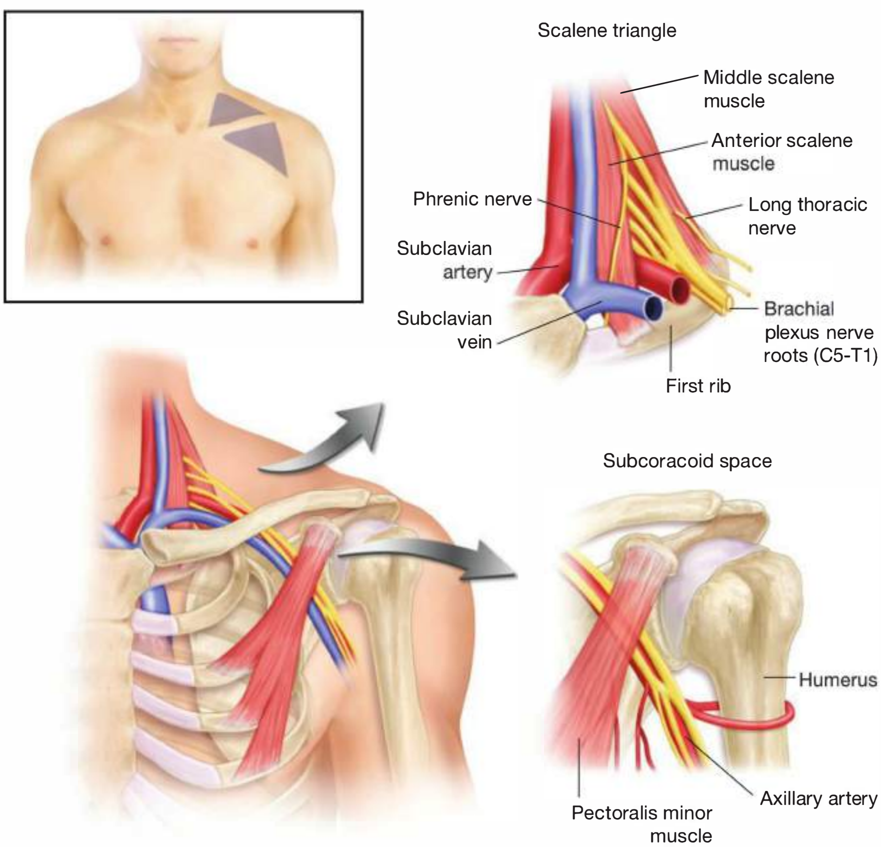

FIG 1 • Anatomy of the thoracic outlet, with emphasis on the supraclavicular scalene triangle and the infraclavicular subcoracoid space.

Table 1: Differential Diagnosis of Neurogenic Thoracic Outlet Syndrome

Acromioclavicular arthropathy	Fibromyalgia and fibromyositis
Arterial atheroembolism	Nerve sheath neoplasm
Brachial plexus (stretch) injury	Pancoast tumor (lung apex)
Carpal tunnel syndrome (median nerve)	Parsonage-Turner syndrome
Cervical dystonia	Psychogenic syndrome
Cervical spine degenerative arthritis	Radial nerve compression (extensor forearm)
Complex regional pain syndrome	Raynaud syndrome
Cervical spine degenerative disc disease	Rotator cuff tendinitis
Cervical spine (muscular) strain	Scleroderma
Cubital canal syndrome (ulnar nerve)	Vasculitis

treatment of NTOS, providing excellent exposure for safe and definitive decompression of the relevant neurovascular structures as well as the flexibility to manage the entire spectrum of circumstances that may be encountered intraoperatively.[6–10]

DIFFERENTIAL DIAGNOSIS

- NTOS-related symptoms may mimic or overlap those observed in other upper extremity neurologic and musculoskeletal disorders, expanding the differential diagnosis (Table 1).[11,12] Successful intervention requires differentiation of NTOS from other cervical–brachial syndromes as well as optimal patient and procedural selection.[13]
- NTOS should be readily differentiated from venous TOS, which produces marked arm swelling, cyanotic discoloration, and distention of subcutaneous veins around the shoulder and chest wall. Venous TOS often presents clinically as axillary-subclavian vein "effort-related thrombosis" (Paget-Schroetter syndrome). NTOS should also be distinguished from arterial TOS, which causes either fixed subclavian artery obstruction or poststenotic aneurysm formation. The former may precipitate arm or hand pain with exercise ("arm claudication"), the latter aneurysm thrombosis and distal embolization, hand ischemia, rest pain, and/or digital ulceration and necrosis.
- Some NTOS patients exhibit severe upper extremity pain and hypersensitivity, with digital swelling and discoloration, suggesting the presence of sympathetic nerve overactivity. In such cases, the coexistence of reflex sympathetic dystrophy (complex regional pain syndrome [CRPS]) should be determined by assessing the symptomatic response to a temporary cervical sympathetic (stellate ganglion) anesthetic block.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Symptoms attributable to brachial plexus nerve compression include pain, numbness, and tingling (paresthesia) in the neck, shoulder, arm, and hand. The distribution of symptoms in the hand often extends beyond that expected for either the median or ulnar nerves, involving all fingers. Patients with NTOS attributable to compression at the pectoralis minor tendon often describe upper anterior chest and axillary pain. The intensity of symptoms of NTOS can vary with the extent of upper extremity activity and are usually reliably exacerbated with arm elevation and abduction.
- Many NTOS patients experience relatively mild symptoms, with gradual progression in severity punctuated by periodic exacerbations. Others experience steady, progressive worsening of symptoms and related disability. Hand muscle weakness and atrophy (Gilliatt-Sumner hand) are rare, typically following long-standing brachial plexus compression due to an associated cervical rib or similar bony anomaly.
- Physical examination typically identifies reproducible tenderness to palpation over the supraclavicular scalene triangle and/or the infraclavicular subcoracoid space (**FIG 2**).
- Most NTOS patients experience recurrent upper extremity symptoms in response to provocative positional maneuvers, such as the upper limb tension test (ULTT) or the 3-minute elevated arm stress test (EAST) (**FIG 2**). Positional dampening of the radial artery pulse at the wrist during arm abduction and external rotation (Adson's test) is nonspecific and inaccurate and is generally not useful in establishing or excluding a diagnosis of NTOS.
- Directed physical examination is performed to determine the presence of cervical spine degenerative disease or peripheral nerve compression (carpal tunnel and cubital canal syndromes) as potential alternative sources of NTOS-like symptoms as well as evidence of arterial or venous compromise to the affected extremity. Signs of increased upper extremity sympathetic tone are also sought, including digital swelling, discoloration, and skin hypersensitivity (allodynia).
- Documentation of patient-reported symptoms and quantification of disability prior to treatment are accomplished by completion of standardized outcomes measurement tools such as the Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire and quality-of-life instruments.[14] Repeated use of these instruments at various intervals before and after treatment has provided increasing insight into the relative value of alternative management strategies.[15]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Although imaging and other diagnostic studies may provide helpful ancillary information, there is no definitive test to confirm or exclude the diagnosis of NTOS. Diagnosis remains quintessentially clinical and dependent on experienced pattern recognition.
- Plain anteroposterior chest radiographs will identify a cervical rib when present. No other currently available imaging study adds significant value to the clinical diagnosis of NTOS (**FIG 3**).
- Conventional electrophysiologic tests (electromyography and nerve conduction studies) are often performed to exclude peripheral nerve compression disorders or cervical radiculopathy. These tests are usually negative or nonspecific in NTOS and cannot be used to establish or exclude the diagnosis.
- Vascular laboratory studies (Duplex ultrasound) may detect alterations in upper extremity blood flow attributable to subclavian artery compression during arm elevation. However, positional subclavian artery compression may represent an incidental and unrelated vascular finding and does not establish a diagnosis of neurogenic or arterial TOS. As they do not assess the presence or severity of brachial plexopathy, vascular laboratory studies add little specificity beyond the clinical diagnostic criteria.
- Performance of image-guided anterior scalene and/or pectoralis minor muscle anesthetic blocks may assist the clinical diagnosis of NTOS.[16] A positive block, characterized as temporary relief or improvement in the presenting

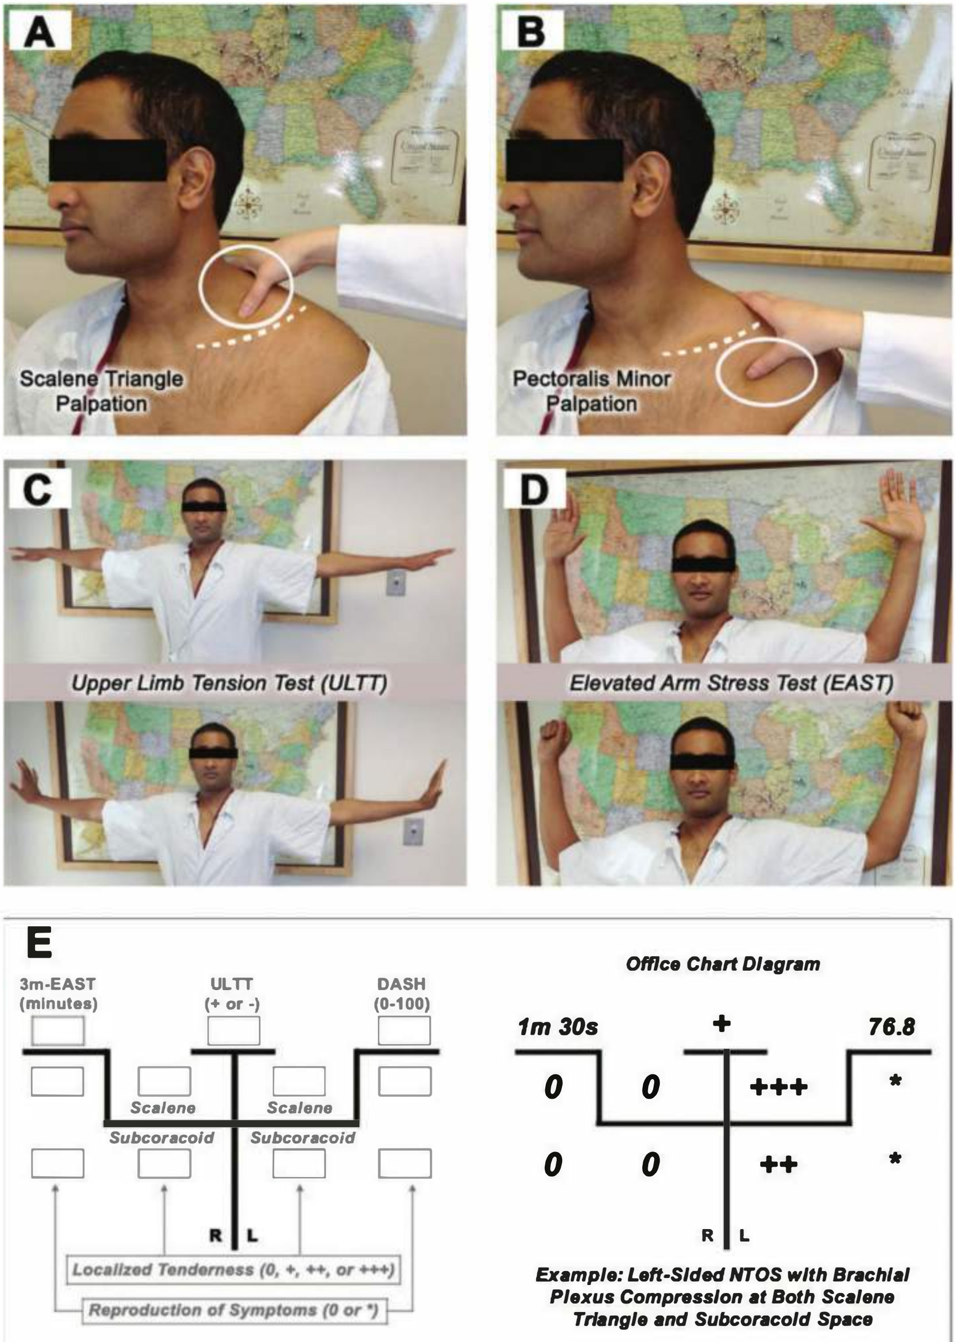

FIG 2 ● Physical examination reveals localized tenderness to palpation over the supraclavicular scalene triangle **(A)** and/or the infraclavicular subcoracoid space **(B)**. The ULTT **(C)** and the 3-minute EAST **(D)** use provocative positional maneuvers that rapidly elicit reproduction of upper extremity symptoms in patients with NTOS. **E.** An office chart diagram is used to easily summarize physical examination findings for patients being evaluated for NTOS.

symptoms, strongly supports the clinical diagnosis of NTOS. A positive block may predict symptomatic relief from surgical decompression and is therefore highly useful in selecting candidates for 1st rib resection. Unfortunately, however, failure of temporary symptom resolution following muscle blockade does exclude the diagnosis of NTOS and should not preclude consideration of surgical management in otherwise compelling clinical candidates.

- Initial treatment for NTOS is based on physical therapy to relieve scalene/pectoralis minor muscle spasm, improve

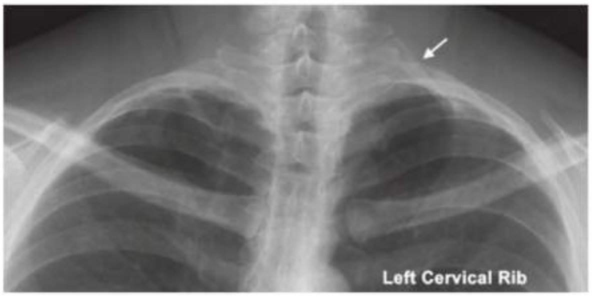

FIG 3 ● A left-sided cervical rib identified by plain chest radiography *(arrow)*.

posture, enhance functional limb mobility, strengthen associated shoulder girdle musculature, and diminish repetitive strain exposure in the workplace. Incorrect approaches to physical therapy can result in worsening of symptoms and failure of conservative management. In many NTOS patients, significant symptomatic improvement may be experienced in response to physical therapy, particularly in the first 4 to 6 weeks. Because NTOS is commonly chronic, however, and subject to acute symptomatic "flare ups" (often related to overuse activities or new injury), such patients should continue prescribed physical therapy exercises during long-term follow-up. Patients that fail a conscientious and effective physical therapy, as well as alternative conservative measures, are referred for consideration of surgical intervention.

SURGICAL MANAGEMENT

- Supraclavicular decompression (scalenectomy, 1st rib resection, and brachial plexus neurolysis) is recommended on the basis of (1) sound clinical diagnosis of NTOS, (2) substantial resulting disability (interference with daily activities and/or work), and (3) an inadequate response to standard physical therapy. Supraclavicular decompression may also provide relief from persistent or recurrent NTOS symptoms following prior surgery, particularly when continued conservative measures prove ineffective.
- For patients with symptoms referable to the subcoracoid space, release of the pectoralis minor tendon should be included in the supraclavicular thoracic outlet decompression procedure. Pectoralis minor tenotomy may also be performed as a stand-alone procedure when nerve compression symptoms are limited to this area.[17,18]
- Decompression should be performed as a staged, sequential procedure in patients with bilateral NTOS symptoms. The initial supraclavicular decompression, with or without pectoralis minor tenotomy, is performed on most symptomatic or dominant extremity. If symptoms remain present or progress, contralateral supraclavicular decompression may be performed within 6 to 12 weeks of the initial procedure. Normal phrenic nerve function should be verified on the side of the previous procedure, by chest fluoroscopic examination, before contralateral intervention.

Preoperative Planning

- The supraclavicular surgical site is marked in the preoperative holding area, including the subcoracoid space when concomitant pectoralis minor tenotomy is planned. Prophylactic antibiotics are administered within an hour of the planned procedure.

Positioning

- After the induction of general endotracheal anesthesia, the patient is positioned supine with the head of the operating table elevated 30 degrees. The neck is extended and turned to the opposite side; a small inflatable pillow is placed behind the shoulders; and the neck, chest, and affected upper extremity are prepped into the field. The arm is wrapped in stockinette to permit free range of movement during the operation and then held comfortably across the abdomen (**FIG 4**). Lower extremity sequential compression devices are used for thromboprophylaxis. Neuromuscular blocking agents are not used following the initial induction of anesthesia.

FIG 4 ● Patient position and planned incisions for left-sided supraclavicular thoracic outlet decompression with pectoralis minor tenotomy.

SUPRACLAVICULAR DECOMPRESSION

Incision and Mobilization of the Scalene Fat Pad

- A transverse neck incision is made parallel to and just above the clavicle, beginning at the lateral edge of the sternocleidomastoid muscle and extending to the anterior edge of the trapezius muscle. The incision is carried through the subcutaneous layer, the platysma muscle is divided, and subplatysmal flaps are developed to expose the scalene fat pad. The sternocleidomastoid muscle is retracted medially but is not divided (**FIG 5**).
- One of the keys to simplifying the supraclavicular exposure is proper mobilization and lateral reflection of the scalene fat pad. This begins with detachment of the fat pad along the lateral edge of the internal jugular vein and the superior edge of the clavicle, with ligation of small blood vessels and lymphatic tissues. The thoracic duct, usually observed near the junction of the internal

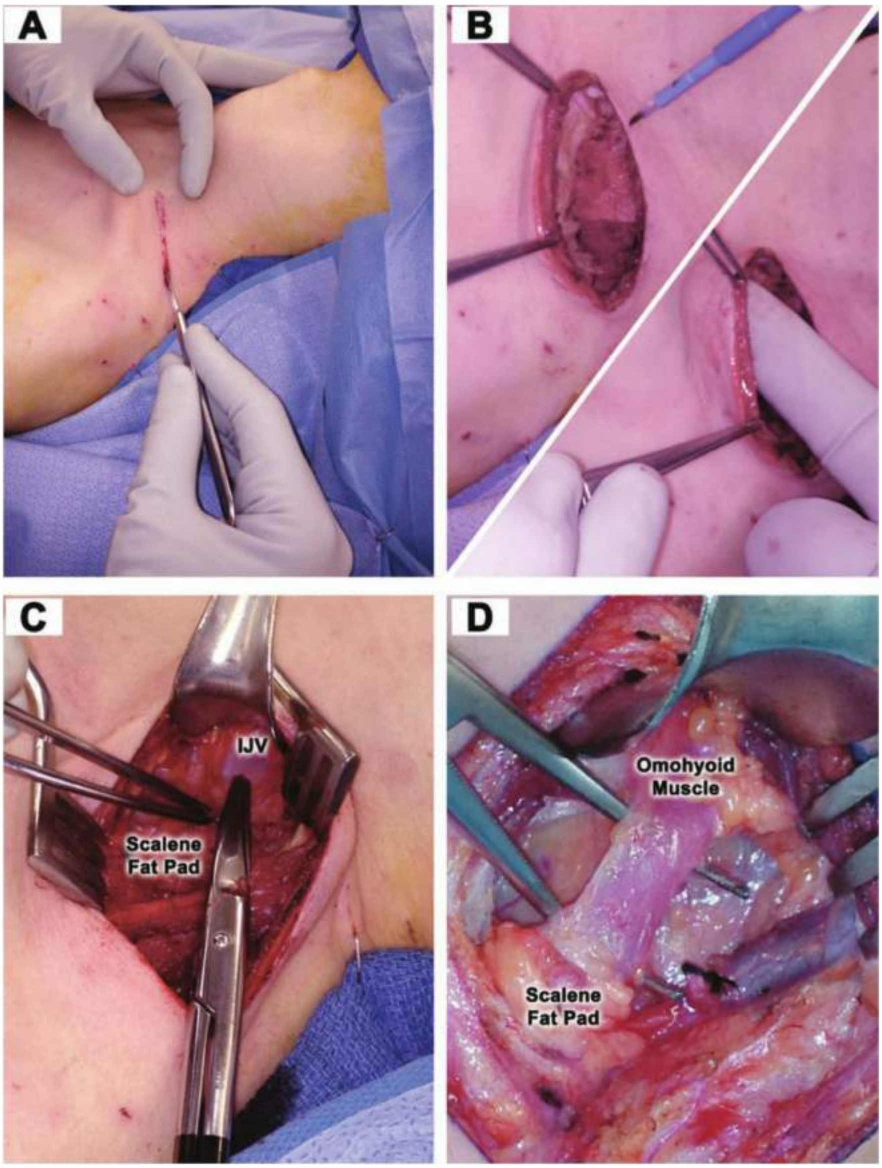

FIG 5 ● **A.** The skin incision is made just above and parallel to the clavicle, extending from the lateral border of the sternocleidomastoid muscle to the anterior border of the trapezius muscle. **B.** Subplatysmal flaps are created to expose the underlying scalene fat pad. The scalene fat pad is mobilized, beginning with its medial attachments to the internal jugular vein *(IJV)* **(C)**, and the omohyoid muscle is divided **(D)**.

Table 2: Critical Views Obtained during Supraclavicular Thoracic Outlet Decompression

1. View of the operative field after lateral reflection of the scalene fat pad, with visualization of the internal jugular vein, anterior scalene muscle, phrenic nerve, brachial plexus, subclavian artery, middle scalene muscle, and long thoracic nerve
2. View of the lower part of the anterior scalene muscle where it attaches to the 1st rib, with space sufficient to allow a finger to pass behind the anterior scalene muscle and in front of the brachial plexus and subclavian artery, prior to division of the anterior scalene muscle insertion from the top of the 1st rib
3. View of the upper part of the anterior scalene muscle at the level of the C6 transverse process, in relation to the C5 and C6 nerve roots, prior to division of the anterior scalene muscle origin
4. View of the insertion of the middle scalene muscle on the 1st rib, with each of the five nerve roots of the brachial plexus and the subclavian artery retracted medially and the long thoracic nerve retracted laterally, prior to division of the middle scalene muscle insertion from the top of the lateral 1st rib
5. View of the posterior neck of the 1st rib, with the T1 nerve root passing from underneath the rib to join the C8 nerve root to form the inferior trunk of the brachial plexus, prior to division of the posterior 1st rib
6. View of the anterior portion of the 1st rib, with placement of the rib shears medial to the scalene tubercle, prior to division of the anterior 1st rib

jugular and subclavian veins on the left side (a prominent accessory thoracic duct may also exist on the right side), may be ligated and divided. The omohyoid muscle is routinely divided (**FIG 5**).

- The scalene fat pad is progressively elevated in a medial to lateral direction, by gentle fingertip dissection over the surface of the anterior scalene muscle. The phrenic nerve is observed passing in a lateral to medial direction as it descends along the muscle surface. Gentle manipulation of the phrenic nerve produces a "dartle" (diaphragmatic startle) response.
- Upon further lateral rotation of the scalene fat pad, the brachial plexus nerve roots (posterior and lateral to the anterior scalene muscle) and the middle scalene muscle (behind the brachial plexus) are brought into view. The lateral aspect of the 1st rib is palpated and visualized, and the long thoracic nerve is identified as it emerges from the body of the middle scalene muscle to course past the lateral part of the 1st rib. The scalene fat pad is then held in position with several silk retraction sutures and the exposure is maintained with a Henley self-retaining retractor (using the third arm to hold the edge of the sternocleidomastoid muscle). The resulting exposure represents the first and most important of six "critical views" to be obtained during supraclavicular decompression (Table 2) (**FIG 6**).

Anterior Scalenectomy

- Attention is turned to the insertion of the anterior scalene muscle on the 1st rib. At the lower lateral edge of the anterior scalene muscle, the subclavian artery and brachial plexus are carefully mobilized until a fingertip can be easily passed behind the muscle just above the 1st rib, thereby displacing the neurovascular structures posterolaterally. Blunt fingertip dissection is continued behind the muscle to its medial edge, taking care to avoid the phrenic nerve. Once the insertion of the anterior scalene muscle onto the 1st rib has been isolated under direct vision to protect the phrenic nerve, the subclavian artery, and the brachial plexus, it is sharply divided from the top of the bone with scissors (**FIG 7**).
- The end of the divided anterior scalene muscle is elevated and its attachments to the underlying extrapleural fascia are sharply divided (electrocautery is not used to avoid inadvertent nerve injury). Muscle fibers extending from the posterior aspect of the muscle often pass around the subclavian artery to form a tethering "sling" and should also be resected to fully release the artery. Any scalene minimus muscle fibers found to be present (passing between the roots of the brachial plexus) are divided as the anterior scalene muscle is mobilized. As the anterior scalene muscle is lifted further, it is passed underneath and medial to the phrenic nerve and its posterior attachments are divided with direct visualization and protection of the upper brachial plexus nerve roots. Dissection of the muscle is carried superiorly to its origin on the C6 transverse process, which is easily palpated in the upper aspect of the operative field (the apex of the "scalene triangle"). The anterior scalene muscle is then divided with scissors from its origin on the transverse process under direct vision and the entire muscle is removed, with a

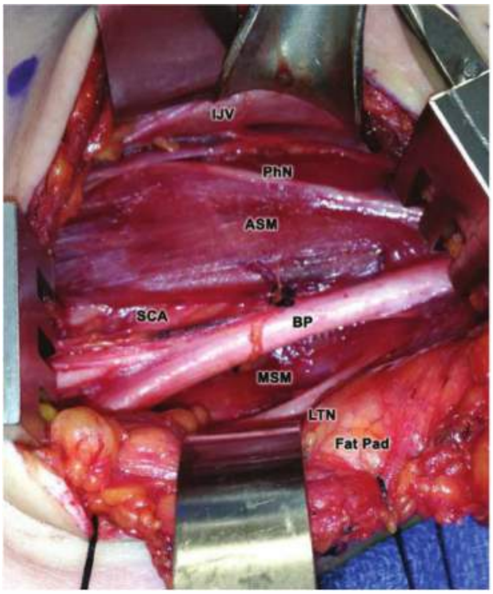

FIG 6 ● Following lateral reflection of the scalene fat pad, direct visualization is obtained of the internal jugular vein *(IJV)*, anterior scalene muscle *(ASM)*, phrenic nerve *(PhN)*, brachial plexus *(BP)*, subclavian artery *(SCA)*, middle scalene muscle *(MSM)*, and long thoracic nerve *(LTN)*.

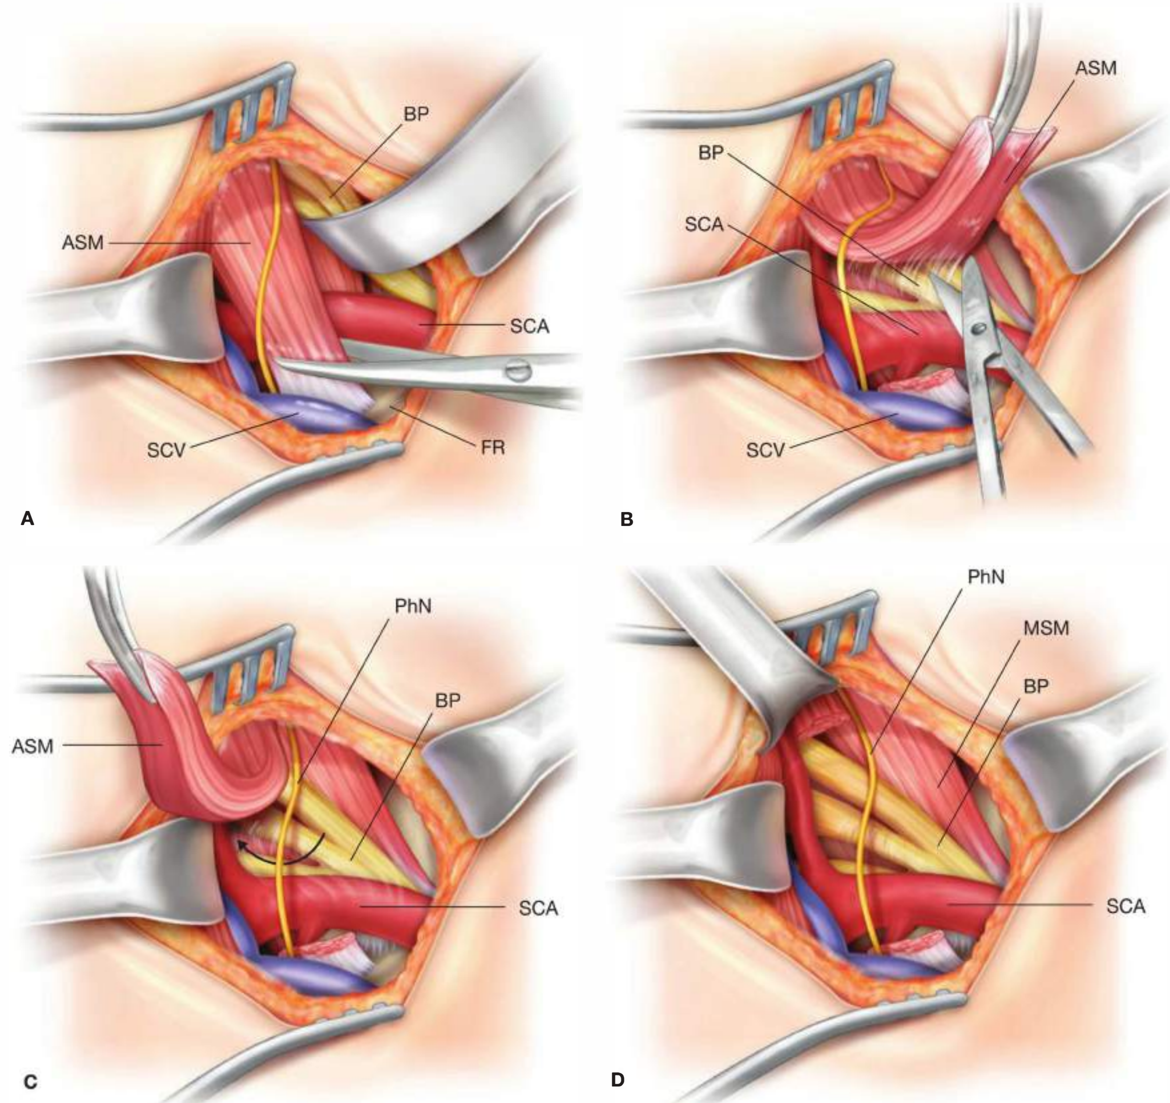

FIG 7 ● **A.** The anterior scalene muscle (ASM) insertion is isolated by displacing the underlying subclavian artery (SCA) and brachial plexus (BP), using blunt fingertip dissection behind the muscle, and the muscle is sharply divided from the top of the 1st rib. **B.** The end of the divided anterior scalene muscle is lifted and sharply dissected free of structures lying behind the muscle, including the subclavian artery. **C.** As it is mobilized, the anterior scalene muscle is passed underneath and to the medial side of the phrenic nerve (PhN). **D.** The dissection is carried up to the level of the C6 transverse process where the anterior scalene muscle can be safely divided from its origin and removed.

typical specimen weighing 5 to 10 g. Any minor bleeding from the edge of the divided muscle origin is controlled with small polypropylene sutures rather than electrocautery, given the proximity of the nerve roots (FIG 7).

- Anomalous fibrofascial bands may be observed after anterior scalene muscle resection, typically passing in front of the lower brachial plexus nerve roots. These structures are also resected as they are encountered to ensure thorough decompression and full nerve root mobility.

Mobilization of the Brachial Plexus and Middle Scalenectomy

- The brachial plexus nerve roots are next separated from the front edge of the middle scalene muscle. Blunt fingertip dissection along the lateral aspect of the nerves is used to extend the exposure deeper to the inner curve of the 1st rib and the extrapleural space, and a small malleable retractor is placed between the brachial plexus

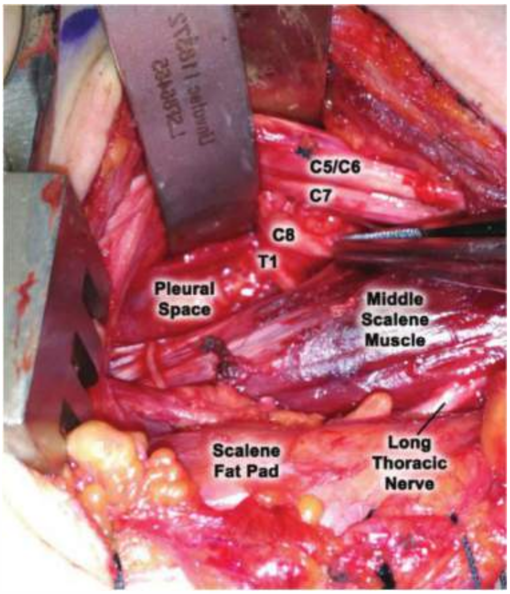

FIG 8 ● The brachial plexus is separated from the anteromedial border of the middle scalene muscle down to the level of the 1st rib and extrapleural fascia and gently retracted medially to visualize all five nerve roots (C5 to T1).

nerves and the middle scalene muscle. With gentle medial retraction of the brachial plexus, each nerve root from C5 to T1 is sequentially identified (**FIG 8**).

- The transverse cervical artery and vein should be ligated and divided where they pass through the brachial plexus and middle scalene muscle to avoid bleeding should these vessels be avulsed during retraction.
- A second malleable retractor is placed lateral to the middle scalene muscle and 1st rib, to displace the long thoracic nerve posteriorly. The oblique attachment of the middle scalene muscle along the top of the posterolateral 1st rib is exposed. This muscle insertion is carefully divided from the surface of the bone with the electrocautery, using a periosteal elevator as the dissection proceeds posteriorly, extending to a point on the 1st rib that is parallel with the underlying T1 nerve root. The bulk of the middle scalene muscle anterior to the long thoracic nerve is then sharply excised, with a typical specimen weight of 3 to 8 g (**FIG 9**). Minor bleeding from the cut edge of the middle scalene muscle should be controlled with sutures rather than the electrocautery to avoid thermal injury to the C8 nerve root or long thoracic nerve.

First Rib Resection

- Once the scalenectomy has been completed, the intercostal muscle attaching to the lateral edge of the 1st rib is separated from the bone with the electrocautery. The 1st rib is fully exposed posteriorly, where the T1 nerve root emerges from underneath the bone to join the C8 nerve root in forming the lower trunk of the brachial plexus. A right-angle clamp is passed underneath the posterior neck of the 1st rib and gently spread to detach additional intercostal tissues. A modified Stille-Giertz rib cutter is inserted around the neck of the 1st rib. After verifying protection of the C8 and T1 nerve roots, the bone is sharply divided. A Kerrison bone rongeur is used to smooth the posterior end of the bone, to a level medial to the underlying T1 nerve root, and the end of the bone is sealed with bone wax (**FIG 9**).
- The free end of the divided posterior 1st rib is elevated, and blunt fingertip dissection is used to separate the remaining extrapleural fascia and intercostal muscle attaching to the undersurface of the rib, progressing anteriorly to the level of the scalene tubercle (the previous site of attachment of the anterior scalene muscle). No effort is made to avoid opening the pleura during 1st rib resection, as the opened pleural space will allow better drainage of postoperative fluids away from the brachial plexus (which might otherwise promote perineural adhesions).
- The soft tissues underneath the clavicle, including the subclavian vein, are elevated with a small Richardson retractor. The posterior 1st rib is displaced inferiorly with fingertip pressure to open the anterior costoclavicular space, and the subclavian artery and brachial plexus are displaced laterally with a small malleable retractor. The Stille-Giertz rib cutter is placed around the anterior 1st rib, immediately medial to the scalene tubercle (**FIG 10**). The 1st rib is then divided under direct vision, and the intact specimen is extracted from the operative field (**FIG 11**). The remaining anterior end of the 1st rib is remodeled to a smooth surface with a bone rongeur, to a level well underneath the clavicle. Oxidized cellulose fabric (Ethicon, Inc., Somerville, NJ) is placed within the bed of the resected 1st rib as a topical hemostatic agent.
- Cervical ribs arise within the plane of the middle scalene muscle, posterior to the brachial plexus and subclavian artery and anterior to the long thoracic nerve. Incomplete cervical ribs typically have a ligamentous extension to the 1st rib, whereas complete cervical ribs attach to the lateral 1st rib in the form of a true joint. The posterior portion of a cervical rib is thereby readily encountered during dissection of the middle scalene muscle and is divided in a manner similar to the posterior 1st rib. The anterior attachment of the cervical rib is then divided and the bone is removed prior to 1st rib resection. When there is a true joint between a complete cervical rib and the 1st rib, the anterior portion of the cervical rib is left attached while the 1st rib resection is completed, and the two are removed together as a single specimen (**FIG 11**).

Brachial Plexus Neurolysis

- The last step of supraclavicular decompression is to fully mobilize each of the individual nerve roots contributing to the brachial plexus. Each nerve root from C5 to T1 is meticulously dissected free of any adherent perineural fibrous scar tissue that might impair

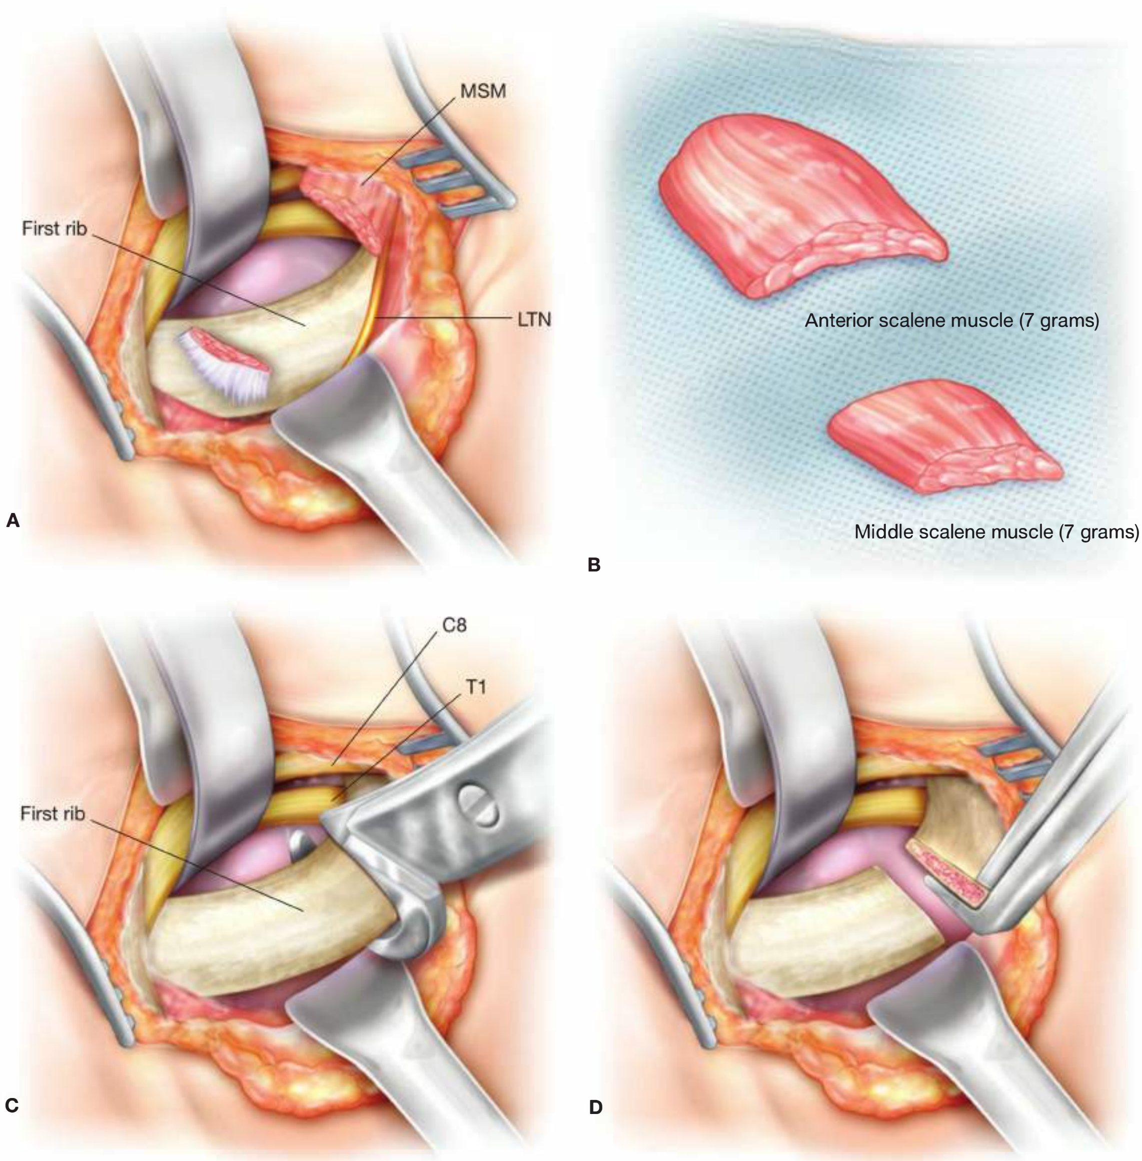

FIG 9 ● **A.** After detaching the middle scalene muscle (MSM) from the top of the posterolateral 1st rib using the electrocautery, the muscle tissue lying anterior to the long thoracic nerve (LTN) is excised. **B.** Typical operative specimens of the anterior and middle scalene muscles. **C.** The posterior 1st rib is exposed with visualization of the C8 and T1 nerve roots, and the rib is divided with a modified Giertz-Stille rib cutter. **D.** The posterior edge of the 1st rib is further remodeled with a Kerrison rongeur to obtain a smooth edge immediately medial to the T1 nerve root.

mobility (external neurolysis). Inspection of the most proximal aspect of the C8 and T1 nerve roots will often reveal a small fibrofascial band overlying these nerves, which should be specifically sought out and resected. This aspect of the operation is not considered complete until each nerve root has been completely cleared throughout its course in the operative field (**FIG 12**).

Drain Placement and Closure

- Upon the completion of supraclavicular decompression, the apex of the pleural membrane is opened to promote postoperative drainage of fluid into the chest cavity, away from the brachial plexus. 19-Fr closed suction drain is placed through a separate stab wound into the operative field, placed posterior to the brachial plexus with its

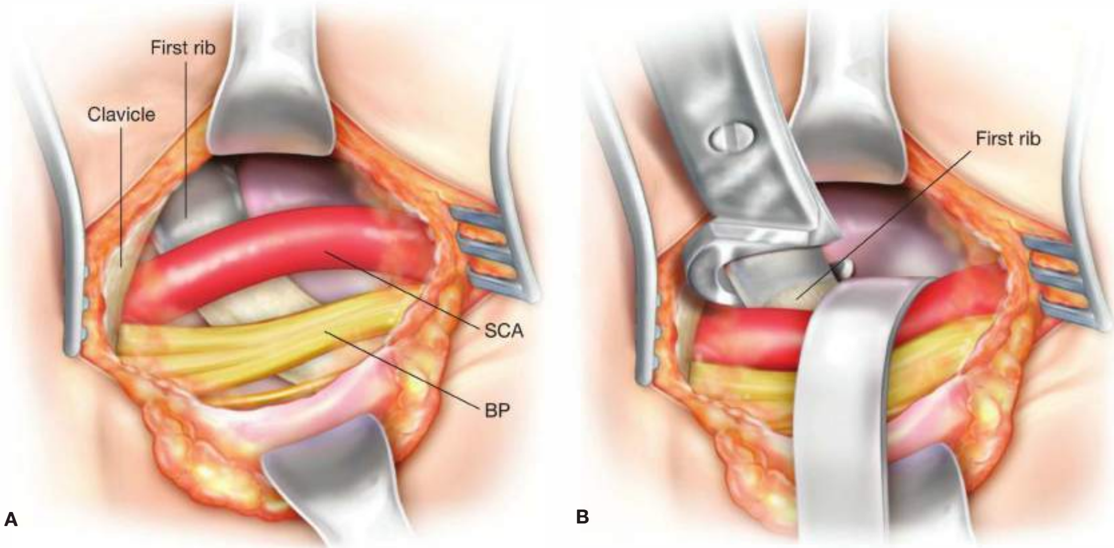

FIG 10 ● **A.** With the posterior end of the 1st rib pushed downward to open the anterior costoclavicular space, the anterior portion of the 1st rib is exposed underneath the clavicle and the subclavian vein. **B.** The subclavian artery (SCA) and brachial plexus (BP) are protected, and the anterior 1st rib is divided with a rib cutter immediately medial to the scalene tubercle.

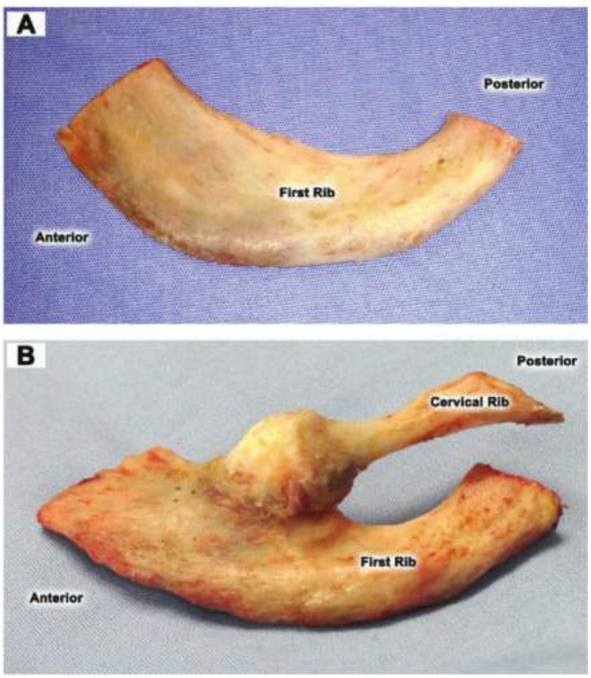

FIG 11 ● Operative specimens following 1st rib resection **(A)** and following combined resection of a cervical rib and 1st rib **(B)**.

tip extending into the posterior pleural space. Two multihole perfusion catheters are placed within the wound, positioned adjacent to the brachial plexus and within the bed of the resected 1st rib, and connected to an osmotic pump for continuous postoperative infusion of local anesthetic (0.5% bupivacaine for 3 days). A bioresorbable polylactide film (Ethicon, Inc., Somerville, NJ) is placed around the brachial plexus to suppress development of postoperative perineural fibrosis and held in place with several 5-0 polydioxanone sutures. The scalene fat pad is restored to its anatomic position overlying the brachial plexus and held in place with several tacking sutures to the back of the sternocleidomastoid muscle and to the periclavicular subcutaneous fascia. The platysma muscle layer is reapproximated with interrupted sutures and the skin is closed with an absorbable subcuticular stitch.

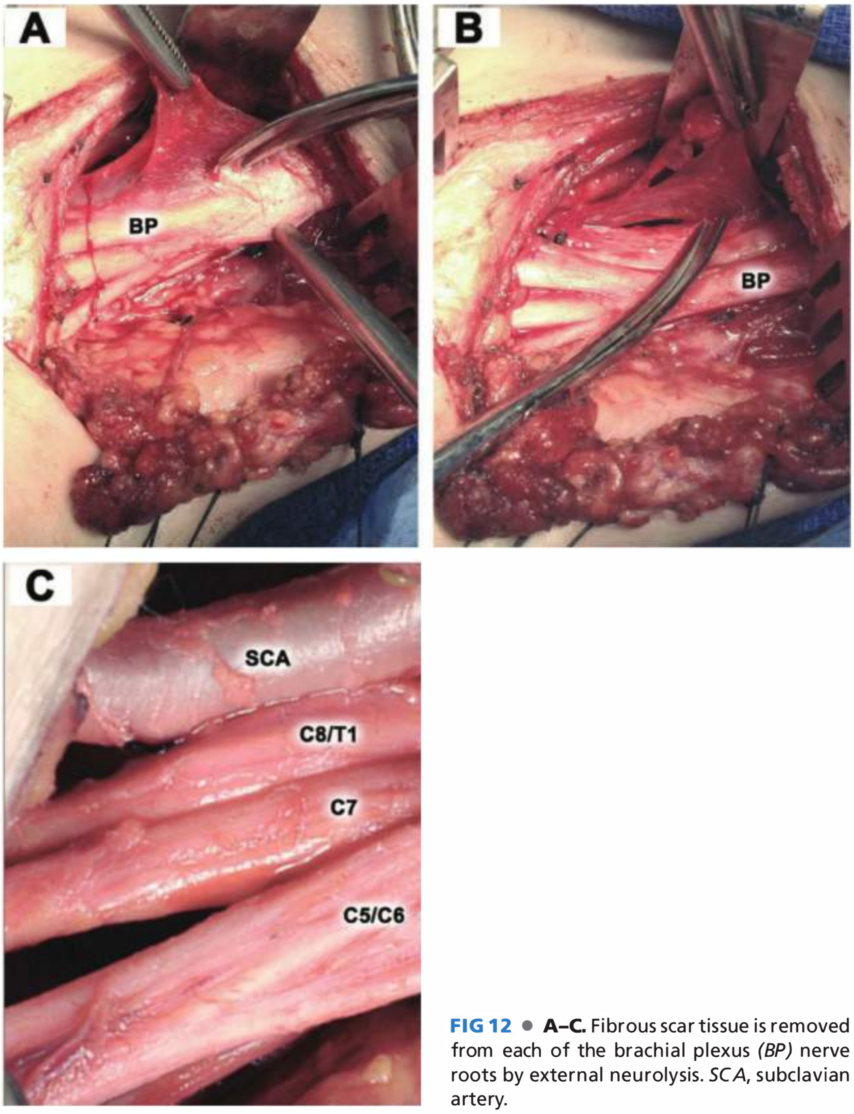

FIG 12 ● **A–C.** Fibrous scar tissue is removed from each of the brachial plexus *(BP)* nerve roots by external neurolysis. *SCA*, subclavian artery.

PECTORALIS MINOR TENOTOMY

Incision and Exposure

- A short vertical incision is made in the deltopectoral groove, beginning at the level of the coracoid process. The deltoid and pectoralis major muscles are gently separated and the plane of deeper dissection is carried medial to the cephalic vein. The lateral edge of the pectoralis major muscle is gently lifted with a small Deaver retractor, and the plane underneath the muscle is separated from the underlying fascia by blunt fingertip dissection. The fascia over the pectoralis minor muscle is exposed, where the muscle can be easily identified by palpation (**FIG 13**).

Division of the Pectoralis Minor Muscle Tendon

- The pectoralis minor muscle tendon is identified where it extends from the anterior chest wall to the coracoid process. The fascia along its medial border is opened and the muscle is encircled using blunt fingertip dissection. The fascia along the lateral border of the pectoralis minor muscle is opened to ensure its separation from the short head of the biceps muscle, which also inserts on the coracoid process. Taking care to protect the underlying neurovascular bundle, the pectoralis minor tendon is then elevated with umbilical tape or rubber tubing and its insertion on the coracoid process is exposed with a small Richardson retractor. A finger is placed behind the muscle to prevent thermal

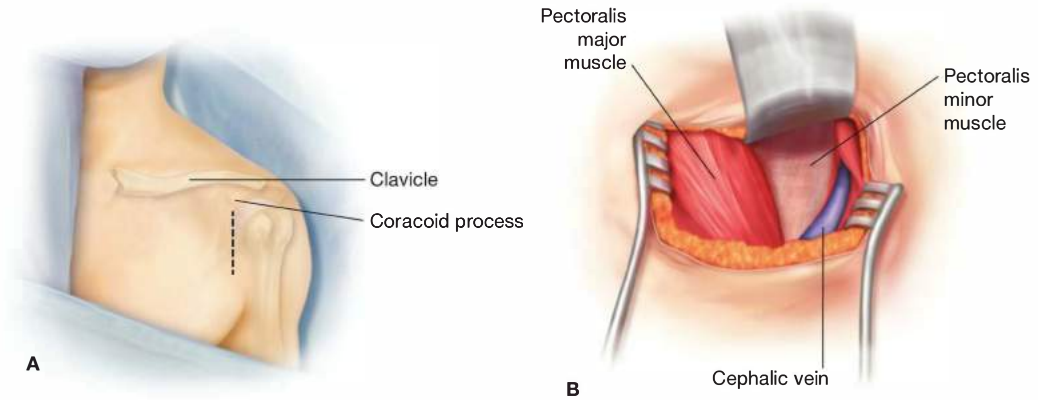

FIG 13 ● **A.** Pectoralis minor tenotomy is performed through a short vertical incision in the deltopectoral groove just below the coracoid process. **B.** The plane of dissection is carried medial to the cephalic vein, and the pectoralis major muscle is lifted to expose the fascia over the pectoralis minor muscle.

injury to the neurovascular structures and the insertion of the pectoralis minor tendon is divided with the electrocautery. After the pectoralis minor muscle has been divided, the lower edge will retract inferiorly to release any compression of the neurovascular bundle (**FIG 14**).

- The inferior edge of the divided pectoralis minor muscle is oversewn with a running suture to ensure hemostasis and to facilitate contraction of the muscle underneath the pectoralis major muscle. The remaining clavipectoral fascia is also incised to the level of the clavicle, along with any other anomalous fascial bands that might be present over the brachial plexus, such as Langer's axillary arch, but no further dissection of the brachial plexus nerves or the axillary vessels is performed. The edge of the pectoralis major muscle is infiltrated with a long-acting local anesthetic and the wound is irrigated, then closed in layers without a drain.

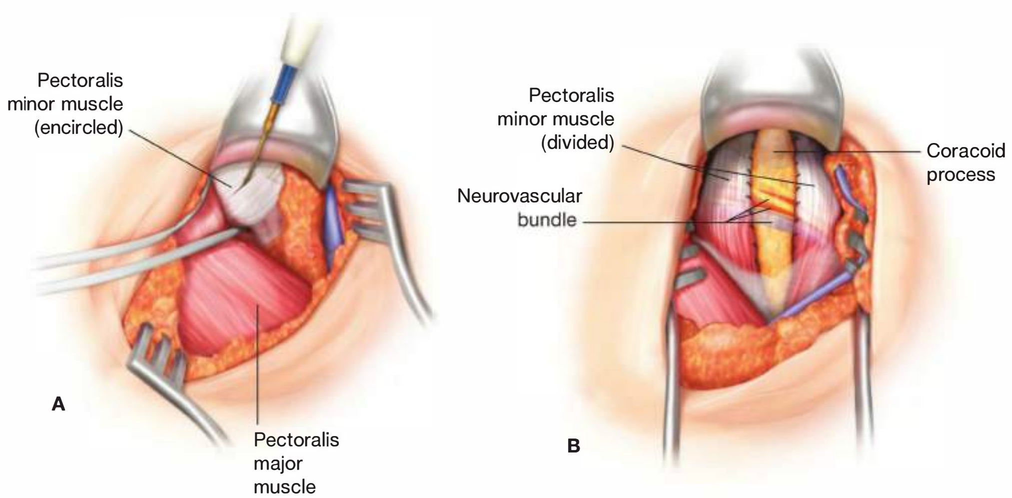

FIG 14 ● **A.** The pectoralis minor muscle is encircled near its insertion on the coracoid process and then divided with the electrocautery. **B.** The retracted edge of the divided pectoralis minor muscle is oversewn with a continuous suture.

PEARLS AND PITFALLS

Indications	■ Operative treatment of NTOS should be based on a sound clinical diagnosis, a substantial level of disability, and failure of symptoms to improve with an adequate trial of conservative management. ■ Imaging studies, electrophysiologic tests, and vascular laboratory examinations add little in the evaluation of NTOS but may be useful in excluding other conditions. ■ A positive anterior scalene muscle block supports the diagnosis of NTOS and indicates a strong likelihood of responsiveness to surgical treatment. ■ Assess the potential contribution of brachial plexus compression at the level of the subcoracoid space and include pectoralis minor tenotomy if present.
Mobilization of the scalene fat pad	■ Avoid division of the sternocleidomastoid muscle. ■ Proper mobilization and lateral reflection of the scalene fat pad is a key step in simplifying supraclavicular exposure for thoracic outlet decompression. This permits the critical view to be obtained in which all of the relevant structures can be visualized in the same operative field (internal jugular vein, phrenic nerve, anterior scalene muscle, brachial plexus, middle scalene muscle, 1st rib, and long thoracic nerve). ■ Ligate and divide the thoracic duct, if necessary, to prevent postoperative lymph leak. ■ Visualize and protect the phrenic nerve.
Anterior scalenectomy	■ Divide all fibers passing from the posterior aspect of the anterior scalene muscle to the subclavian artery and extrapleural fascia. ■ Divide any scalene minimus muscle encountered. ■ Pass the anterior scalene muscle underneath the phrenic nerve to facilitate dissection of the muscle up to its superior origin on the C6 transverse process.
Mobilization of the brachial plexus	■ Visualize all five nerve roots of the brachial plexus. ■ Ligate and divide the transverse cervical vessels where they pass through the brachial plexus and middle scalene muscle.
Middle scalenectomy	■ Visualize and protect the long thoracic nerve. ■ Control minor bleeding from the cut edge of the muscle with silk sutures rather than electrocautery.
1st rib resection	■ Visualize the T1 and C8 nerve roots at the level of the posterior 1st rib, prior to division of the bone, to avoid nerve injury. ■ Remove a small segment of the divided posterior 1st rib to facilitate fingertip dissection underneath the remaining lateral and anterior portions of the bone. ■ Do not try to avoid opening the pleura. ■ Divide the anterior 1st rib at a level medial to the scalene tubercle, underneath the clavicle and subclavian vein, while protecting the subclavian artery and brachial plexus. ■ Resect any cervical rib present along with the 1st rib.
Brachial plexus neurolysis	■ Thoroughly remove fibrous scar tissues from around each nerve root (C5 to T1) of the brachial plexus to avoid one of the causes of persistent symptoms. ■ Resect any small fibrofascial bands overlying the proximal aspect of the C8 and T1 nerve roots.
Drain placement and closure	■ Wrap the brachial plexus with a bioresorbable film to minimize perineural fibrosis. ■ Place a closed suction drain behind the brachial plexus with its tip extending into the pleural space. ■ Use continuous postoperative infusion of a local anesthetic to diminish the need for opiate pain medications.
Pectoralis minor tenotomy	■ Include pectoralis minor tenotomy as part of the supraclavicular decompression if there are concomitant symptoms of NTOS referable to the subcoracoid space. ■ Divide the pectoralis minor tendon close to its insertion on the coracoid process. ■ Oversew the divided edge of the pectoralis minor muscle for hemostasis. ■ It is not necessary to place a separate drain in the subcoracoid space.

POSTOPERATIVE CARE

- An upright chest radiograph is performed in the recovery room and each morning for 3 days, and any small air or pleural fluid collections are observed with the expectation of spontaneous resolution. Postoperative analgesia is provided by continuous-infusion perineural local anesthesia (discontinued on postoperative day 3) and patient-controlled intravenous opiates until adequate pain control is achieved by oral medications alone. Oral narcotics, a muscle relaxant, and a nonsteroidal antiinflammatory agent are routinely prescribed at hospital discharge and for at least several weeks following surgery. Postoperative hospital stay is typically 3 to 4 days. The closed suction drain is removed in the outpatient office when its output is less than 50 mL per day, usually 5 to 7 days after surgery.
- Physical therapy is resumed the day after surgery to maintain range of motion and limit muscle spasm. The patient is allowed to use the extremity as tolerated, with no use of a sling or other restraint. Physical therapy is continued after hospital discharge, with advice to avoid excessive reaching overhead or heavy lifting with the affected upper extremity and other

activities that might result in muscle strain, spasm, and significant pain in the sternocleidomastoid, trapezius, and other neck muscles. Further rehabilitation is overseen by a physical therapist with expertise in the management of NTOS, usually in conjunction with a physical therapist located near the patient, emphasizing a gradual steady return to normal use of the upper extremity.

- The majority of patients are permitted cautious light duty work activities by 4 to 6 weeks. Restrictions on upper extremity activity are progressively lifted between 6 and 12 weeks, when recovery from surgery is typically considered complete. Patients are seen in follow-up every 3 months in the first year to assess long-term results. Physical therapy and other aspects of care are continued as long as necessary to achieve an optimal level of function.

OUTCOMES

- In properly selected patients with disabling NTOS, approximately 80% to 85% can expect a substantial improvement in symptoms and increased functional use of the upper extremity within several months of supraclavicular decompression.[1–3,19] This estimate is elevated to approximately 90% to 95% in those who exhibited a positive anterior scalene/pectoralis minor muscle block prior to treatment. Factors that tend to diminish responsiveness to treatment include extremely long-standing (>5 years) and debilitating symptoms, widespread pain syndromes, multiple previous operations (cervical spine, shoulder, or peripheral nerves), depression, older age (>50 years), and preexisting use of opiate pain medications.
- Patients with long-standing NTOS can often display residual symptoms that may not be completely eliminated by thoracic outlet decompression. Although these symptoms may be tolerable and are expected to gradually improve, the surgeon must provide continuing support and reassurance during the prolonged period of recovery and rehabilitation.
- Patients in the adolescent age-group (<21 years) tend to have even better outcomes than adults, based on assessment of patient-reported survey instruments and postoperative use of opiate pain medications.[14] Patients that have been selected for isolated pectoralis minor tenotomy can exhibit early outcomes similar to those of patients that have undergone combined supraclavicular decompression and pectoralis minor tenotomy but require ongoing follow-up for recurrent symptoms to determine if supraclavicular decompression may be warranted at a later time.[17,18]
- Recurrent symptoms of NTOS that might warrant reoperation occur in 1% to 2% of patients, usually within the first 2 years of treatment. Reoperations for NTOS are generally performed using the supraclavicular approach, because this provides the most complete exposure of the anatomy with the greatest margin of safety.[20] Following lateral reflection of the scalene fat pad, the brachial plexus nerve roots are carefully exposed and mobilized. Great care must be taken during this dissection to avoid nerve and blood vessel injury, given the dense fibrous scar tissue that is usually present within the operative field. Any structures that were retained at the initial operation are then resected, including the scalene muscles, anomalous fibrofascial bands, and/or the 1st rib. A complete brachial plexus neurolysis is performed and the nerves are protected with a bioabsorbable film and soft tissue coverage with the scalene fat pad.

COMPLICATIONS

- Persistent pain, numbness, and/or paresthesias
- Postoperative bleeding, localized hematoma, or hemothorax
- Wound infection (cellulitis or abscess)
- Pleural effusion (serosanguineous)
- Persistent lymph leak, chylothorax
- Brachial plexus nerve dysfunction (temporary or sustained)
- Phrenic nerve dysfunction (temporary or sustained)
- Long thoracic nerve dysfunction (temporary or sustained)
- Recurrent NTOS

Chapter 8

Neurogenic Thoracic Outlet Syndrome Exposure and Decompression: Transaxillary

George J. Arnaoutakis   Thomas Reifsnyder   Julie Ann Freischlag

DEFINITION

- In 1821, Sir Astley Cooper recognized the constellation of neurovascular symptoms involving the thoracic outlet. Ochsner called this the *scalenus anticus syndrome* in 1936 and described the presence of muscle abnormalities secondary to repetitive trauma. Peet assigned this condition its contemporaneous moniker *thoracic outlet syndrome (TOS)* in 1966.[1]
- TOS is a condition defined as compression of one or more of the neurovascular structures contained within the thoracic outlet.
- The thoracic outlet is a narrowly defined anatomic region encompassing the space between the neck and the shoulder, cephalad to the thoracic cavity, and beneath the clavicle. From the surgeon's point of view the thoracic outlet can be visualized as an anatomic triangle: the two sides being the anterior and middle scalene muscles with the 1st rib serving as the base of the triangle. The scalene muscles, which originate from the lower cervical spine, may hypertrophy with repetitive neck motion or minor trauma. This hypertrophy is believed to contribute to compression of thoracic outlet structures.
- TOS is subdivided into three discrete entities.
  - Neurogenic
  - Venous
  - Arterial
- Appropriate classification of the type of TOS is important in guiding perioperative management, as well as surgical approach. This chapter focuses on transaxillary decompression and 1st rib resection for neurogenic TOS.

DIFFERENTIAL DIAGNOSIS

- Carpal tunnel syndrome
- Ulnar nerve compression
- Rotator cuff tendinitis
- Pectoralis minor syndrome
- Cervical spine strain
- Cervical disc disease
- Cervical arthritis
- Brachial plexus injury
- Fibromyositis

PATIENT HISTORY AND PHYSICAL FINDINGS

- A careful history and physical examination enables proper classification of TOS.
- The neurogenic form accounts for the majority of cases in modern series (>95%).[2] Symptoms of neurogenic TOS, which is more prevalent in women, include paresthesia; pain; and impaired strength in the affected shoulder, arm, or hand along with occipital headaches and neck discomfort. There is commonly an antecedent history of hyperextension neck injury or repetitive neck trauma. Patients frequently manifest tenderness on palpation in the supraclavicular fossa over the anterior scalene muscle. A careful vascular physical examination should confirm the presence of normal circulation.
  - Three physical examination maneuvers support the diagnosis of neurogenic TOS.
    - Rotation of the neck and tilting of the head to the opposite side elicit pain in the affected arm.
    - The upper limb tension test in which the patient first abducts both arms to 90 degrees with the elbows in a locked position, then dorsiflexes the wrists, and finally, tilts the head to the side. Each subsequent step imparts greater traction on the brachial plexus, with the first two positions causing discomfort on the ipsilateral side and the head-tilt position causing pain on the contralateral side.
    - During the elevated arm stress test (EAST), the patient raises both arms directly above the head and repeatedly opens and closes the fists. Characteristic upper extremity symptoms arise within 60 seconds in patients with neurogenic TOS.
- Approximately 4% of patients with TOS present with venous involvement. **Venous TOS** patients typically present with acute onset of dull aching pain of the upper extremity associated with arm edema and cyanosis. Paresthesias may be present but are due to hand swelling instead of thoracic outlet nerve involvement. A history of strenuous and repetitive work or athletics involving the affected extremity is common, and most patients are young. This specific condition is also known as Paget-Schroetter syndrome or effort vein thrombosis, as the entrapped subclavian vein has progressed to thrombosis. Some patients will present less acutely with nonthrombotic subclavian vein occlusion or stenosis manifested by intermittent swelling with activity. Regardless, the etiology of venous TOS is mechanical, and treatment is ultimately aimed at eliminating not only the venous obstruction but also the muscular bands and ligaments that have entrapped and damaged the vein.
- **Arterial TOS** typically presents in one of three ways: (1) asymptomatic, (2) arm claudication, and (3) critical ischemia of the hand. The majority of these patients have a cervical rib, which may or may not be fused to the 1st rib and is most commonly posterior to the subclavian artery. The etiology is chronic repetitive injury to the subclavian artery as it exits the thoracic outlet. This injury may cause subclavian artery stenosis but more commonly leads to ectasia or a true aneurysm.
  - In asymptomatic patients, a pulsatile mass or supraclavicular bruit can be detected on physical examination.
  - Arm claudication is caused by areas of stenosis which may be static due to long-standing repetitive injury or dynamic, occurring only with arm abduction or extension.

- Critical ischemia is due to emboli of fibrinoplatelet aggregates that originate from an ulcerated mural thrombus in the aneurysmal segment.

PREOPERATIVE EVALUATION AND OTHER DIAGNOSTIC STUDIES

- In young patients (<40 years of age) with a classic presentation of neurogenic TOS, there is no need for extensive preoperative testing.
- Older patients and those with a history of neck trauma should undergo magnetic resonance imaging (MRI) to rule out cervical disc pathology.
- Preoperative physical therapy should be attempted for at least 8 weeks in patients with a diagnosis of neurogenic TOS. The aims of therapy are to improve posture and achieve greater range of motion. Patients with persistent symptoms of neurogenic TOS despite 8 weeks of physical therapy merit surgical intervention. At least 60% of patients will improve with physical therapy and lifestyle alterations.
- A radiographically guided anterior scalene block with local anesthetic (lidocaine) injection may provide a few hours of symptomatic relief. Patients with suspected neurogenic TOS often present with a wide constellation of physical complaints, not all of which are directly attributable to the disorder. A scalene block not only helps confirm the diagnosis but also simulates the expected postoperative result, especially in older patients.[3] This provides the patient and the surgeon reassurance that surgical intervention will be of benefit and demonstrates which symptoms can be reliably expected to improve.
- As an alternative to surgical therapy, patients can then opt for a Botox (Allergan, Irvine, CA) injection. The Botox takes an average of 2 weeks to work and may be repeated. This may provide symptomatic relief for 2 to 3 months, allowing participation in physical therapy. However, not all TOS patients respond to Botox. This practice is especially helpful in patients who have had cervical spine fusions or shoulder operations as they can strengthen the muscles of their neck and back, which may alleviate the TOS symptoms.
- Plain film chest x-ray is recommended for all patients undergoing surgical intervention for TOS to rule out a cervical rib.
- Nerve conduction studies are typically normal in neurogenic TOS but may be useful in ruling out nerve compression such as carpal tunnel or cubital compression syndrome.
- Duplex ultrasonography is the initial diagnostic modality to confirm pathology in patients with arterial TOS. Although useful to confirm axillosubclavian vein thrombosis in patients with suspected venous TOS, venography often supplants it for both diagnostic and therapeutic reasons. Lastly, venous TOS is frequently bilateral.

SURGICAL MANAGEMENT

Surgical Approach

- Patients with a diagnosis of TOS who are appropriate surgical candidates should undergo surgical decompression of the thoracic outlet.
- The optimal approach should be individualized depending on the patient's symptoms, anatomy, and surgeon's experience.
- The transaxillary approach is preferred by many surgeons because of its relative ease, low-risk profile, and documented improvement in patients' quality of life.[4,5] This approach effectively decompresses the thoracic outlet and is generally reserved for patients with neurogenic or venous TOS.
- If vessel reconstruction is anticipated, a different approach should be considered as the transaxillary approach limits vessel exposure.

Surgical Anatomy

- The subclavian artery and the five nerve roots (C5–T1) to the brachial plexus are located within the thoracic outlet. The artery courses anterior to the brachial plexus nerve roots and exits the mediastinum in its course over the 1st rib behind the posterior border of the anterior scalene muscle. The cervical spine nerve roots join to form the initial trunks of the brachial plexus within the thoracic outlet and are located posterior to the subclavian artery. Subsequent merging and branching of these trunks into divisions, cords, and terminal nerves occurs outside the thoracic outlet.
- Other significant nerves within the thoracic outlet are the phrenic and long thoracic nerves.
  - The phrenic nerve receives fibers from C3–C5 and courses in a descending oblique direction from the lateral to the medial edge of the middle portion of the anterior scalene muscle. The phrenic nerve approaches the mediastinum posterior to the subclavian vein.
  - The long thoracic nerve, composed of nerve fibers from C5–C7, passes through the center of the middle scalene muscle and heads toward the chest wall to innervate the serratus anterior muscle.
- The subclavian vein technically does not course through the thoracic outlet. It passes over the 1st rib anterior to the anterior scalene muscle. However, the middle segment of the vein remains susceptible to compression between the anteromedial 1st rib, clavicle, and the subclavius muscle (**FIG 1**). Hypertrophy of the subclavius muscle and tendon may occur in athletes and is often implicated in venous TOS.
- Several anatomic anomalies are relevant to the surgeon, as they predispose patients to the development of TOS.
  - The most common is a cervical rib, and a preoperative chest radiograph is adequate for its detection. When present, cervical ribs appear as extensions of the transverse process of C7. Cervical ribs may be complete or partial, with the anterior end attaching to the 1st rib or floating freely. Additionally, the anterior end may be fibrous and not calcified and thus not completely visualized on chest radiograph. By rigidly confining the thoracic outlet, cervical ribs render the neurovascular structures more prone to compression. Although present in the general population with an incidence of 0.5% to 1%, they are found in 5% to 10% of all TOS patients.
  - A prominent C7 transverse process or bifid 1st rib is also associated with TOS.

Positioning

- General endotracheal anesthesia is induced and sequential compression devices are applied.

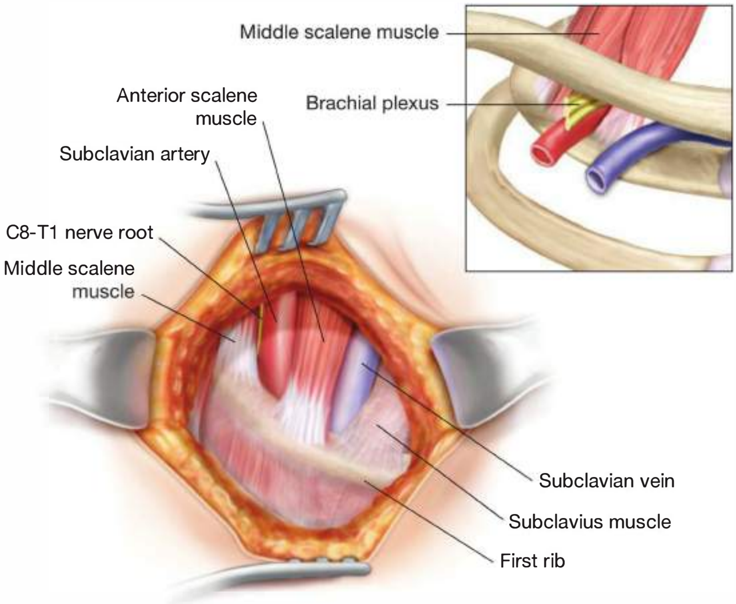

FIG 1 ● Right-sided thoracic outlet anatomy from the surgeon's perspective as viewed through the operative field in a transaxillary approach. *Inset*, normal anatomic relationships of important thoracic outlet structures.

- The patient is then moved to the lateral decubitus position using a beanbag to facilitate positioning.
  - Care should be taken to pad the dependent axilla and support the head. The sterile field incorporates the arm, axilla, and shoulder.
- An adjustable Machleder arm support is affixed to the operating table with the vertical support bar attached to the operating table at the level of the patient's chin.
  - Generous padding around the patient's arm prior to placement in the arm holder protects the median and ulnar nerves from compression as they cross the elbow joint (**FIG 2**).

FIG 2 ● A photograph depicting proper patient positioning for right transaxillary 1st rib resection and use of the Machleder arm support with generous padding to prevent compression nerve injury. A padded axillary roll is placed under the dependent (left) axilla, and the patient is stabilized in the left lateral decubitus with the aid of a beanbag. The *dashed line* indicates the preferred location of the skin incision. (Reprinted from Arnaoutakis G, Freischlag JA, Reifsnyder T. Transaxillary rib resection for thoracic outlet syndrome. In: Cambria R, Chaikof E, eds. *Atlas of Vascular and Endovascular Surgery: Anatomy and Technique*. Philadelphia, PA: Elsevier; 2014:193–203, with permission from Elsevier.)

INCISION

- Prophylactic antibiotics are administered. A first-generation cephalosporin is preferred. In patients with penicillin allergy, clindamycin or vancomycin is used.
- After securing the arm in the retractor, the surgeon identifies the anterior border of the latissimus dorsi muscle and the posterior surface of the pectoralis major muscle.
- A transverse skin line incision should be made in the inferior axillary hairline extending between these two muscle borders.

EXPOSURE

- Electrocautery is used to divide the subcutaneous tissue until thin areolar tissue superficial to the chest wall is encountered. A self-retaining Cerebellar or Weitlaner retractor is then inserted into the wound. Upon encountering the chest wall—and if in the correct anatomic plane—gentle blunt dissection with the surgeon's fingers or a pair of Kittner or peanut dissectors easily separates the soft tissues from the chest wall. This dissection is in a cephalad direction and the 2nd rib will rapidly come into view.

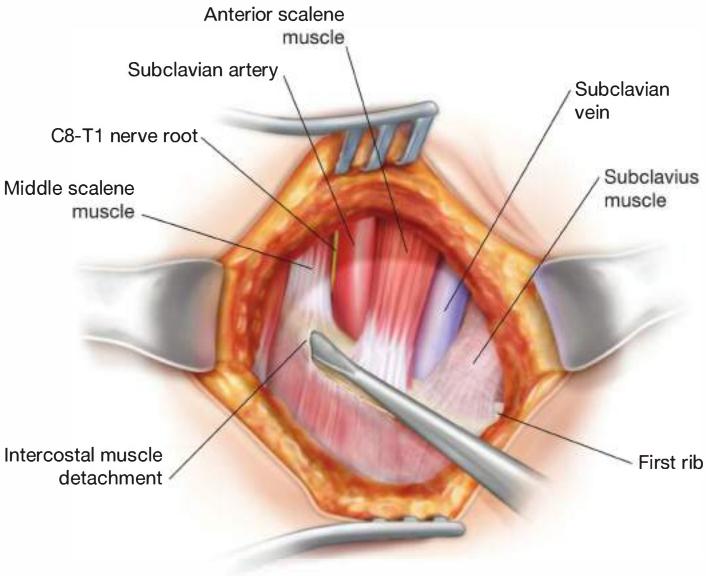

FIG 3 ● A periosteal elevator is used to dissect along the superior surface of the 1st rib in order to divide intercostal muscle attachments.

- The intercostobrachial nerve is located in the 2nd intercostal space. Although frequently difficult to avoid, care should be taken not to impart excess traction as injury results in numbness or dysesthesia of the medial aspect of the proximal arm.
- Raising the Machleder arm support at this point allows for optimal access to the 1st rib and thoracic outlet. The aid of fiberoptic-lighted Deaver retractors facilitates visualization during this portion of the dissection. Alternatively, the surgeon should wear a headlight.
- The 1st rib is identified near its insertion at the sternoclavicular joint and generally encountered higher than anticipated. A Kittner or peanut dissector is then used to gently sweep away the loose fibrous tissue overlying the 1st rib partially exposing the brachial plexus, subclavian artery and vein, and scalene muscles. There is occasionally a small branch of the subclavian artery that must be ligated and divided in order to fully expose the operative field.
- The next step is to fully expose the rib. Depending on the patient's anatomy, it generally is easiest to first clear off the intercostal muscles laterally. A Cobb periosteal elevator works best, but any type of long elevator may be used (**FIG 3**). The dissection proceeds in the anterior and posterior directions until all the intercostal muscle attachments are divided from the rib. The elevator can then be used to elevate the 1st rib, thus separating the rib from the underlying parietal pleura. This mobilization should continue from behind the brachial plexus in the posterior direction to beyond the subclavian vein in the anterior direction.
- Attention is then directed to the superior border of the 1st rib, where the periosteal elevator is used to bluntly detach the scalene medius fibers from the rib. The long thoracic nerve courses along the lateral edge of the scalene medius muscle but is generally not visualized. Avoiding sharp dissection and closely adhering to the surface of the rib during blunt dissection prevents injury to the long thoracic nerve.
- The anterior scalene muscle should now be clearly identified as it arises from the medial superior aspect of the 1st rib (**FIG 4**). A right-angled clamp is passed behind the anterior scalene muscle near its insertion on the scalene tubercle. Gently lifting the anterior scalene with the

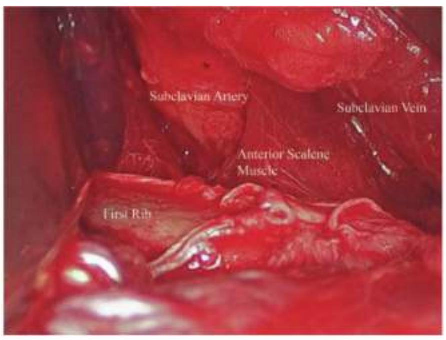

FIG 4 ● An image of the gross anatomy from a close-up perspective of the right-sided thoracic outlet. The important relationships between the 1st rib, anterior scalene muscle, and subclavian vessels can be seen. (Reprinted from Arnaoutakis G, Freischlag JA, Reifsnyder T. Transaxillary rib resection for thoracic outlet syndrome. In: Cambria R, Chaikof E, eds. *Atlas of Vascular and Endovascular Surgery: Anatomy and Technique*. Philadelphia, PA: Elsevier; 2014:193–203, with permission from Elsevier.)

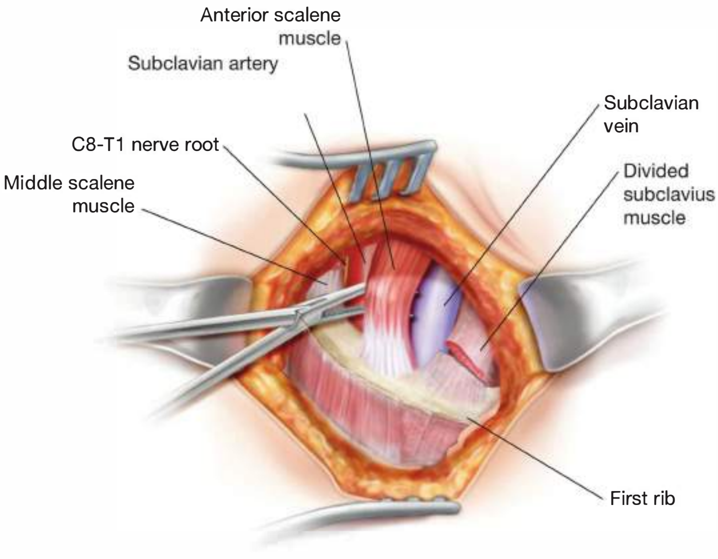

FIG 5 ● A right-angled clamp is insinuated behind the anterior scalene muscle. Gentle elevation pulls the muscle away from the underlying subclavian artery thereby protecting the artery prior to dividing the muscle with scissors. The subclavius muscle is a crescent-shaped ligamentous attachment to the 1st rib adjacent to the subclavian vein. The subclavius muscle is sharply divided with scissors with care not to injure the subclavian vein.

right-angled clamp protects the subclavian artery as it courses posterior to the muscle (**FIG 5**). It is important to free several centimeters of the muscle prior to dividing it with Metzenbaum scissors (**FIG 6**). This maneuver facilitates resection of a portion of the anterior scalene muscle, which has been shown to reduce recurrence rates when compared with division at its insertion point on the rib.

- Lastly, the subclavius muscle will appear as a crescent-shaped ligamentous attachment to the 1st rib adjacent to the subclavian vein. With care not to injure the subclavian vein, the subclavius muscle is sharply divided with scissors.

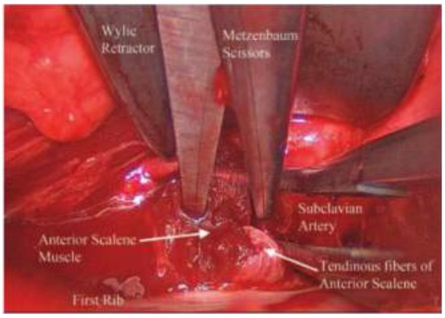

FIG 6 ● The 1st rib is seen in the foreground of the operative photo taken during a left 1st rib resection. Metzenbaum scissors are used to sharply divide the anterior scalene muscle, with the right-angled clamp elevating the muscle to protect the subclavian artery as it courses behind the muscle. The divided ends of the tendinous anterior scalene fibers can be seen. (Reprinted from Arnaoutakis G, Freischlag JA, Reifsnyder T. Transaxillary rib resection for thoracic outlet syndrome. In: Cambria R, Chaikof E, eds. *Atlas of Vascular and Endovascular Surgery: Anatomy and Technique*. Philadelphia, PA: Elsevier; 2014:193–203, with permission from Elsevier.)

RIB RESECTION

- With the rib completely mobilized, a bone cutter is used to divide the 1st rib. Generally, it is divided anteriorly and then posteriorly; however, the patient's body habitus may make the reverse order easier (**FIG 7**).
- In its anterior extent, the rib is divided adjacent to the subclavian vein, and in the posterior direction, it is divided just anterior to the brachial plexus; this ensures that the nerve roots are not inadvertently injured. The rib is then removed.
- A bone rongeur is used to remove residual rib and to smooth the cut ends until there is no residual nerve impingement. A Roos retractor or similar instrument may be used to protect the nerves during use of the rongeur (**FIG 8**).
- It is important to ensure that no residual fibers from the anterior scalene muscle crosses beneath the subclavian artery and inserts onto the thickened surface at the apex of the pleura, known as Sibson's fascia. Any such fibers should be identified and divided.

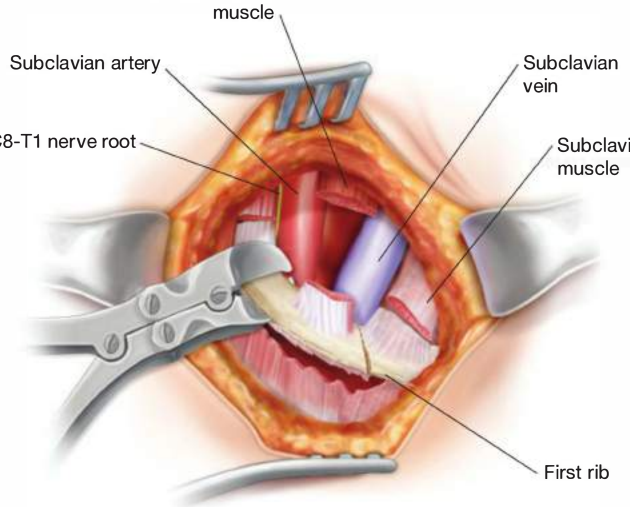

FIG 7 ● A bone cutter is used to divide the 1st rib in its anterior and posterior direction. Once removed, the rongeur is used to achieve smooth rib edges.

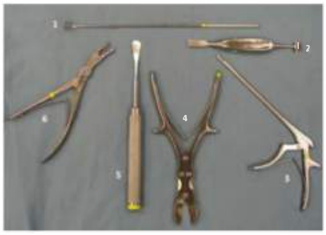

FIG 8 ● From the top of the image in the clockwise direction, the instruments depicted are *(1)* Roos retractor, *(2)* Alexander periosteotome, *(3)* Kerrison punch upbiting instrument, *(4)* double-action bone cutter, *(5)* Cobb periosteal elevator, and *(6)* Rongeur. (Reprinted from Arnaoutakis G, Freischlag JA, Reifsnyder T. Transaxillary rib resection for thoracic outlet syndrome. In: Cambria R, Chaikof E, eds. *Atlas of Vascular and Endovascular Surgery: Anatomy and Technique*. Philadelphia, PA: Elsevier; 2014:193–203, with permission from Elsevier.)

CLOSURE

- The surgical field is next inspected for bleeding. Temporarily packing the wound reliably controls minor bleeding. The wound is then reinspected, and hemostasis is completed with judicious use of electrocautery.
- The wound is then filled with saline. Several positive pressure ventilations are administered with saline left in the wound to assess for an air leak indicative of a postoperative pneumothorax. If an air leak is present, a small caliber (12 French [Fr]) chest tube is warranted prior to closure.
- If the irrigation drains into the pleural space but there is no air leak, the pleura has been breached, but a chest tube may not be necessary. In this situation, a 12- or 14-Fr red rubber catheter is placed into the bed of the 1st rib and attached to gentle suction. The Machleder arm holder is lowered to facilitate a tension-free closure. The subcutaneous fascia is then closed around the tube. While suction is applied to the red rubber catheter, the anesthesia team provides a sustained Valsalva and the fascial suture is tied as the suction tube is rapidly removed. This maneuver generally avoids a clinically significant postoperative pneumothorax.
- Closure is performed with absorbable 2-0 suture in the fascia and a 4-0 subcuticular skin closure.

PEARLS AND PITFALLS

Operative mantra	■ Look twice and cut once. Always double-check placement of the bone cutters before dividing the 1st rib.
Incorrect diagnosis	■ A successful operation hinges on an accurate preoperative diagnosis. A thorough history and physical and the anterior scalene block help to identify patients likely to benefit from 1st rib resection.
Brachial plexus injury	■ Proper positioning and careful retraction help prevent excessive traction and injury to the brachial plexus.
Misidentification of the 1st rib	■ During initial exposure, the 2nd rib is often mistaken for the 1st rib. The cephalad surface of the 1st rib is flat unlike the 2nd, which is more concave.

Incomplete 1st rib resection	■ Incomplete 1st rib resection has been associated with recurrent TOS. After cutting and removing the rib, take your time to trim back the ends with the rongeur.
Hemostasis	■ To keep a clean operative field, pack a 4 × 4 gauze into the wound, lower the arm retractor, and wait a couple of minutes. This often aids in hemostasis.

POSTOPERATIVE CARE

- A chest x-ray is performed in the recovery room.
  - Small, clinically asymptomatic pneumothoraces may be observed with a follow-up chest x-ray the next morning.
- Patients are typically discharged from the hospital when adequate oral analgesia has been achieved.
  - Activity is restricted by the amount of postoperative pain. Occasionally, a sling is required for patient comfort, but it is preferable to have the arm as mobile as tolerated.
- Physical therapy should be prescribed after 2 weeks in all patients undergoing transaxillary 1st rib resection, regardless of the cause, to restore range of motion and strength.

OUTCOMES

- Improvement after surgery for neurogenic TOS is somewhat subjective and based on the patient's perception of disability before and after decompression. Improvement in symptoms exceeds 90%.[6]
- Over time, the durability of these results may decrease, reinforcing the need for close follow-up of these patients beyond 2 years.[7,8]
- Factors that predict surgical failure include major depression, chronic symptoms, work-related injury, lack of response to anterior scalene muscle blocks, and a short segment of divided anterior scalene muscle.[9]

COMPLICATIONS

- **Vascular injury**
  - A national query identified injury to the subclavian vessels as the most common complication following transaxillary rib resection for neurogenic TOS, occurring in 1% to 2% of cases.[4]
  - Patients experiencing a vascular injury have greater lengths of stay as well as increased hospital charges.
  - It is difficult to obtain proximal control of these vessels from the transaxillary approach, and therefore, the surgeon should exercise extreme caution when dissecting near these vessels.
- **Nerve injury**
  - Major nerve injury has been traditionally regarded as the most common complication following surgery for TOS. However, large contemporary series disprove this belief, with rates of brachial plexus injury for patients undergoing transaxillary 1st rib resection approaching 0%.[4,8]
  - Temporary or permanent numbness of the upper medial arm due to excessive traction or division of the intercostobrachial nerve occurs in up to 10%. Frequently, these symptoms will improve over time.
- **Pneumothorax**
  - This complication occurs in 2% to 10% of patients.[8] Accordingly, an upright chest x-ray is routinely performed in the recovery room.
  - Radiographically detected pneumothoraces only require a chest tube if symptomatic or enlarging.
  - Adhering closely to the inferior surface of the 1st rib during blunt dissection will help protect against postoperative pneumothorax.
- **Recurrence**
  - Symptoms of TOS recur in 10% to 20% of patients.[10–12]
  - Two intraoperative factors are known to reduce recurrence rates.
    - Resecting a significant portion (2 to 3 cm) of the anterior scalene muscle as opposed to simply dividing it at its insertion point
    - Ensuring that the posterior edge of the 1st rib is resected sufficiently so as to leave as short a rib stump as technically feasible
  - Patients with spontaneous recurrence compared to those that are reinjured have worse outcomes when reoperation is performed.

Chapter 9 Venous and Arterial Thoracic Outlet Syndrome

Jason T. Lee

DEFINITION

- Venous thoracic outlet syndrome (vTOS), also known as effort thrombosis or Paget-von Schrotter syndrome, involves repetitive subclavian venous compression that leads to endothelial injury and intermittent stasis that ultimately contributes to acute thrombosis of the axillosubclavian venous system. The external compression of the vein occurs between the clavicle and subclavius muscle from above and by the 1st rib and the anterior scalene muscle insertion from below (**FIG 1**).
- Arterial thoracic outlet syndrome (aTOS) is the least common presentation of thoracic outlet syndrome and most often involves subclavian artery compression leading to extrinsic compression, poststenotic dilatation, aneurysmal degeneration, and subsequent distal embolization.[1] Bony and muscular abnormalities are typically present in patients with aTOS and can include a cervical rib, anomalous 1st rib, anterior or middle scalene muscle bands, or hypertrophic callus from a healed clavicular injury or fracture (**FIG 2**).

DIFFERENTIAL DIAGNOSIS

- Compared to neurogenic thoracic outlet syndrome (TOS), vTOS and aTOS are much more straightforward in their diagnostic workup. vTOS patients with swelling must be distinguished from secondary causes of axillosubclavian thrombosis, namely iatrogenic catheterization or instrumentation of the venous system leading to thrombosis, which is obvious upon eliciting a careful history. Also, a hypercoagulable state or malignancy can present as isolated upper extremity venous thrombosis and there is some debate about the need for additional medical workup in patients suspected of having vTOS.[2]

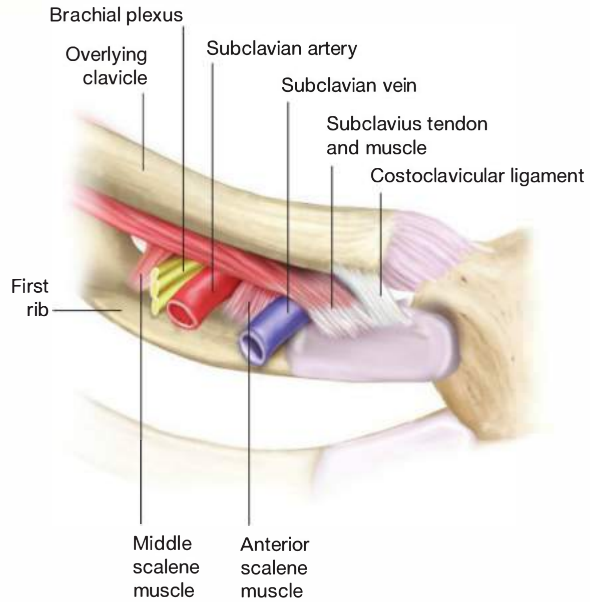

FIG 1 • Normal structures in the thoracic outlet that can contribute to venous compression.

- Because aTOS usually involves distal embolization to the hand from thrombus in a subclavian aneurysm, a thorough workup for a cardiogenic source should be sought before assigning the etiology to aTOS. Transesophageal echocardiography, with bubble enhancement to identify paradoxical

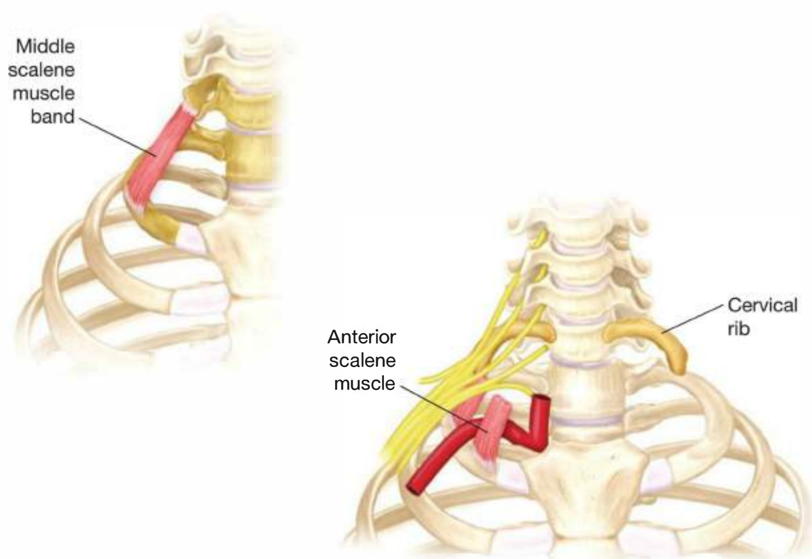

FIG 2 • Abnormal anterior and middle scalene bands and abnormal cervical ribs lead to compression and subsequent poststenotic dilatation of the subclavian artery, causing arterial TOS.

FIG 3 • 18-year-old baseball catcher presenting with arm swelling, pain, cyanosis, and prominent superficial vasculature after a strenuous workout after a game.

emboli, may be necessary to exclude cardiogenic emboli. Computed tomography angiography (CT-A) of the arch and upper extremity vessels would also be reasonable to exclude other arterial causes including axillary branch artery aneurysms, congenital abnormalities, or traumatic injuries and dissections of the axillosubclavian arterial system, which can be seen in high-performance athletes and individuals performing repetitive upper extremity motions.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients with vTOS are young, healthy, and often athletically inclined who present with the abrupt onset of unilateral arm swelling in their dominant arm after repetitive, strenuous use for sport, work, or recreation. Athletes affected can include baseball pitchers, rowers, swimmers, water polo players, weightlifters, volleyball players, surfers, football quarterbacks, or any others relying on repetitive upper extremity effort. The swelling is noted in the shoulder, arm, and hand and can be accompanied by aching, throbbing, or tightness that worsens with more activity. Because most patients are otherwise young and healthy, an orthopedic cause such as strain, muscle pull, or joint injury is often considered initially. Cyanosis of the affected extremity, visible chest wall venous collaterals, or progressively worsening symptoms suggest a vascular etiology, prompting referral to an interventionalist. On exam, the arm is swollen, tender to palpation, warm, and often has visible superficial collaterals that track onto the anterior chest wall (**FIG 3**). Range of motion of the affected extremity can be impeded due to patient discomfort.
- aTOS patients will present with mild hand ischemia due to distal embolization, which manifests as digital ischemia or splinter hemorrhage. The diagnosis is often delayed due to the fact that these patients have no typical atherosclerotic risk factors and are mostly young and athletic. A pulsatile mass or bruit may be present in the supraclavicular fossa or a bony prominence in that region may hint toward a cervical rib or muscular abnormality. Symptoms often are gradual and unnoticed by patients until occurring more frequently or when complete thrombosis occurs and the patient presents with critical upper extremity ischemia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients suspected of having vTOS should undergo duplex ultrasound of the affected area. Axillosubclavian venous imaging can be challenging due to the clavicle's location as well as many of these patients being quite muscular. Color flow duplex, phasicity of flow with respiration, and augmentation with compressive maneuvers can all aid in confirming the diagnosis of deep venous thrombosis (DVT). An experienced vascular sonographer and interpreter can make the diagnosis with high accuracy based on duplex alone. Cross-sectional imaging with magnetic resonance imaging (MRI) or computed tomography (CT) venography is rarely needed or indicated in the workup of vTOS. Catheter-based venography is the key confirmatory imaging study to document the extent of vTOS and leads to the initial recommended therapeutic strategy of thrombolysis and reduction of clot burden.
- Patients presenting with digital ischemia suspicious for aTOS should undergo plain radiographic imaging to assess for a cervical rib (**FIG 4**). Digital plethysmography of bilateral upper extremities can be performed to visualize blood flow to each finger and can rule out Raynaud's type etiologies in the differential diagnosis. Wrist–brachial indices should be documented prior to any further intervention to establish baseline flow characteristics. CT-A of the neck and upper extremity in provocative positioning (arms at 180 degrees overhead) provides the most definitive visualization of the affected region, confirming the presence of the cervical rib, delineating the amount of thrombus in the subclavian aneurysm, and documenting the proximal and distal vasculature for operative planning (**FIG 5**).

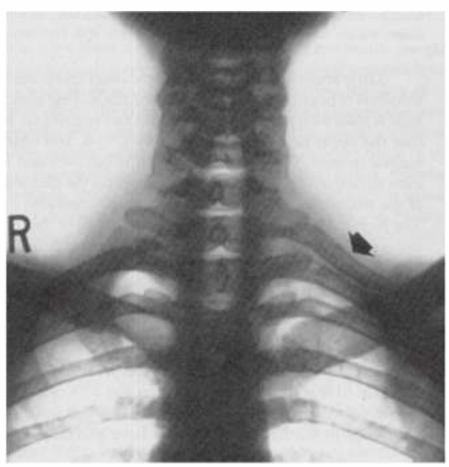

FIG 4 • Chest x-ray demonstrating left cervical rib *(arrow)*.

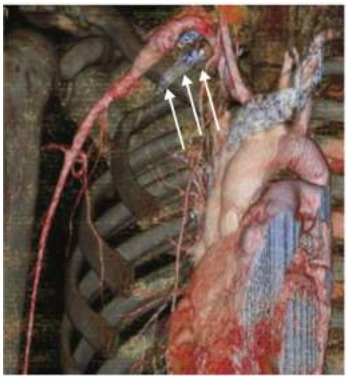

FIG 5 ● CT-A reconstruction of 19-year-old collegiate tennis player with cervical rib *(arrows)* that led to subclavian aneurysm formation. Patient presented with fingertip emboli after playing long matches.

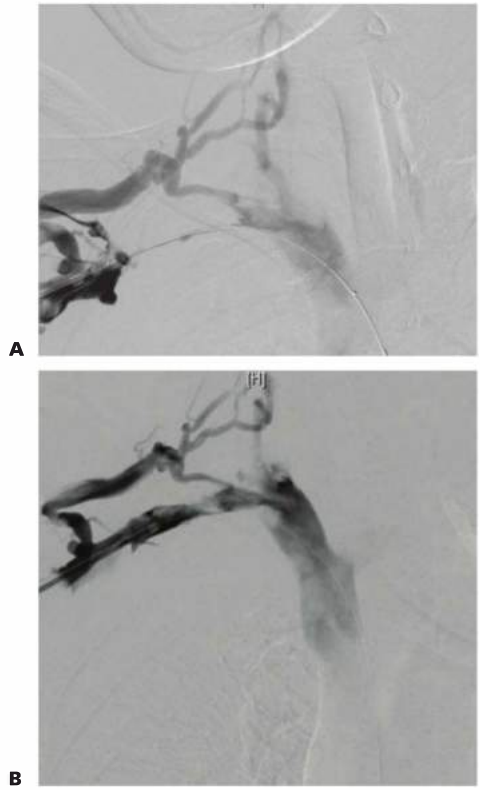

FIG 6 ● **A.** Initial venogram demonstrating right axillosubclavian occlusion with large collateral development. Wire was passed through this region and pharmacomechanical thrombolysis initiated. **B.** Follow-up venogram 24 hours later with resolution of majority of thrombus load. Vein still shows signs of disease and scarring particularly in the region of compression.

SURGICAL MANAGEMENT

Preoperative Planning

- vTOS patients diagnosed with acute axillosubclavian DVT should be anticoagulated with weight-based dosing of unfractionated heparin or low-molecular-weight heparin. Depending on the resource availability, admission for thrombolysis or urgent referral to a center capable of catheter-directed interventions has been generally accepted as standard of care.[3] There are patients that are simply put on anticoagulation that get referred much later (more than 2 weeks) due to lack of recognition of the TOS etiology of the DVT and this leads to a diminished success rate of thrombolysis.[4]
- Successful thrombolysis involves a combination of chemical and mechanical thrombectomy and is often quite effective in decreasing clot burden and reducing long-term sequelae of upper extremity DVT (**FIG 6A,B**). Technical details of thrombolysis are well described and can be performed with minimal morbidity.[5]
- Definitive therapy for vTOS after thrombolysis involves thoracic outlet decompression, consisting of anterior and middle scalenectomy, resection of the subclavius tendon, 1st rib resection, and venolysis or venous reconstruction. Timing of definitive surgery after thrombolysis is somewhat controversial and is limited by anecdotal reports and various surgeon biases.[6] Successful outcomes can be achieved with definitive thoracic outlet decompression performed during the same hospitalization as the thrombolysis[7] and up to 3 months later with nonresolution of mild venous obstructive symptoms,[5] leading some to adopt a more selective approach for offering rib resection. This lack of consensus provides some flexibility in offering definitive surgery as many of these young patients are often student-athletes and cannot miss certain periods of the school year. Management of anticoagulation during this time also impacts decisions about planning surgery, as intolerance to blood thinners or difficulty with maintaining adequate anticoagulation can affect the urgency of the required definitive decompression. If there is a delay in scheduling definitive rib resection, a duplex immediately prior to surgery after successful thrombolysis is important to document the status of the vein during the immediate pre-operative period.
- In contradistinction to the numerous pathways for vTOS surgery planning aTOS in the presence of an ipsilateral cervical rib and subclavian aneurysm presents a strong indication for definitive surgical intervention. Preoperative planning consists mainly of ensuring adequate and healthy vasculature proximal and distal to the diseased segment and determining a bypass route that is reasonable. Extraanatomic bypass via a carotid–subclavian or carotid–axillary with interval ligation may be necessary, depending on the size and length of the subclavian aneurysm and thrombus. Direct repair of the subclavian aneurysm with interposition grafting can be accomplished only when there is a short segment of disease that limits itself to the visualized region in the supraclavicular fossa. The preoperative CT-A provides the best road map to help decide amongst these reconstructive strategies. Endovascular techniques of the subclavian artery such as stent grafting in the setting of aTOS are generally not recommended, given the age of the typical patient, the compression that can occur from scarring even after cervical

or 1st rib decompression, and the likely desire to resume prior activities that often brought about these symptoms in the postoperative period.

Positioning

- vTOS decompression will often involve an infraclavicular incision (some prefer only this incision; some prefer a paraclavicular approach; still others prefer transaxillary), which is facilitated by positioning the patient with a small bump between the shoulder blades and in a "head up" position of 30 degrees. The affected arm is prepped out and placed in a stocking on the side of the patient to allow full movement during the case. This affords the anterior visualization of the 1st rib and particularly the subclavius tendon and costoclavicular ligament for safe and effective decompression. The entire ipsilateral neck, shoulder, arm, and anterior chest wall are prepped into the field as well as a region on the lateral chest wall should there be a small pneumothorax postprocedure.
- aTOS decompression with cervical rib is most often performed with a supraclavicular approach. When arterial reconstruction is planned, preparations should be made for saphenous or femoral vein harvesting.

VENOUS THORACIC OUTLET SYNDROME

Infraclavicular Approach

- A 5-cm transverse incision is made one fingerbreadth below the clavicle, starting along the edge of the sternum travelling laterally, and is carried through the subcutaneous tissue and pectoralis fascia to expose the upper fibers of the pectoralis muscles (FIG 7). Gentle spreading between muscle fibers in this region exposes the anteromedial quadrant of the axillary fat pad and allows easy palpation of the 1st rib. Appropriate retractors can be placed to fully expose the most anterior portion of the 1st rib beneath a layer of axillary fat (FIG 8).
- When the rib is visualized, cautery is used to separate the inferior-lying intercostal musculature from the rib, with curved dissection heading superolaterally along the C curve of the rib (FIG 9). Lung pleura are often visualized immediately beneath the rib and care should be taken to not injure lung parenchyma. Superiorly, the subclavius tendon and costoclavicular ligament are taken down sharply with cautery to free up the anterior portion of the 1st rib from the overhanging

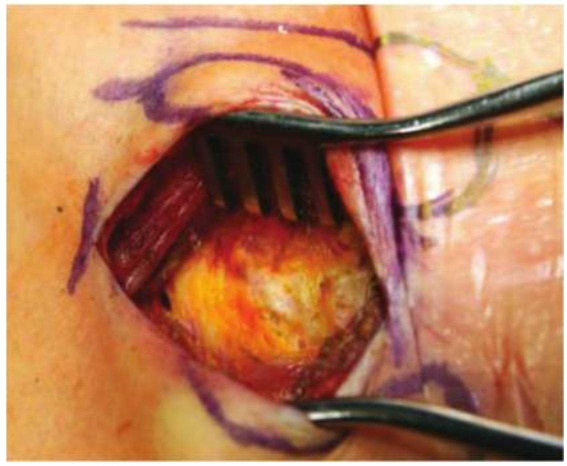

FIG 8 ● Incision is carried down through pectoralis fascia, then the muscle fibers are split until axillary fat that covers the 1st rib is reached.

FIG 7 ● Infraclavicular incision is made one fingerbreadth below clavicle.

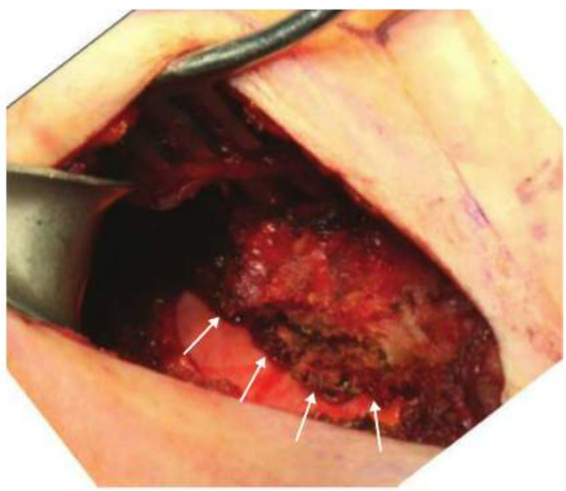

FIG 9 ● Further dissection around the 1st rib involves sharp dissection of intercostal musculature along inferior aspect of 1st rib *(arrows)*.

clavicle. Following along the superior aspect of the 1st rib, the anterior scalene fibers are also sharply taken down and further superior dissection takes place along the lateral edge of the 1st rib until palpation of the subclavian artery is noted. This level is as far necessary to decompress the subclavian vein. Often, moving the arm in a superior position facilitates more superior exposure of the 1st rib near the artery.

- When the rib is clear on its superior, lateral, and inferior edge, a rib cutter can be inserted superiorly, taking care to visualize the jaws, and then the superior cut is made in the rib. The inferior cut is done near the manubrial junction, commonly with a power saw. As the rib is pulled away from the body, sharp cautery can be used to facilitate hemostasis of individual muscle fibers (intercostals, anterior and middle scalene) holding the 1st rib in place.

Venous Reconstruction

- With the anterior half to two-thirds of the rib removed from this infraclavicular approach, the vein is often palpable in a bed of tissue and muscle fibers immediately below the clavicle. Venolysis consists of freeing up these muscle fibers to expose the vein (**FIG 10**). More proximal exposure of the vein can be accomplished via a transmanubrial extension of the infraclavicular incision to the center of the sternum and vertically up to the sternal notch (**FIG 11**). This can be necessary to obtain adequate vascular control for patching of chronically diseased venous segments. When a strictured segment of vein is localized, saphenous vein or bovine pericardial or bovine pericardial patching provides an excellent strategy for restoration of luminal diameter and can be performed with adequate proximal and distal control of the vein under direct visualization (**FIG 12**).

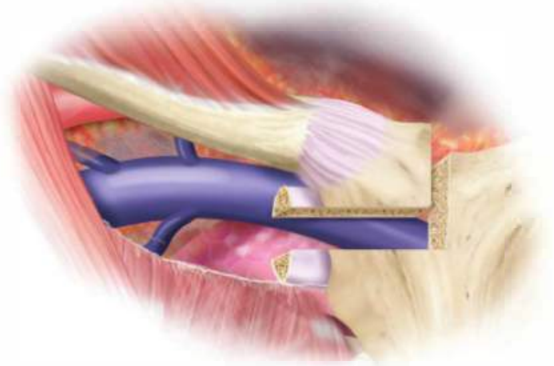

FIG 11 ● If more proximal exposure is needed to clamp for control, extension of the incision into the manubrium and toward sternal notch allows wider visualization of the origin of subclavian vein and junction with jugular into the innominate.

Closure

- Careful attention to the stump of rib remaining for hemostasis is performed, as well as the region of vein after venolysis and/or reconstruction.
- If the pleura or lung parenchyma has been injured, a small-caliber (12 Fr) pediatric chest tube can be place in the anterior pleural space under direct visualization.

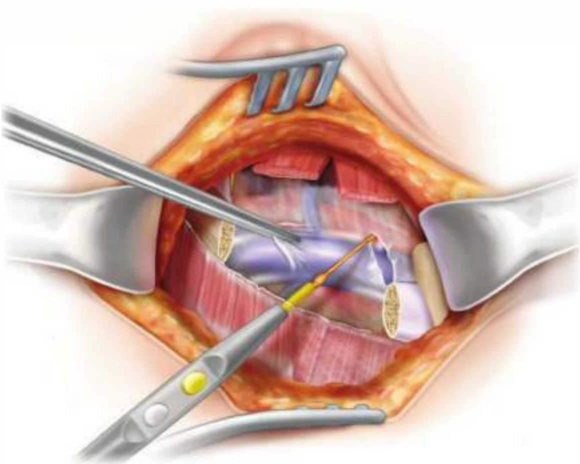

FIG 10 ● After 1st rib is resected, careful dissection around vein with venolysis and takedown of fibers surrounding vein allows adequate visualization to check for stenotic regions.

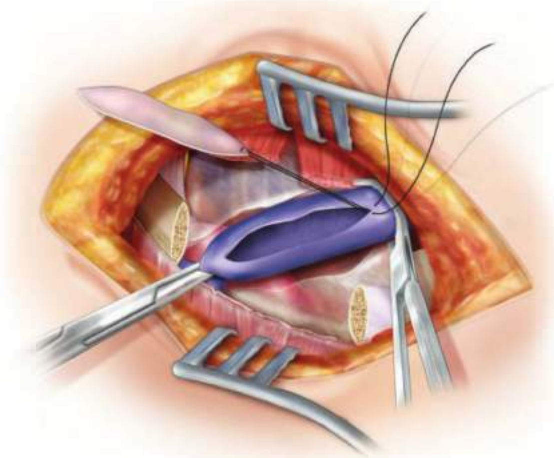

FIG 12 ● Stenotic region of the subclavian vein repaired with patch venoplasty using greater saphenous vein.

ARTERIAL THORACIC OUTLET SYNDROME

Supraclavicular Approach

- A 7-cm incision is made one fingerbreadth above the clavicle, starting lateral to the palpable edge of the sternal head of the sternocleidomastoid muscle and carried through the platysma. This exposes the clavicular head of the sternocleidomastoid, which is transected with a cuff to sew back together later, which now exposes the anterior scalene fat pad (**FIG 13**). The fat pad is dissected along three borders, inferiorly, laterally, and medially, to allow it swing northward to expose the anterior scalene muscle and the phrenic nerve (**FIG 14**). When operating on the left side, extra care is taken to visualize the thoracic duct when present, which is suture ligated to prevent postoperative chyle leaks if it becomes injured.
- With the phrenic nerve slung and protected, transection of the anterior scalene muscle off the superior edge of the 1st rib is done using bipolar scissors. Care is taken to stay on the bone during this portion so as not to injure the underlying subclavian artery. After the inferior edge of the anterior scalene is removed, a portion of muscle can be transected to allow room for further visualization and subsequent dissection around the brachial plexus (**FIG 15**). The long thoracic nerve is identified laterally, and the entire nerve structures are slung around a thick clear silastic loop.
- A cervical rib, when present, is often visualized at this time, with abnormal vasculature or musculature surrounding it, and can be fused to the 1st rib (**FIG 16**). Care is taken to dissect nerves and vessels away from the abnormal rib or its osseus portions that may not have appeared on radiography.
- The 1st rib is visualized by maneuvering the subclavian artery and the nerve bundle back and forth while dissecting middle scalene fibers and intercostal musculature off the 1st rib (**FIG 15**). This can be done sharply with bipolar scissors or by using a periosteal elevator. One should

FIG 14 ● With the scalene fat pad retracted superiorly, the anterior scalene muscle and phrenic nerve are clearly seen. The nerve is slung with a silastic loop.

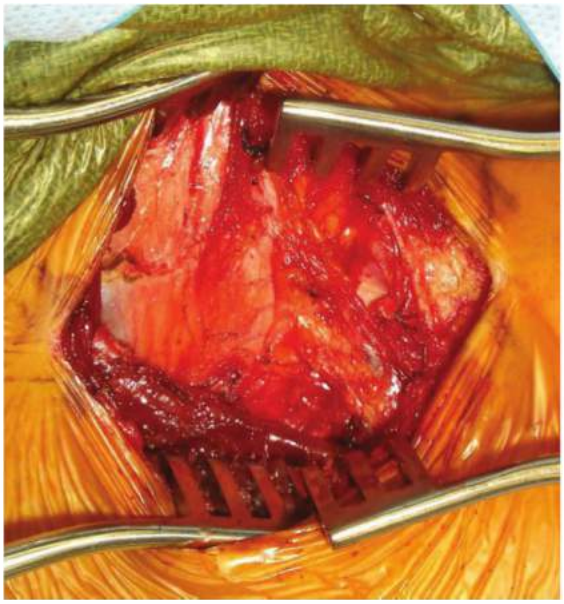

FIG 13 ● Supraclavicular incision one fingerbreadth above the clavicle continues after transecting clavicular head of the sternocleidomastoid and exposure of the anterior scalene fat pad.

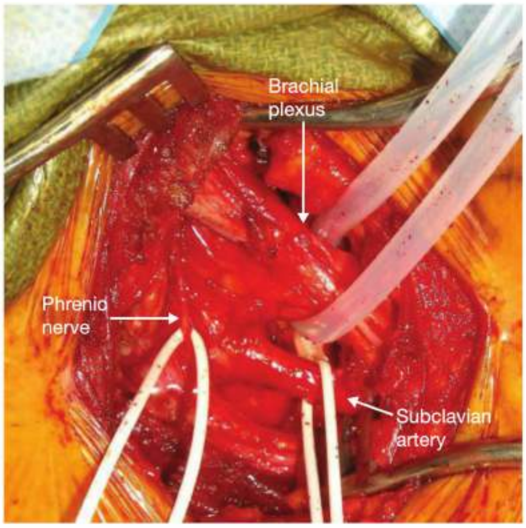

FIG 15 ● The 1st rib is cleared on both sides of the subclavian artery and the brachial plexus fibers, which are all slung to allow easy mobilization.

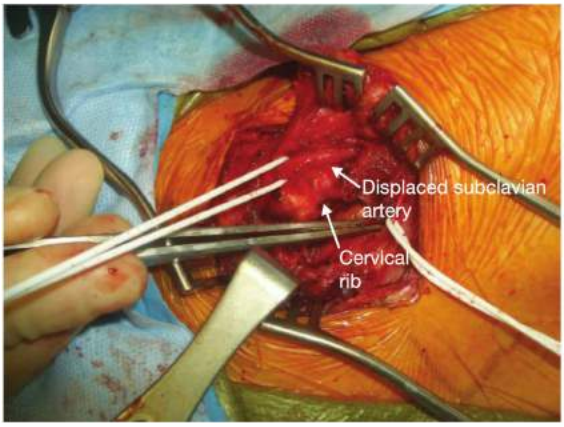

FIG 16 ● In this case, a fused cervical rib to the 1st rib is prominently tenting up the subclavian artery and brachial plexus fibers.

FIG 17 ● Removal of the congenitally fused cervical rib to the 1st rib as an en bloc piece, allowing the neurovascular bundle to return to its normal position without being kinked or displaced.

avoid the use of cautery in this area as it is likely to transmit to the brachial plexus or phrenic nerve.

- When the rib is clear from the region inferior to the subclavian artery and superior to the upper aspect of the brachial plexus, a power saw can be used to transect the rib. If there is a fused portion of cervical rib, it should be attempted to be removed as a single piece (FIG 17) to assure that all bony abnormalities have been freed up to allow for adequate decompression.

Arterial Reconstruction

- Subclavian aneurysm resection, when needed, consists of appropriate bypass principles and replacement with an autogenous or prosthetic interposition graft or extraanatomic bypass of carotid to distal subclavian or carotid to axillary graft. Typical sizes and types required for prosthetic grafts include 6- or 8-mm ringed polytetrafluoroethylene (PTFE) or Dacron.

PEARLS AND PITFALLS

Indications	■ vTOS definitive therapy consists of prompt diagnosis, venography and subsequent thrombolysis, and appropriate selection of patients to undergo thoracic outlet decompression. ■ aTOS patients often present with hand ischemic symptoms that will have some delay in management due to a wide differential. Abnormal bony or muscular anatomy along with presence of subclavian aneurysmal disease requires definitive repair including arterial reconstruction.
Preoperative workup	■ Venous duplex, venography, and pharmacomechanical thrombolysis provides the optimal reduction of clot burden to restore functional venous patency in patients with vTOS. Timing of rib resection and definitive thoracic outlet decompression are somewhat variable and the approach should be individualized. ■ aTOS patients should undergo plain radiography to search for a cervical rib and CT-A to determine the portions of diseased subclavian artery that might need resection.
Patient setup	■ Prepping the affected arm in the vTOS patients affords the ability to move the arm and, from the infraclavicular approach, gain access to the majority of the rib that is responsible for venous compression. ■ For cervical rib and arterial reconstructions, the supraclavicular approach gives numerous options for reconstructive purposes as well as the possibility of the carotid artery as an inflow source.
Infraclavicular approach	■ Visualization of the subclavius tendon and its fibers as well as the costoclavicular ligament is paramount in decompressing the region that compresses the subclavian vein in vTOS. ■ Liberal patching of the subclavian vein and extensive venolysis provide the best long-term patency results after vTOS decompression.
Supraclavicular approach	■ Carefully mobilizing the anterior scalene fat pad allows good visualization of the anterior scalene muscle and phrenic nerve. ■ When performing left-sided supraclavicular TOS decompression, one must be careful to identify and ligate the thoracic duct. ■ Slinging the subclavian artery and brachial plexus fibers allows gentle traction back and forth to expeditiously dissect free the entire 1st rib.

POSTOPERATIVE CARE

- At the conclusion of the procedure, patients are extubated and an immediate chest x-ray is obtained to ensure there is no pneumothorax. A small pneumothorax can be treated with oxygen and incentive spirometry, but a 25% lung volume reduction requires a chest tube to suction for 24 hours.
- Patients do not need a sling for their arms. They are given range-of-motion exercises immediately to encourage strengthening and are given a taper of muscle relaxant and opioid narcotics for pain control. Most patients are discharged the following day after surgery.
- Anticoagulation for vTOS patients is usually resumed 3 to 4 days postoperatively at home, typically consisting of Lovenox for a week, then they return for postoperative venography to see if further balloon venoplasty is necessary.[8]
- Anticoagulation for aTOS patients, especially if arterial reconstruction was performed, consists of antiplatelet therapy with aspirin.

OUTCOMES

- Patients treated for vTOS with lysis and subsequent thoracic outlet decompression have a very low recurrence rate of thromboembolic disease. Morbidity and mortality is minimal, as these are often young and healthy patients, but typically revolve around wound issues and bleeding given the need for a short course of anticoagulation. Satisfactory quality of life scores and return to full function are reported in the 80% to 90% range, and most patients can be counseled to expect a near full return to sport.[9]
- aTOS and the cervical rib patients often have the most dramatic recovery, as they are often the most symptomatic to begin with. Although the literature is much sparser with regard to this entity, results are uniformly positive with resolution of hand ischemic symptoms and lack of significant disease recurrence.

COMPLICATIONS

- Perioperative complications related to either form of thoracic outlet decompression revolve around lung injury and wound issues. Pneumothoraxes are often self-limited and treated effectively with chest tubes. Wound complications can include chyle leaks, seromas, and skin breakdown. Most of these are managed expectantly. Brachial plexus injuries may also occur, most commonly as a function of not recognizing important anatomic structures or not providing sufficient exposure to eliminate collateral damage during rib transection and removal.
- Timing of restarting anticoagulation in vTOS patients can lead to postoperative bleeding, which can manifest as delayed hemothorax. The cause of this bleeding is often related to recent thrombolysis and raw surfaces of muscle and cut bone, and this has led to the general recommendation of holding off on restarting anticoagulation until 3 or 4 days postoperation.

Chapter 10

Proximal to the Wrist: Upper Extremity Reconstruction/ Revascularization

Mohamed A. Zayed   Ronald L. Dalman

DEFINITION

- The content discussed in the following text assumes the reader has familiarity with standard upper extremity arterial anatomy and its most common variations. For additional information, the reader may refer to excellent existing references.[1,2]
- Various occlusive and/or aneurysmal disease processes in the upper extremity arterial system may necessitate revascularization or reconstruction (Table 1).
- Acute upper extremity ischemia is less common than in the lower extremity due to the rich preexisting collateral circulation in both the upper arm and forearm. The majority (~50%) of acute ischemic complications in the upper extremity occur in elderly females as a result of embolic phenomenon rather than primary vessel thrombosis (which accounts for ~25% of acute ischemic events).[3] The differential diagnosis for embolic sources includes intracardiac sources, proximal arterial atherosclerotic plaque, proximal arterial aneurysm thrombus, endocarditis, or paradoxical embolus from venous circulation.
- Chronic arterial occlusive disease is rarely symptomatic. Associated comorbid conditions include diabetes, chronic atherosclerotic occlusive disease, subclavian or arteriovenous steal syndromes, or failure of prior arterial repair or grafting.[4,5]
- Venous occlusive disorders in the upper extremity are common and are usually associated with iatrogenic injury, indwelling catheters, or thoracic outlet pathology. For further information regarding venous thoracic outlet disorders. Distal to the thoracic outlet, venous occlusive disorders are for the most part managed expectantly with anticoagulation therapy. Open surgical and endovascular therapies are rarely used and, due to high recurrence and failure rates, are not enthusiastically recommended. For further recommendations regarding upper extremity venous disease management, please refer to additional references.[6,7]

Table 1: Upper Extremity Vascular Disease

Pathology	Etiology
Arterial stenosis or occlusion	• Atherosclerosis • Dissection/trauma • Extrinsic compression • Vasculitis • Hypercoagulable state
Arterial aneurysmal degeneration	• Atherosclerotic degeneration • Blunt or penetrating trauma • Connective tissue disorder • Iatrogenic injury
Venous stenosis or occlusion	• Deep venous thrombosis • Hypercoagulable state • Extrinsic compression

PATIENT HISTORY AND PHYSICAL FINDINGS

- Initial evaluation should include an assessment of associated comorbidities, including cardiac pathologies (myocardial infarction, arrhythmia, heart failure, or prior coronary artery revascularization), hypertension, hyperlipidemia, diabetes, hypercoagulability, smoking, prior upper or lower extremity arterial intervention, or index extremity trauma.
- Symptoms and signs of acute arterial ischemia include pain, paresthesia, pulselessness, paralysis, and/or poikilothermia. A thorough vascular, sensory, and motor examination will help assess the severity of arterial insufficiency. Although dated, the Rutherford classification system remains useful for prognostic determinations.[8] For classes 5 and 6 ischemia, urgent or emergent intervention may be necessary to preserve limb function and viability. Prompt removal of embolic debris in limbs with sufficient residual viability produces excellent long-term results.[3]
- Chronic limb ischemia may also present with symptoms of rest pain, pain with extremity use, paresthesia, pulselessness, poikilothermia, and/or ulcerations/wounds/gangrene of fingers or fingertips. Subjects should be asked to describe what, if any, activities exacerbate these potential symptoms (i.e., lifting or carrying material with affected arm/hand, arm raising, or repetitive arm/hand movement). Patients with vocational or recreational activities that require regular or frequent use of their upper extremities should describe convincing symptoms they experience in relation to these activities. More commonly, chronic upper extremity arterial ischemia is asymptomatic, particularly in older and less physically active individuals. In general, revascularization is not necessarily indicated in these circumstances. Discrepancy in upper extremity pulses, or brachial blood pressure differential of more than 15 mmHg, is a hallmark of chronic upper extremity arterial insufficiency with or without accompanying symptoms.
- Traumatic or iatrogenic injury accounts for 25% of patients presenting with acute upper extremity arterial insufficiency. Consideration of the mechanism of injury (blunt, penetrating, hyperextension, or avulsion) will help delineate the likely nature of the resulting arterial disruption (transection, dissection, or thrombosis, with or without ongoing extravasation). Following completion of the trauma primary survey, determination of extremity arterial continuity should be performed following reduction of obvious ipsilateral upper extremity fractures and dislocations. In complex injuries, including avulsions and crush injuries, baseline sensory and motor status should be documented early to formulate the most appropriate course of therapy. When severe arterial injury is associated with transection or avulsion of the brachial plexus and compound long bone fractures, meaningful functional recovery, despite ultimately successful revascularization, may not be possible.[9]

- More commonly, upper extremity arterial injuries can be more subtle and are frequently missed on primary or secondary surveys. The extensive collateral network present around the elbow often masks the presence of brachial artery thrombosis following posterior elbow dislocation, or dissection and thrombosis following brachial artery catheterization. When physical signs suggest asymmetric or reduced upper extremity arterial perfusion, objective imaging should be obtained promptly to direct therapy and maximize long-term function. Depending on hand perfusion and viability, occasionally, immediate revascularization can be at least temporarily deferred to allow for more urgent resuscitation and stabilization procedures to proceed. Similarly, non–flow-limiting dissections may be monitored without immediate intervention, particularly when the patient's overall condition merits observational management.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Depending on clinical circumstances, revascularization may be undertaken on the basis of clinically apparent injuries and limb ischemia. More commonly, physiologic assessment is indicated and necessary to determine the most efficacious method of revascularization. Arteriography, typically performed during or immediately prior to revascularization, remains an essential tool to guide intervention and confirm procedural success. As a general observation, physiologic testing helps determine when intervention is necessary, whereas arteriography provides the necessary anatomic information to ensure procedural and functional success.
- Computed tomography (CT) arteriography can potentially add useful information to surgical planning for upper extremity revascularization. However, unlike in the abdomen and lower extremities, significant insight into disease localization and severity in the upper extremities can be gleaned from physical examination and nonionizing imaging modalities such as ultrasound. The potential additional diagnostic benefit associated with CT angiography needs to be balanced with the not insignificant radiation dosage delivered with this imaging modality, particularly in regard to the longer life expectancy of younger patients. When vascular disease is known to be limited to the extrathoracic upper extremity arterial system, CT angiography provides little additional, useful information over diagnostic arteriography alone, especially when the latter can be paired with a therapeutic intervention.
- Noninvasive vascular testing for evaluation of the upper extremities includes segmental systolic pressure measurements using a Doppler flow detector, digital plethysmography, and arterial duplex scanning.
- Serologic tests are the basis for the workup of patients with suspected vasculitic pathologies (e.g., Takayasu's arteritis, giant cell arteritis, Buerger's disease, and/or scleroderma). Customary tests include baseline complete blood count, platelets, fibrinogen, C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR).[10,11] In certain circumstances, color duplex evaluation may also provide additional clues to aid in the diagnosis.[12] Additional serial serologies and rheumatologic consultation may be necessary depending on the severity and progression of the suspected vasculitic disease process.
- Young patients with acute primary arterial thrombosis, patients with recurrent arterial thrombosis, or patients with a prior history of unprovoked deep venous thrombosis preceding an arterial event should be considered for a hypercoagulability workup and hematology consultation. Initial testing may include protein C function, free protein S, antithrombin III activity, anticardiolipin antibodies, factor V Leiden mutation, prothrombin mutation, and homocysteine level.[13]

SURGICAL MANAGEMENT

Preoperative Planning

- Prior to attempted upper extremity arterial repair or revascularization, a clear understanding of the extent and location of arterial pathology is essential. This knowledge guides the location of arterial exposure or optimal method of arterial access, the identification of optimal inflow sources and outflow targets, and the most effective and efficient methods of reconstruction. When uncertainty persists, intraoperative arteriography provides essential and timely guidance.
- As in all methods of peripheral arterial reconstruction, heparin is typically administered when an interventional sheath is first placed, or arterial control is anticipated. Typically, 100 units/kg of intravenous heparin is administered, with additional anticoagulation guided by the activated clotting time monitored during the course of the procedure.
- As discussed in Part 6, Chapter 2, the preferred extrathoracic method of innominate or proximal left subclavian artery surgical reconstruction is carotid subclavian bypass. Frequently, however, endovascular options are available and preferable in patients who cannot tolerate the risks or morbidity associated with open reconstruction. For example, in the setting of uncontrolled, life-threatening hemorrhage from penetrating or crush injuries or limb avulsion, bleeding may be controlled by insertion of covered, self-expanding stents across the area of injury in the subclavian or axillary arteries. However, with few other exceptions (such as lesions associated with giant cell or Takayasu's arteritis), angioplasty and stenting of arterial lesions at or distal to the clavicle is poorly tolerated and ill advised. Stents placed in this area are at high risk for fragmentation and subsequent arterial thrombosis, pseudoaneurysm formation, or stent migration.
- Surgical management of arterial pathology distal to the subclavian artery (surgical management of arterial disease of the arch vessels and subclavian artery are discussed in Part 6, Chapters 1, 2, and 9) and proximal to the wrist (surgical management of arterial disease distal to the wrist is discussed in Part 6, Chapter 11) will depend on acuity, cause/type of pathology (penetrating trauma, blunt trauma, occlusion, stenosis, or aneurysm), severity of patient symptoms, patient comorbidities, and required durability of the planned repair.
- Axillary artery exposure is guided by the nature of the planned reconstruction. The proximal artery is most easily exposed via a transverse infraclavicular incision. Exposure of the second and third portions requires deltopectoral or axillary approaches, respectively.[1]
- Acute symptomatic embolic occlusion of the axillary or brachial arteries are best managed by open, preferably image-guided, balloon catheter or direct thromboembolectomy.[1,2] Essential elements required for thromboembolectomy include (1) determination of the optimal treatment environment (operating room [OR] with portable vs. fixed imaging), (2) arterial access (level of incision), (3) acquisition of catheters and guidewires

required to transverse the embolus and accumulated luminal thrombus, (4) availability of balloon and over-the-wire embolectomy catheters, (5) need for adjuncts such as aspiration catheters (Export™ catheter, Medtronic, Minneapolis, MN) and thrombolytic agents (tissue plasminogen activator [tPA]), (6) options for managing postischemic hyperemia and elevated compartment pressures, and (7) consideration of treatment alternatives should preexisting atherosclerotic occlusive disease preclude or complicate catheter-directed thromboembolectomy.

- For symptomatic axillary or brachial artery thrombosis not amenable to direct or catheter-based, image-guided thromboembolectomy, open surgical bypass or interposition grafting is the preferred method of repair. When considering open bypass or interposition grafting distal to the clavicle, key planning elements include (1) determination of optimal inflow and outflow, (2) conduit (almost exclusively autogenous vein), and (3) assessment of distal compartment pressures and potential need for fascial release. Commonly, more vasospasm is engendered by injury and surgical manipulation in the upper extremity arteries as compared to those of the lower extremities, and accommodations may need to be made to ensure graft and bypass patency in this context.
- Branch vessel injuries and aneurysms, particularly those arising from the axillary and brachial arteries, are best treated with ligation and excision.[14] Preoperative planning of these procedures involves selection of an appropriate exposure through the muscles of the upper extremity that will facilitate rapid recovery and minimize risk of disability in a usually young and active patient cohort.
- The relatively superficial location of the brachial artery in the antecubital fossa increases its vulnerability to traumatic and iatrogenic injury.[15] Most brachial injuries are associated with penetrating trauma; however, blunt injuries also occur, particularly in the distal brachial artery, following posterior elbow dislocations and supracondylar fractures (the latter more commonly in children).[16] In these situations, key elements for repair will include inspection of injured arterial segment on preoperative imaging for possible intimal disruption, short segment thrombosis, or thrombosis extending distally into the forearm.
- An increasing number of cardiac catheterizations and coronary interventions are performed via radial or brachial access.[17] Cannulation site complications, including thrombosis or pseudoaneurysm formation, often necessitate operative repair.[17,18] For these patients, preoperative planning will include identifying the extent of injury, options for graft conduit (smaller diameter vein), and alternative management options including arterial ligation in extenuating circumstances.
- The ulnar artery at the wrist is the dominant hand artery in the majority of patients. Achieving or maintaining sufficient arterial outflow at the wrist is essential to the hemodynamic and clinical success of forearm revascularization procedures. The status of the radial and ulnar arteries at the wrist should be confirmed in the course of evaluating all patients for upper extremity revascularization options.

Operating Room Setup

- The majority of upper extremity revascularization procedures are suited for a hybrid operating environment, or an OR equipped with a radiolucent, floating-point carbon fiber operating table and fluoroscopy radiation source and image intensification system, preferably equipped with digital subtraction angiography and last-image hold capabilities. When optimal x-ray penetration and resolution is not available, or in circumstances when diagnostic angiography alone is anticipated, less sophisticated portable imaging systems may suffice.
- Elective and emergent upper extremity surgical revascularization procedures may be performed with either regional or general anesthesia. Considerations include the overall status of the patient, ability to tolerate the specific challenges associated with either anesthetic techniques, and the abilities of the anesthesiologist responsible for anesthetic management.
- For the majority of upper extremity procedures, the operative limb is typically extended at 90 degrees. For optimal surgical exposure, we prefer arm positioning systems that move freely with the OR table rather than those with separate floor extensions. To avoid exacerbation of potential brachial plexus injuries in appropriate clinical settings, care should be taken to avoid hyperabduction and extension of the limb. The operative field should include, at a minimum, the ipsilateral axilla, chest, and neck, with the head rotated and extended to the contralateral side. A shoulder roll may be positioned under the ipsilateral shoulder to aid with neck and shoulder extension (**FIG 1A**). Alternatively, for optimal deltopectoral exposure of the axillary artery, the arm can be externally rotated and abducted at 30 degrees relative to the lateral chest.
- In situations where venous interposition conduit may be needed, a lower extremity should also be prepared into the surgical field to allow for greater or lesser saphenous vein harvest as indicated by the estimated diameter of the target artery. In the setting of extensive traumatic injuries, vein should be harvested from the least affected lower extremity.

- Systemic anticoagulation should be considered whenever major open or endovascular revascularizations are undertaken. Exceptions include profound systemic coagulopathy or concern related to concomitant risks such as occult intracranial hemorrhage. Sufficient intravenous unfractionated heparin should be administered to achieve an activated clotting time of more than 250 seconds.
- Open surgical revascularization and repair techniques are described in the sections in the following text relative to upper extremity anatomic location.
- The last section describes general endovascular techniques used for upper extremity interventions.

PROXIMAL AXILLARY ARTERY

First Step

- Exposure of the proximal (first) portion of the axillary artery is best achieved through an incision placed one fingerbreadth below the middle third of the clavicle (**FIG 1B**). Deep to the subcutaneous tissue, the pectoral fascia is opened longitudinally. The pectoralis major muscle is divided with a muscle-splitting incision. The underlying clavipectoral fascia is then sharply incised to expose the proximal axillary sheath. Additional exposure is aided by lateral retraction or division of the pectoralis minor muscle.

Second Step

- Fine dissection should be used to expose and control the axillary artery deep to the clavipectoral fascia. Careful dissection and retraction minimizes injury to the cords of the brachial plexus surrounding the artery. The lateral pectoral nerve and proximal cephalic vein are also prone to injury during dissection or traction from misplaced self-retaining retraction devices.

Third Step

- The axillary vein lies anterior and caudal to the artery within the axillary sheath. Mobility of the vein is achieved with gentle dissection, ligation of associated venous tributaries, and mild caudal retraction with a circumferential vessel loop or small handheld retractor (**FIG 1C**).
- In smaller patients, division of the thoracoacromial artery and vein may be required to facilitate proximal axillary exposure. Once again, injury to the lateral pectoral nerve is avoided by gentle, deliberate dissection.

Fourth Step

- Once circumferential dissection and exposure of the proximal axillary artery is complete, the artery is optimally controlled with silastic vessel loops (**FIG 1C**).
- Familiar anatomic relationships may be less recognizable during redo or complex exposures, or in the setting of traumatic injuries, ongoing extravasation, and hematoma formation. The risk of associated brachial plexopathy is heightened in these situations. Extending exposure through the deltopectoral groove may help delineate otherwise indistinct tissue planes. Repositioning the arm throughout the range of available abduction may also reduce position-related anatomic distortion.

Fifth Step

- For axillofemoral bypass grafting, the first or most proximal axillary segment is chosen for anastomotic access to minimize the risk of traction and potential graft disruption from shoulder and arm movement. Locating the anastomosis as proximate to the clavicle as possible optimizes long-term performance and durability. Based on the patient's body habitus and planned graft configuration (uni- or bifemoral), an appropriately sized (6, 8, or 10 mm) externally supported expanded polytetrafluoroethylene (ePTFE) is employed. For most patients, in most situations, an 8-mm diameter, removable ring graft is optimal. The axillary arteriotomy is always created proximal to the overlying pectoralis minor muscle, which is itself usually divided to further minimize undue traction on the graft.
- When considering direct ipsilateral axillo–axillo or axillo-brachial bypass grafting, conduit choice depends on surgical context. In contaminated fields (with open penetrating or avulsion injuries of the axillary artery), vein is preferred and is sourced from the long or short saphenous or superficial femoral veins in the (least involved) lower extremity, or contralateral arm vein. For elective revascularization procedures, depending on the age of the patient, bypass length, target artery diameter, and indications for reconstruction, ePTFE or knitted polyester prosthetic grafts may provide acceptable alternatives. However, in nearly all situations requiring upper extremity bypass at or distal to the clavicle, autogenous vein is optimal and highly preferred.
- For ipsilateral revascularization, graft is tunneled parallel to the existing axillary artery beneath the pectoralis major and minor muscles to the anterior axillary line.
- For upper extremity revascularization procedures, tunneling is extended distally through subcutaneous planes along the arm and forearm as necessary to reach the target artery. In the case of axillofemoral bypass grafting, the ePTFE graft tunnel is created retrograde, extending from the femoral incision superiorly to the exposed axillary artery, with care being taken to position the graft anterior to the anterior superior iliac crest and advanced upward along the anterior axillary line. The tunnel must not breach the abdominal fascia or thoracic cavity. With a tunneling device of sufficient length, a counterincision is not usually necessary to reach the axillary artery. At the inferior border of the pectoralis muscle, the tunnel transitions to a subfascial plane extending below the pectoralis major muscle to reach the exposed axillary artery medial to its intersection with the pectoralis minor muscle. Use of a purpose-specific tunneling device for this maneuver will not only obviate the need for a counterincision but also minimize risks of kinking, twisting, or graft compression.
- The conduit should be beveled appropriately for end-to-side anastomoses at both ends. At the axillary anastomosis, slightly more graft length redundancy is needed to prevent excessive traction on the anastomosis and late graft or arterial injury. The use of stretch polytetrafluoroethylene (PTFE) is also preferred for this reason.

Sixth Step

- Traumatized, thrombosed, or aneurysmal proximal axillary artery segments may be transected or resected as necessary, reconstituted by interposition grafting with venous or prosthetic conduit (**FIG 1D**).
- For interposition grafting, the damaged or diseased arterial segment is fully transected and removed. The lumen within the proximal and distal arterial segments should be inspected for trauma, dissection, or thrombus formation. In the case of the distal artery, flushing with heparinized saline may help confirm patency and sufficient runoff. Retrograde flushing of diseased or damaged brachial, axillary, or subclavian arteries is not recommended given the potential risk for vertebral artery embolization of residual luminal detritus and subsequent central nervous system (CNS) infarction or injury.
- When uncertainty exists regarding the extent of axillary injury, further exposure may be necessary to ensure success. In rare and extenuating circumstances, clavicular resection and replacement (or removal) may be required for satisfactory arterial exposure. Similarly, when fragmented or chronically infected, the clavicle should be removed as necessary to optimize long-term graft patency and limb viability.
- For upper extremity arterial reconstruction, once exposure is complete and the appropriate tunnel is created, the appropriate conduit is selected for use and prepared for interposition grafting (**FIG 1D**). The conduit should be fashioned to an appropriate length to avoid potential kinking during future arm motions. Proximal and distal anastomoses are performed end-to-end or end-to-side depending on the respective diameters of the inflow and outflow segments.

Seventh Step

- Catheter embolectomy should be performed as necessary, often using over-the-wire, image-guided techniques, to remove luminal thrombus from inflow or outflow arterial segments as necessary. Care should be taken with proximally directed embolectomy to avoid dislodging clot fragments into the vertebral artery.
- To minimize iatrogenic injury from embolectomy catheters, proximal embolectomy is best initiated at the level of the axillary rather than brachial artery. Attempting antegrade embolectomy proximally from an antecubital brachial access incision risks traumatic injury to the axillary or brachial artery at the origin of the deep brachial artery, where the diameter of the brachial artery decreases significantly, just distal to the axillary fossa.
- Appropriately sized Fogarty thrombectomy catheters for upper extremity embolectomy include sizes 2 through 5 Fr, depending on the diameter of the artery being instrumented and the technique (antegrade or retrograde) being employed.

MID-DISTAL AXILLARY ARTERY

First Step

- The mid-distal axillary artery may be exposed via an axillary or deltopectoral incision. For distal exposure, the incision is extended through the posterolateral border of the pectoralis major muscle to allow for partial mobilization and medial retraction of that muscle (**FIG 2A**). In the superior aspect of the surgical incision, the coracobrachialis muscle will be visualized at 90 degrees relative to the medially retracted pectoralis major muscle. Within this angle, gentle blunt dissection is applied to identify the axillary sheath running along the inferoposterior border of the coracobrachialis muscle.
- For deltopectoral exposure, dissection is performed along the anterior border of the deltoid muscle, extending

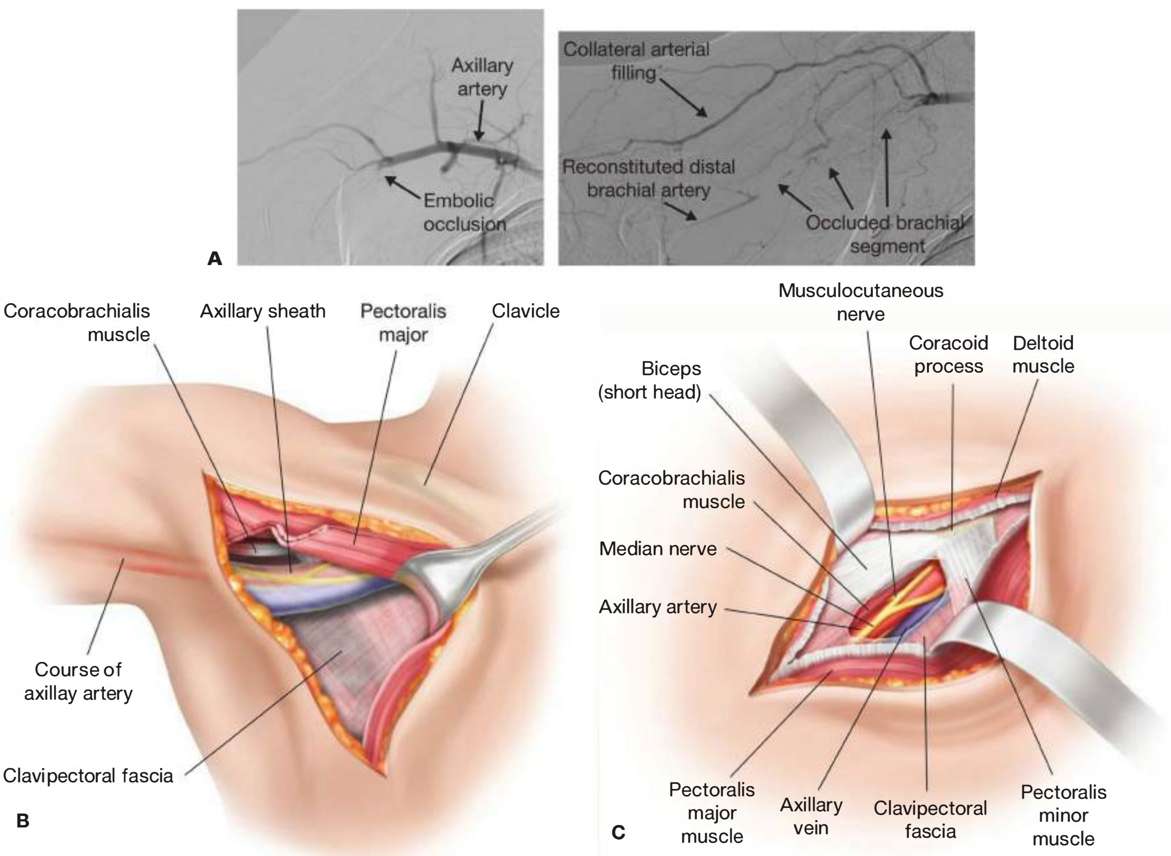

FIG 2 ● **A.** Right upper extremity arteriogram demonstrating distal axillary and brachial artery occlusion, with substantial filling of unnamed collateral arterioles. **B.** Axillary exposure of the mid-distal axillary artery. **C.** Deltopectoral exposure of a long segment of axillary artery. *(continued)*

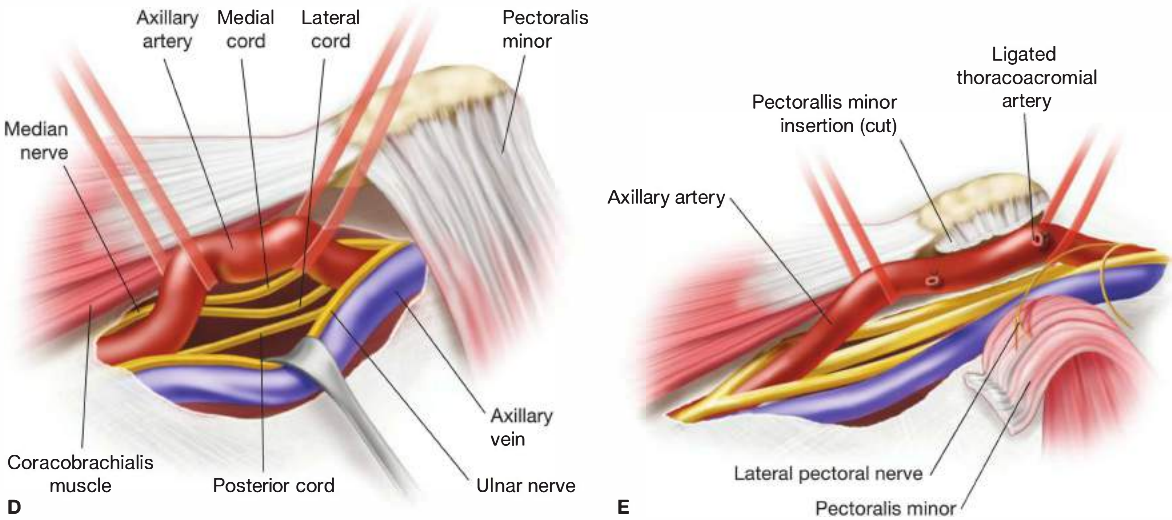

FIG 2 ● *(continued)* **D.** Exposure of the distal axillary artery and associated axillary sheath structures. **E.** Exposure of the midaxillary artery via reflection of the pectoralis minor muscle.

through the subcutaneous tissue in the deltopectoral groove (**FIG 2B**). With medial retraction of the pectoralis major, the neurovascular bundle is then exposed in the underlying clavipectoral fascia.

Second Step

- Upon entry of the axillary sheath, the axillary artery is visualized directly under the median nerve. At the lateral border of the pectoralis major muscle, the medial and lateral cords form the median nerve form over the anterior surface of the axillary artery. The ulnar nerve and axillary artery are visualized along the inferoposterior border of the mid-distal axillary artery in this exposure. Identification of surrounding structures during axillary exposure minimizes risks of inadvertent injury. Elevation and caudal retraction of the exposed axillary artery with vessel loops also augments exposure and reduces risk of adjacent nerve injury during arterial clamping (**FIG 2C**).

Third Step

- When further exposure of the second portion of the axillary is required, the pectoralis minor muscle is divided near its insertion on the coracoid process. The pectoral nerves should be identified and protected during this maneuver. Caudal retraction of the muscle allows for exposure of the underlying neurovascular bundle (**FIG 2D**).
- In the second portion, the axillary artery is surrounded on three sides by brachial plexus nerves, leaving the anterior surface of the artery uncovered. For sufficient circumferential exposure of the vessel, the thoracoacromial artery can be ligated and divided at its origin. However, during mobilization of the axillary artery segment, care should be taken to not injure the lateral thoracic artery and the lateral and medial cords as they join over the distal axillary artery to form the median nerve.

Fourth Step

- Similar to the steps outlined for reconstruction of injuries to the first or second portion, traumatized, thrombosed, or aneurysmal segments in the second or third portions of the axillary artery may be transected or bypassed, with interposition grafting or bypass as necessary.
- Repair of axillary branch injuries and aneurysms requires sufficient segmental exposure of the axillary artery itself, as well as the branch artery of concern. Subscapular, medial humeral circumflex, or lateral humeral circumflex branch artery aneurysms can be exposed through the axillary fossa and divided free from the axillary artery once ligated to prevent persistent distal arterial embolization and hand ischemia in the setting of chronic overuse or athletic injuries. Occasionally, aneurysmal degeneration of the branch compromises the integrity of the axillary artery itself, and interposition grafting may be required for optimal reconstitution of distal limb blood flow. Autogenous vein (or artery harvested from the distal internal iliac circulation in the pelvis) is the optimal conduit choice for this application (**FIG 3**).
- Axillary or branch artery injuries resulting in substantial distal and symptomatic upper extremity arterial emboli and digital ischemia may benefit from a trial of intraarterial thrombolytic therapy, administered preoperatively, to improve runoff, graft patency, hand perfusion, and functional status.

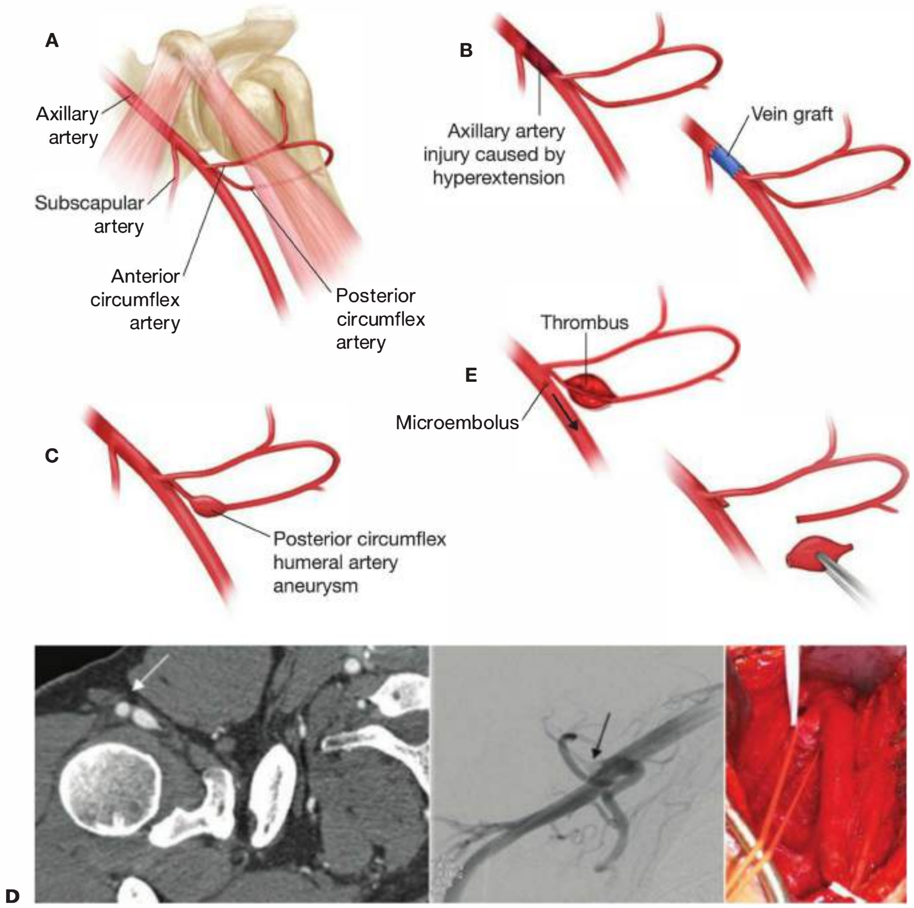

FIG 3 ● **A.** Relative anatomy of the distal axillary artery and associated anterior and posterior circumflex humeral arteries. **B.** Axillary artery injury at the origin of a circumflex humeral branch repaired with an interposition vein graft. **C.** Circumflex humeral branch aneurysm. **D.** CTA of right upper extremity circumflex humeral branch artery aneurysm *(arrow)*. BRACHIAL ARTERY

First Step

- In the upper arm, the proximal brachial artery is optimally exposed via a 5- to 8-cm longitudinal incision in the medial groove between the biceps and triceps muscles (**FIG 4A**).
- As the subcutaneous tissue is dissected, care should be taken to visualize and avoid injury to the basilic vein as it crosses near the brachial sheath in the distal upper arm. To aid in exposure, the basilic vein can be retracted into the posterior wound, and vein branches crossing over the brachial artery sheath can be ligated and divided. Significant plexus of sensory nerves are also encountered in this dissection and should be protected from injury.

Second Step

- By incising the deep fascia at the medial border of the biceps muscle, the neurovascular bundle may be further exposed. The median nerve will be the first structure to be encountered in the brachial sheath with this exposure. Wide mobilization of the nerve allows for its gentle retraction into the anterior wound (**FIG 4B**).
- Just deep to the median nerve, the brachial artery will be visualized along with two flanking brachial veins. Interconnecting communications between these veins may be ligated to aid in further exposure of the brachial artery.

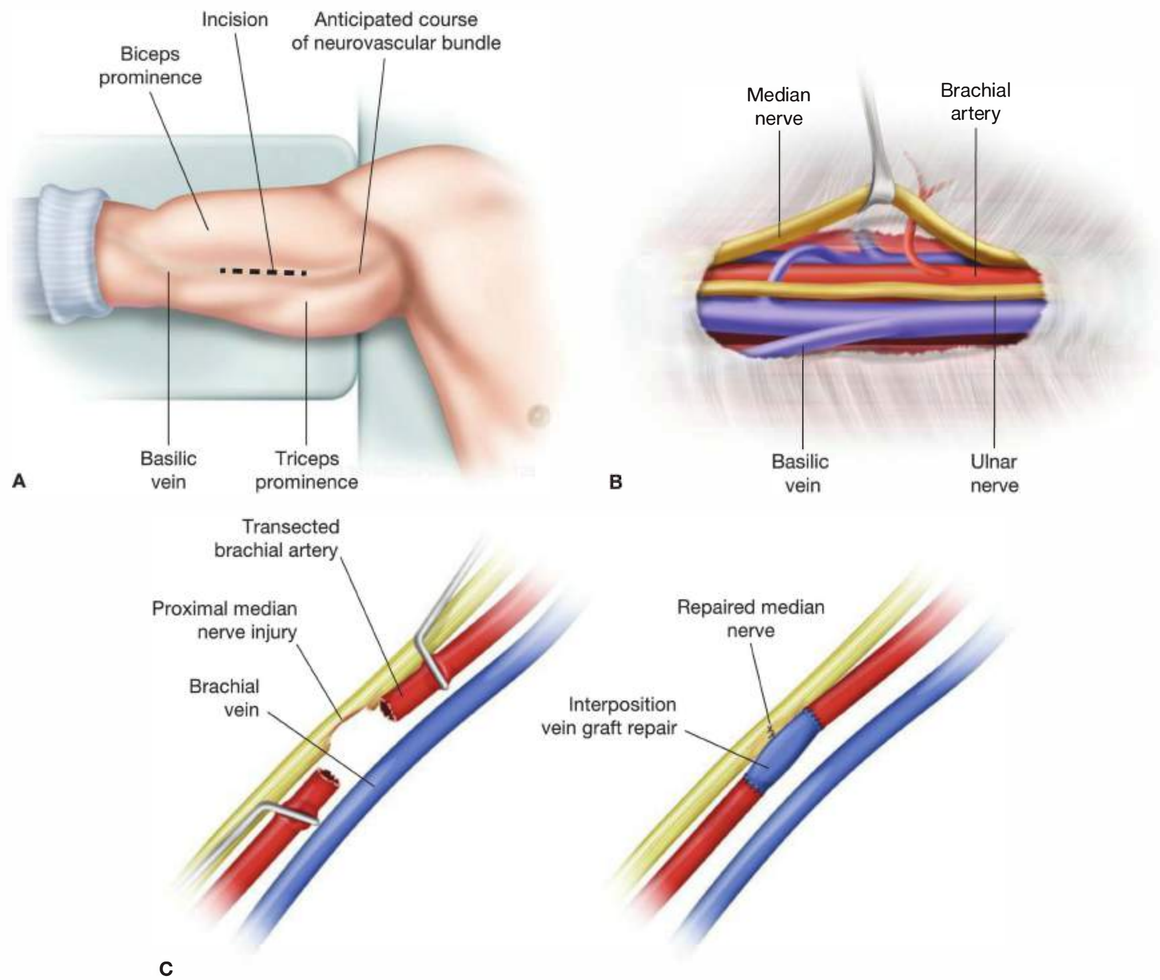

FIG 4 ● **A.** Incision created for exposure of the proximal brachial artery in the upper arm. **B.** The brachial artery in the upper arm is adjacent to the median and ulnar nerves. **C.** Traumatic transection of the brachial artery with associated intimal damage, along with partial injury to the median nerve. Subsequent repair is performed with a brachial artery interposition graft using a vein conduit and median nerve repair.

Third Step

- Exposure of the brachial artery in the mid-upper arm may require identification and control of the deep brachial artery, which arises on the posteromedial surface of the brachial artery, just distal to the lateral border of the teres major muscle in the distal axillary fossa. In the distal upper arm, the superior and inferior ulnar collateral arteries may also require control during brachial artery exposure.

Fourth Step

- Alternatively, the brachial exposure can be gained through an oblique incision along the anticipated course of the brachial artery in the distal upper arm proximal to the antecubital fossa.
- Once again, care should be taken to avoid injury of the median nerve, which can be found posteromedial relative to the brachial artery in this area (FIG 5). Elevation of the brachial artery with vessel loops prior to clamping can decrease the chance of nerve injuries during this process.

Fifth Step

- Pseudoaneurysm or transection of the brachial artery can be repaired following proximal and distal brachial artery exposure and control. In the setting imminent rupture or exsanguination, proximal control in this area may be obtained with a proximal sterile tourniquet. Following tourniquet control, the injured brachial artery segment or pseudoaneurysm sac can be isolated and explored with confidence. This technique is particularly useful in preventing catastrophic rupture and contamination of the OR environment with blood-borne pathogens in the setting of iatrogenic or self-inflicted mycotic aneurysms.
- Puncture wounds may be amenable to primary suture repair or minimal resection of the injured segment and primary reapproximation. Larger defects and partial

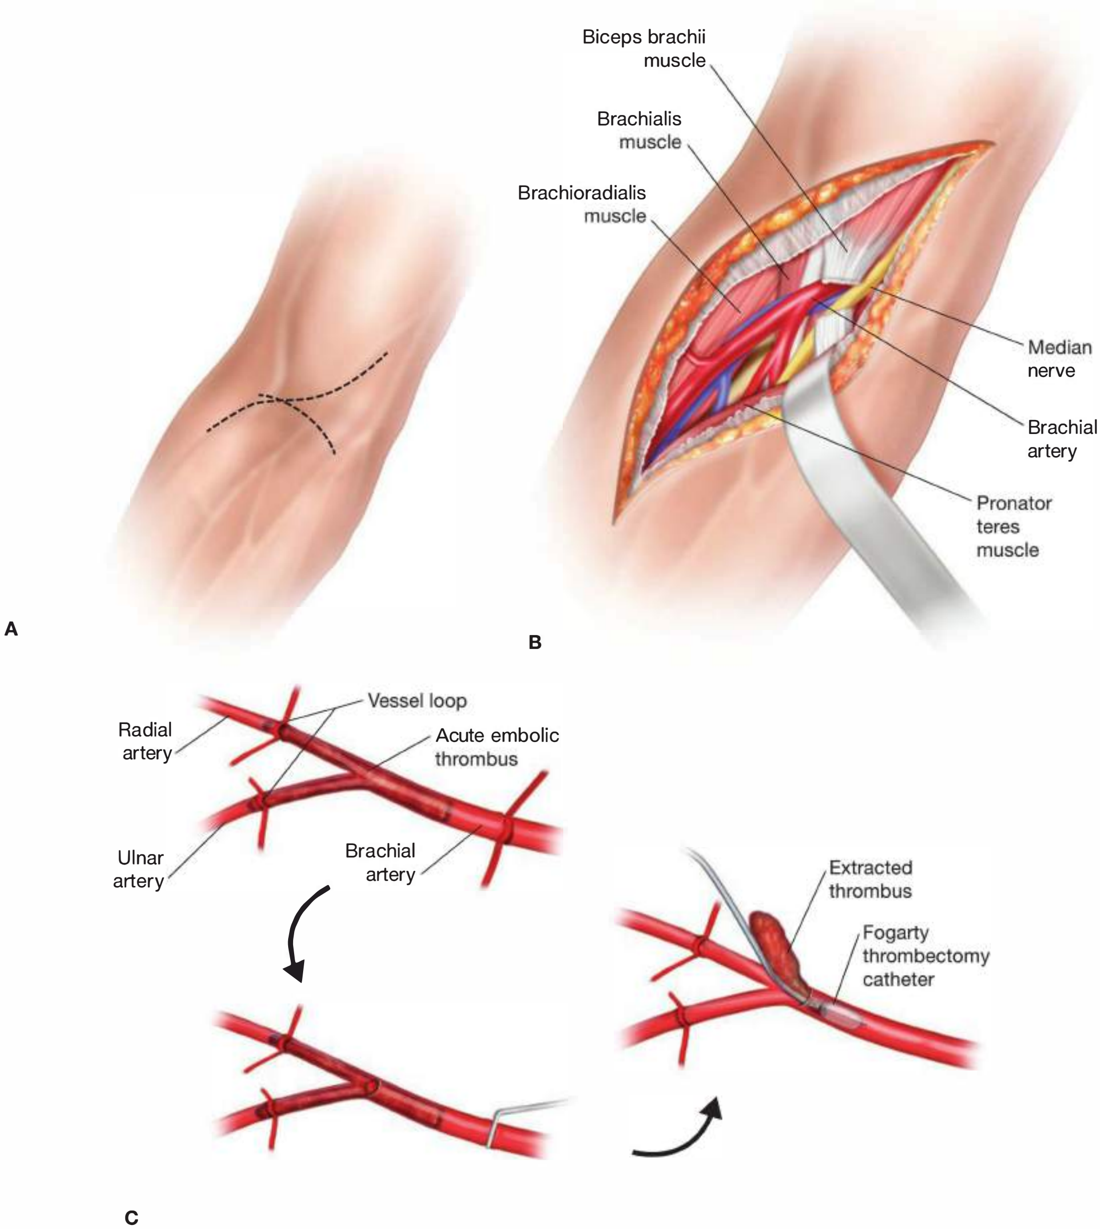

FIG 5 ● **A.** Typical incisions used for exposure of the distal brachial artery and proximal radial and ulnar arteries at the antecubital fossa. **B.** Relative anatomy of the brachial, radial, and ulnar arteries and adjacent median nerve. **C.** Acute embolic occlusion of the brachial artery bifurcation can be treated following proximal and distal control of the brachial, radial, and ulnar arteries. Arteriotomy is created over the occluded vascular segment. Following distal thrombectomy of the ulnar and radial arteries, a Fogarty thrombectomy catheter can also be used to extract thrombus from the brachial artery.

transections may require patch angioplasty for satisfactory repair (FIG 4C).

- When uncertain as to whether a primary repair is indicated or even possible, the most reliable course of action is interposition vein grafting, usually harvested from a long saphenous vein, with care taken to account for differences in length based on movement at the elbow (e.g., avoid kinking while limiting tension). Risk of kinking is also reduced by reconstructing other injured structures in the antecubital fossa (e.g., biceps brachialis tendon) to limit graft motion during elbow flexion.
- Distal forearm thrombectomy is best performed through a brachial incision created in the antecubital fossa. Exposure of the distal brachial artery may be necessary to sequentially catheterize the individual forearm arteries. Alternatively, proximal sheath access in the axillary fossa may facilitate image-guided access of the forearm arteries and over-the-wire embolectomy.
- In the antecubital fossa, distal thromboembolectomy may be performed with a 2- or 3-Fr Fogarty catheter (FIG 5C). Further endovascular imaging and treatment (see in the following text) may be required to optimally restore distal arterial perfusion.
- Apropos the prior discussion regarding axillary exposure and embolectomy, attempting removal of proximal emboli from antecubital brachial access (e.g., "retrograde" positioning of the embolectomy catheter into the proximal brachial and axillary arteries) carries a significant risk of catheter-related injury to the proximal brachial artery at the origin of the deep brachial artery, where a significant diameter reduction occurs due to the bifurcation of superficial and deep brachial arteries. For proximal embolectomy, the safer approach is to generally gain access in the axillary rather than antecubital fossa.
- Brachial occlusion associated with elbow or shoulder dislocation typically results from intimal disruption or dissection beginning at the point of injury and extending distally. Accordingly, when focal arterial injury is present in the setting of complete occlusion, the injured segment is optimally repaired by resection and replacement rather than attempts at anticoagulation or embolectomy alone.

RADIAL ARTERY

First Step

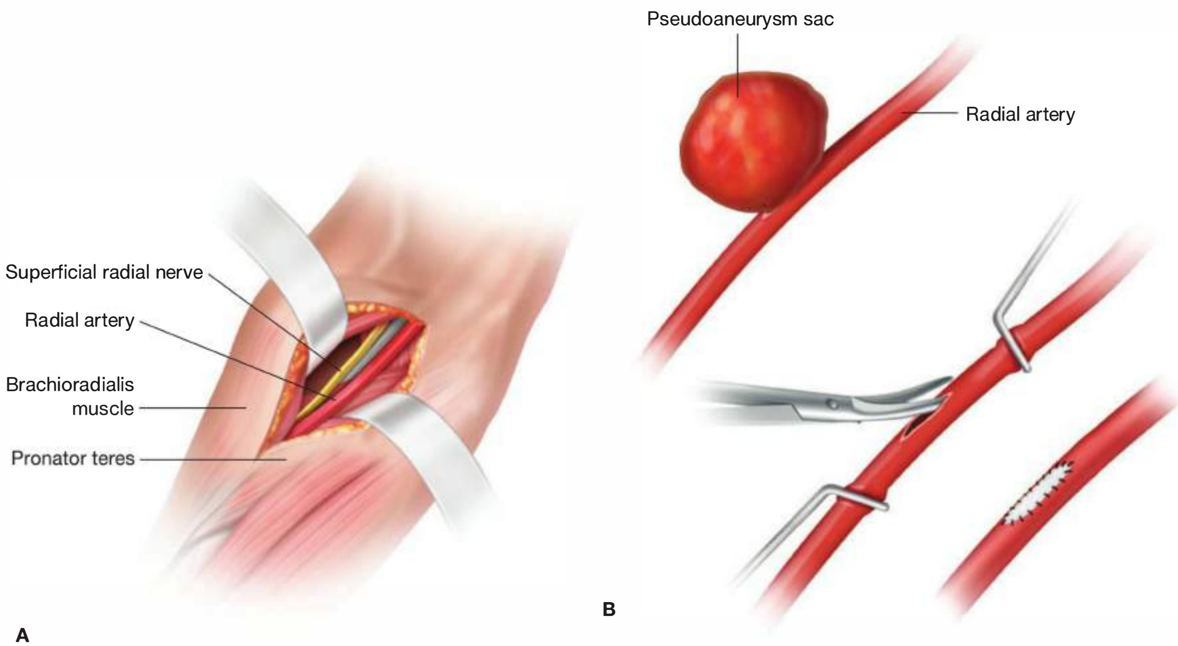
- Direct open exposure of the radial artery can be performed at almost every level proximal to the wrist. As with other arterial segments, exposure of the radial artery should be sufficient to allow both proximal and distal arterial control.
- The brachial artery typically bifurcates to give rise to the radial artery and ulnar/interosseus trunk at the level of the radial tuberosity (FIG 5B). However, not infrequently, the radial artery originates from the upper arm brachial artery or even the axillary artery (up to 15% incidence in cadaveric studies).[19] Several clinical circumstances highlight the significance of this anomaly, including the need to base distal bypass or arteriovenous access procedures off the "brachial" artery in the antecubital fossa. To ensure adequate arterial inflow, it is essential to identify which arterial conduits are present and identified in the antecubital fossa. Preoperative CT angiography, catheter-based contrast arteriography, or ultrasonography can provide essential information in this regard.
- Alternative exposure options exist for the brachial bifurcation and proximal radial artery in the antecubital fossa. A 4- to 5-cm transverse incision, two fingerbreadths distal to the antecubital crease, provides optimal exposure for the distal brachial artery as well as the origins of the forearm arteries (interosseus, radial, and ulnar). Alternatively, for more extensive brachial artery exposure, an S-shaped incision is employed extending from the medial aspect of the biceps muscle tendon, through the midpoint of the antecubital fossa, and toward the lateral aspect of the volar forearm (FIG 5A).
- Exposure of the mid- or distal radial artery can be performed through 4- to 5-cm longitudinal incisions along the lateral aspect of the volar forearm (FIG 6A). A useful landmark for these incisions is the imaginary line extending from the midpoint of the antecubital crease to the styloid process of the radius, which often anatomically corresponds to the groove of the medial edge of the brachioradialis muscle.

Second Step

- Superficial, subcutaneous veins overlying the target arteries (medial antecubital vein in the antecubital fossa and cephalic vein branches in the forearm) may be mobilized or ligated to aid with the exposure process. Prior to ligation, care should be taken to consider the totality of remaining forearm runoff veins, especially in the setting of blunt or avulsive traumatic injuries.
- In the proximal forearm, the antebrachial fascia will need to be excised along the medial edge of the brachioradialis muscle along the length of the incision. The radial artery can then be visualized with lateral retraction of the brachioradialis muscle.
- Similarly, in the midforearm, the radial artery can be visualized following excision of the overlying antebrachial fascia and retracting apart the brachioradialis and pronator teres muscles (FIG 6A).
- During exposure maneuvers, care should be taken to visualize and avoid injury to closely associated radial artery structures. This includes the paired radial artery veins that accompany the radial artery throughout its course in the forearm. The superficial radial nerve is also closely associated with the lateral aspect of the radial artery in the midforearm and can be preserved with gentle lateral retraction.

Third Step

- Given the dominance of the ulnar circulation in most patients, isolated distal radial reconstruction may be optional, depending on the totality of coexisting conditions and injuries. Superimposed acute or chronic traumatic injury,



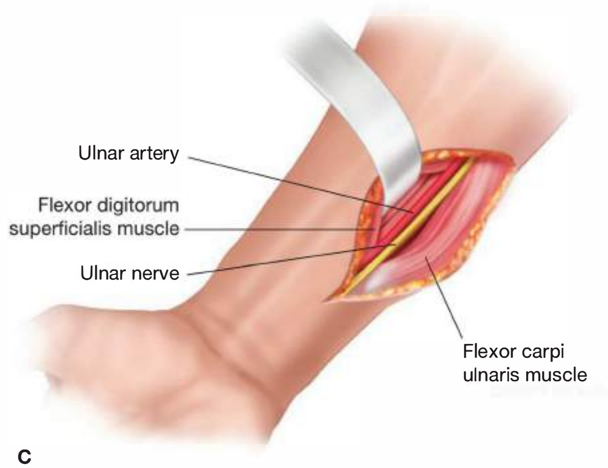


FIG 6 ● **A.** Exposure of the radial artery in the proximal and distal forearm. **B.** Following proximal and distal radial artery control, a primary repair of a radial artery pseudoaneurysm is performed. **C.** Exposure of the proximal midulnar artery in the forearm.

renal failure, diabetes mellitus, or chronic embolization may justify radial reconstruction, particularly in circumstances where hand viability is at significant risk.

- Radial artery transections or pseudoaneurysms, like all types of arterial reconstruction, are best approached following adequate exposure and proximal/distal control. Detailed exploration and arterial exposure follows shortly thereafter. Depending on extent of injury and integrity of the arterial lumen at the site of injury, either primary repair or interposition grafting may be considered (FIG 6B).
- Acute embolic occlusions of the radial artery can be removed through retrograde embolectomy, performed through a controlled proximal, transverse arteriotomy. Given the caliber of the forearm arterial system, a 2-Fr Fogarty catheter is best suited for this purpose. As was the case more proximally in the upper extremity arterial system, image-guided, over-the-wire embolectomy, combined with judicious use of intraarterial thrombolytic agents such as tPA (see "Upper extremity angiography and stenting" section in the following text), may be necessary to achieve satisfactory runoff and hand and digital perfusion. Thus, arrangements should be made preoperatively to initiate the embolectomy procedure in an operating environment that can support image-guided intervention.
- Both forearm arteries at the wrist may provide appropriate inflow for dialysis access procedures. Considerations for arteriovenous access creation and maintenance are beyond the scope of this chapter. Interested readers are referred to other references for options regarding dialysis access creation.

ULNAR ARTERY

First Step

- Similar to the radial artery, the ulnar artery may also be exposed along its course in the forearm, and the extent of exposure will depend on the site and type of pathology as well as ability to obtain adequate proximal and distal arterial control (FIG 6C).
- The proximal ulnar artery can also be exposed at the brachial bifurcation in the antecubital fossa through an S-shaped incision (see "Radial artery" earlier; FIG 5A,B).
- Although more challenging, the proximal ulnar artery may also be exposed in the medial aspect of the proximal forearm. Four fingerbreadths below the medial epicondyle, a 7- to 9-cm longitudinal incision can be created along a line extending from the medial epicondyle to the pisiform bone. Incising the deep fascia facilitates exposure of the ulnar artery through the space between the flexor carpi ulnaris and flexor digitorum superficialis muscles (FIG 6C).
- The distal ulnar artery, proximal to the wrist, is optimally exposed through a longitudinal incision just lateral to the flexor carpi ulnaris muscle. The ulnar nerve lies medial to the artery at this level and is prone to injury with this exposure. Care should be taken to identify and mobilize it safely. The superficial palmar branch of the ulnar artery and nerve also crosses superficial to the antecubital fascia at the wrist level, and care should be taken to prevent traction or compression injuries to these structures during ulnar artery exposure.

Second Step

- Thrombectomy of the ulnar artery proceeds in a fashion similar to that previously described for the radial artery.
- Ulnar artery traumatic transections may be repaired primarily or with an appropriately sized interposition vein graft. Vein harvested from the dorsum of the foot frequently serves this purpose well.
- Ulnar artery arteriovenous dialysis accesses are rarely performed due to this vessel's relative difficulty in exposure compared to the radial artery, its close proximity to the ulnar nerve throughout its length, and its relative dominance in maintaining adequate perfusion to the hand.

UPPER EXTREMITY ANGIOGRAPHY AND STENTING

First Step

- Access depends largely on the area and type of anticipated arterial pathology. For innominate or proximal subclavian artery disease or injury, retrograde transbrachial or transfemoral artery approach may both suffice. For distal diagnostic or interventional procedures, retrograde radial or antegrade access may be considered.
- Standard Seldinger technique is used for percutaneous arterial access, using either ultrasonographic or fluoroscopic guidance. Placement of a 4-Fr microsheath may help stabilize the initial cannulation site and allow for preliminary diagnostic imaging.

Second Step

- Intraarterial pharmacologic adjuncts may be administered through appropriately positioned arterial infusion systems.
- For arterial thrombosis, catheter-directed, limb-specific, intraarterial tPA is administered in doses related to the extent of thrombus load, ranging from 0.25 to 2.0 mg per hour, following an initial "seeding" dose of 4 mg across the region in question over 10 to 30 minutes. Combined pharmacologic/mechanical thrombus disruption systems useful in other arterial and venous beds, including the Trellis™ system (Covidien, Mansfield, MA), may be too large or unwieldy for the upper extremity arterial vasculature. Newer low-profile systems, however, such as the MicroLysUS™ infusion catheter (EKOS Corporation, Bothell, WA), may be more useful and appropriate in this application. Care should always be taken to account for risk of particulate embolus in the vertebral artery when planning embolectomy or thrombectomy procedures in the upper extremity.
- Similarly, the upper extremity arterial system is particularly prone to vasospasm during catheterization. During diagnostic examinations, particularly in younger patients, care should be taken to avoid catheterization distal to the antecubital fossa to minimize artifactual degradation of the angiographic image due to vasospasm. Similarly, using warm flush solutions may minimize this effect. When the radiographic appearance of vasospasm is encountered ("string sign" or "string of beads" appearance), direct intraarterial infusion of papaverine (10 to 50 mg) or nitroglycerine (50 to 200 μg) may improve image resolution in hand or digital arteries. Papaverine will precipitate out of solution when exposed to heparin and may not be optimal for all potential clinical applications for this reason.

Third Step

- If further endovascular diagnostic or interventional procedures are planned, wire access with a 0.018-in or 0.035-in guidewire to the arterial segment of interest must be achieved.
- From a brachial artery approach, a short guide sheath and a guide catheter combination usually allows for successful catheterization of adjacent proximal upper extremity arterial segments.
- From a femoral artery approach, a long (90 cm) 6- or 7-Fr sheath is typically advanced over the guidewire to facilitate stable catheterization of innominate or proximal left subclavian artery. Long, curved 5-Fr catheters (i.e., angled, JB 2, headhunter, or vertebral catheter) may be used to aid in successful cannulation and subsequent catheterization of the arch vessel of interest. Confirmatory angiograms will help confirm successful cannulation and aid in identifying the arterial segment of interest (FIG 7A).
- Once stable catheterization of the target vessel is achieved, magnified angiograms may be obtained in the

appropriate obliquities to accurately assess the arterial segments of interest. Additional runoff imaging may be necessary to evaluate the arterial outflow distal to the diseased segment. The operator should inspect these angiograms to determine once again the candidacy for endovascular treatment and obtain additional measurements to facilitate appropriate device selection.

Fourth Step

- Successful wire advancement across the lesion of interest is the next step in order to facilitate any planned treatments with angioplasty or stenting.
- With the guidance of a 4- or 5-Fr guide catheter, a 0.018-in or 0.035-in hydrophilic wire can be advanced across a hemodynamically significant stenosis (e.g., innominate artery, proximal subclavian artery, or upper arm brachial artery). During advancement, care should be taken to remain intraluminal as much as possible to minimize the risk of dissection and reentry. Adequate wire purchase should be acquired past the stenosis after crossing the lesion of interest to decrease the chance of losing subsequent wire access across the lesion.
- In situations where stenoses or occlusions preclude access from a "preferred" side, crossing the lesion from the alternate side and advancing a wire from the opposite direction using a snare technique may be required.
- Simultaneous antegrade and retrograde, through and through ("body floss") cannulation may facilitate lifesaving management of traumatic subclavian artery injuries. In dire circumstances where arterial continuity has been completely lost, and transluminal wire passage is not possible, advancing snare and wire from opposite directions simultaneously, employing multiple-angled view may allow for successful snaring in perivascular soft tissue and subsequent spanning of the arterial tissue defect with a flexible covered stent (e.g., Viabahn™). This technique may generate immediate and effective hemostasis while maintaining luminal patency and limb viability, especially as an alternative to ligation or emergency embolization (FIG 7).

Fifth Step

- Proximal subclavian artery and innominate stenoses are typically well managed by precise placement of stiff, balloon-expandable stents or stent grafts. Compared to the axillary artery, proximal to the costoclavicular junction, there is little or no movement in the proximal subclavian artery. In the setting of a prior internal mammary-to-coronary artery revascularization, or a history of vertebral–basilar insufficiency, precise stent placement is tantamount to procedural success. For this reason, appropriately sized covered (e.g., Atrium iCAST) or bare metal (e.g., Omnilink, Abbott, Redwood City, CA; Palmaz, Cordis Endovascular, Warren, NJ.) balloon-expandable stents are generally preferred.
- Appropriately size-matched, covered stents are also essential adjuncts for management of proximal subclavian artery injuries or chronic pseudoaneurysms (FIG 7).
- As noted earlier, however, stents of any kind should not be deployed in proximity to the junction of the 1st rib and clavicle, as chronic traumatic damage from compression between these bony structure will cause certain stent failure and further compromise limb viability.

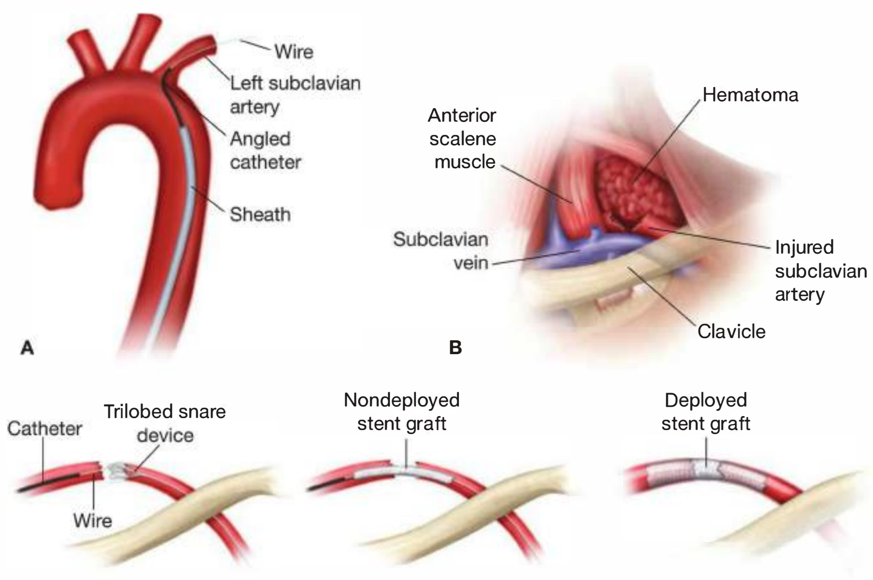

FIG 7 ● **A.** Retrograde cannulation of the proximal left subclavian artery using a triaxial flexible sheath, angled catheter, and glidewire combination. **B.** Traumatic injury to the left subclavian artery. **C.** Through and through (body floss) wire accesses the injured subclavian artery. **D,E.** Positioning and deployment of a covered stent to seal the subclavian arterial wall disruption while maintaining luminal flow.

PEARLS AND PITFALLS

Upper extremity nerve injuries	■ Upper extremity arterial injuries frequently are associated with concomitant nerve injuries.[20] Early recognition and diagnosis of these associated injuries is paramount to long-term functional restoration. ■ When nerve injury is identified or suspected, prompt repair in the same setting is recommended. Plastic surgery consultation in these circumstances is usually required.
Iatrogenic nerve injury during axillary artery exposure	■ As a general rule of thumb, whenever possible, axillary exposure proximal to the axilla should be acquired as proximal as possible, to limit the risk of nerve injury, as the cords of the brachial plexus become more intimately related to the axillary artery as it proceeds laterally from the clavicle. Also, the amount of axillary artery displacement and traction as a result of arm movement is minimized with far proximal anastomotic positioning. ■ Unless repair of the axillary artery requires a deltopectoral exposure, the preferred choices for axillary artery exposure are proximal or distal to the second portion of the axillary artery.
Arterial repair following segmental resection	■ In the setting of arterial trauma, the extent of arterial injury should be precisely determined prior to attempts at reconstruction. Failure to completely delineate the extent of injury will complicate attempts at repair. ■ As a general rule of thumb, all involved arterial segment should be resected and/or bypassed prior to attempts at reconstruction. Although primary repair with native arterial preservation is often appealing, long-term success typically requires interposition vein grafting for anything more than the simplest of injuries.[15,21]
Inflow assessment	■ Prior to completion of an upper extremity arterial repair, the operator must ensure that arterial inflow is adequate. ■ This can be confirmed on preoperative CTA if available, or alternatively, with an intraoperative angiogram.
Outflow assessment	■ Adequate arterial outflow is paramount to maintain patency of proximal repairs and help alleviate potential extremity ischemic symptoms. ■ Some authors recommend routine outflow assessments following upper extremity revascularization.[22] However, if this strategy is not regularly employed, intraoperative outflow assessment should be performed in circumstances where the distal arm and/or wrist vascular examination is abnormal following operative revascularization. ■ Because the ulnar artery is the dominant vessel of the distal forearm and hand, restoration of flow to this outflow vessel is often necessary to avoid subsequent complications.
Compartment syndrome of the upper extremity	■ With prolonged acute ischemia (>4–6 hours), upper extremity compartment release via fasciotomies is highly recommended. ■ Upper arm fasciotomies include two incisions into the brachium's two compartments. ■ Forearm fasciotomies are performed with three or more discrete incisions to decompress the volar forearm, dorsal forearm, and mobile wad.[23] ■ The hand may also require decompression via multiple incisions.[24] A carpal tunnel release may be necessary if median and ulnar nerve dysfunction is evident. Consultation with hand or plastic surgeons is recommended when considering the potential benefit of hand fasciotomy to maximize compartmental release and long-term functional and cosmetic recovery.

POSTOPERATIVE CARE

- At the conclusion of arterial reconstructive procedures, reversal of heparin-induced coagulopathy with protamine may or may not be indicated, depending on the status of the limb, the patient, and the reconstructive procedure itself. Care should be taken to provide a test dose of protamine before full reversal, if indicated, to minimize associated hypotension when antiprotamine antibodies are present.
- Motor and sensory examination as well as determination of upper extremity arterial status (including a Doppler and pulse examination) should be performed immediately postoperatively to determine the new baseline for subsequent serial examinations and to document improvement.
- Patients are typically observed for an extended period (at least several hours) following upper extremity arterial intervention to ensure procedural success and recovery from anesthesia. During this period, the patient is observed for bleeding, hematomas, or change in serial vascular examinations.
- Patients treated for primary thrombosis or occlusion of an arterial segment are typically managed with long-term, adjunctive systemic anticoagulation. The length of treatment period is debated and is variable between practitioners but may be directed by severity of presenting symptoms, frequency of prior occurrences, or history of a hypercoagulable condition.[25]
- Patients who presented with a presumed embolic occlusion of an arterial segment should undergo a medical workup for possible cardiac, proximal arterial atherosclerotic, endocarditis, paradoxical, or tumor embolic sources.
- Patients who underwent angioplasty or stenting of an arterial segment in the upper extremity are typically initiated on a single-agent antiplatelet regimen with either aspirin or clopidogrel.

- Patients who had a concomitant nerve injury or required fasciotomy compartment release should be engaged in rehabilitation activities promptly to aid in restoration of extremity function.[23]
- Postoperative surveillance of patients with upper extremity arterial interventions is necessary. Duplex evaluation of the repaired arterial segment 1 to 3 months following intervention is usually recommended followed by serial duplex evaluations every 6 months for at least 1 to 2 years. Patients with no evidence of repair site compromise may then be imaged on a yearly basis. If there is evidence of arterial segment compromise (stenosis, decreased flow, or occlusion), primary assisted patency and secondary patency may be enhanced with reintervention.

OUTCOMES

- Upper extremity revascularization with open arterial bypass has a reported average primary patency of 82% to 87% and excellent limb salvage rates.[26]
- Some series suggest arterial graft patency is lowest in female smokers with long bypass segments that cross multiple joints.[27]
- Because acute embolic episodes more commonly occur in elderly patients, the perioperative mortality and morbidity in this patient cohort is higher compared to age-matched background populations.[28]
- Catheter-based revascularization of the proximal subclavian artery and innominate artery have a high reported technical success rate (>98%), with excellent primary rates and low associated procedure morbidity.[29]
- Percutaneous treatment of upper extremity traumatic arterial injuries of subclavian artery are associated with decreased operative time and intraoperative blood loss while maintaining equivalent patency rates to standard open repairs.[30,31]
- Axillary artery branch vessel repair outcomes are met with high success rates of symptom resolution and lack of recurrence if distal emboli are lysed and proximal branch vessel embolic source is completely isolated from the circulation.[14]

COMPLICATIONS

- Intraoperative arterial vasospasm or occlusion
- Missed concomitant venous or nerve injuries during traumatic arterial injuries
- Iatrogenic brachial plexus, median, or ulnar nerve injuries from intraoperative electrocautery, traction, or accidental transection
- Iatrogenic injury to the brachial artery when attempting retrograde catheter embolization, especially when failing to take into account the significant taper present in the proximal brachial artery
- Arterial bypass graft stenosis or thrombosis
- Repair site bleeding
- Wound or graft site infection
- Digital or vertebral artery embolization, complicating thromboembolectomy
- Postrevascularization compartment syndrome in the arm or hand
- Stent failure when deployed in proximity to the clavicle/1st rib

Chapter **11**

Upper Extremity Arterial Reconstruction and Revascularization Distal to the Wrist

Michael G. Galvez   James Chang

DEFINITION

- Arterial reconstruction and revascularization distal to the wrist requires reconstituting the complex vascular supply to the hand. This includes the ulnar and radial arteries, superficial and deep palmar arches, and common and proper digital arteries. This reconstitution is performed with either end-to-end primary vascular repair, interposition vascular graft bypass with proximal and distal anastomoses, or addressing the digital arteries individually. Additionally, fasciotomy for compartment syndrome following trauma or reperfusion injury may be a necessary adjunct.

DIFFERENTIAL DIAGNOSIS/PRECIPITATING CAUSES OF HAND ISCHEMIA

- Arterial injury
  - Traumatic (laceration, high energy or crush injury, etc.) or iatrogenic injury (including inadvertent or intentional cannulation for vascular access).
- Proximal embolization
- Intraluminal thrombosis
  - Hypothenar hammer syndrome occurs when the base of the hypothenar eminence sustains repeated blunt trauma resulting in chronic injury to the distal ulnar artery and the superficial palmar arch. In this scenario, compression occurs between the roof of Guyon's canal and the hook of the hamate bone, resulting in aneurysmal degeneration of the ulnar artery, luminal thrombus accumulation, and digital embolization (typically the ring and small finger). This typically occurs on the dominant hand of individuals participating in vocational or avocational activities involving repeated palmar impact (e.g., pipe fitters and mountain bike riders).
  - Spontaneous radial artery thrombosis may be associated with Buerger's disease and is not as common as ulnar artery thrombosis.
- Chronic digital ischemia secondary to vasospastic and rheumatologic disease:
  - Primary Raynaud's syndrome refers to cold-induced vasospasm present in the absence of concomitant disease. The etiology of this condition remains uncertain but is likely due to an exaggerated adrenergic receptor–mediated response to cold exposure.
  - Secondary Raynaud's syndrome refers to digital vasospasm which occurs in the setting of known autoimmune collagen vascular diseases and related rheumatologic disorders (such as rheumatoid arthritis). In this circumstance, a normal vasospastic response to cold or environmental stimuli is superimposed on chronic digital artery occlusive disease. Differentiation from primary Raynaud's syndrome is most commonly made based on digital ulceration and tissue loss, conditions which uniformly develop in secondary Raynaud's syndrome.
  - CREST syndrome encompasses the most common phenotypic presentation of systemic scleroderma/sclerosis: calcinosis, Raynaud's phenomenon, esophageal stenosis, sclerodactyly, and associated telangiectasias.
  - Buerger's disease, or thromboangiitis obliterans, represents a progressive, recurring necrotizing arteritis of small and medium vessels closely linked to tobacco exposure.
- Compartment syndrome occurs in response to increased pressure within a fixed osteofascial anatomic space, leading to decreased arterial perfusion, irreversible myonecrosis, neuropathy, and potential limb loss. In the hand, compartment syndrome most commonly develops following crush injuries; however, intravenous infiltration, external compression, and other mechanisms may also induce increased compartment pressure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Determine the hand dominance of the patient and relevant history of trauma, tobacco use, medical history (coagulopathic disorders), and occupational exposures. Additionally, the presence of palpable masses, pain, sensory changes, or color changes should be evaluated.
- An Allen's test may provide additional information regarding the relative contribution of the ulnar and radial arteries to hand perfusion. This test is performed by manual compression of both the radial and ulnar arteries, with elevation and successive opening and closing performed to drain venous blood from the hand. The time differential to reperfusion, following respective arterial release, provides qualitative insight into relative radial or ulnar dominance. In most cases, however, the ulnar artery is dominant, and modern quantitative arterial perfusion assessment by duplex imaging and digital plethysmography has largely supplanted subjective physical exam findings in the assessment of adequacy of arterial inflow.
- Patients with hypothenar hammer syndrome can have complaints of pain and tenderness of the hypothenar mass, with cold sensitivity and numbness of the ring and small finger secondary to digital embolization and direct ulnar nerve compression. A pulsatile mass may, on occasion, be appreciable in the palm. Discoloration of the lateral three fingers of the hand may also be present as a result of chronic digital embolization.
- Patients with spontaneous radial artery thrombosis present with pain, numbness, and discoloration of the tips of the

radial-sided digits. The area of occlusion is commonly beneath the first and third extensor compartments and can be related to compression of the radial artery by the extensor pollicis longus.[1]

- Patients with Raynaud's syndrome report ischemic symptoms and digital discoloration on exposure to cold. Cold-induced vasospasm may be elicited by cold emersion testing in an ice bath. A positive test is elicited by the elimination of plethysmographic pulsatile phasicity on exposure to cold, in addition to the onset of symptoms. Most patients, however, cannot tolerate this provocative test, and the clinical use of eliciting vasospastic symptoms, particularly in the presence of existing digital ulceration, is uncertain.
- Compartment syndrome is a clinical diagnosis. Cardinal signs include persistent and progressive pain unrelieved with immobilization/elevation, tightness of skin, pain with passive extension, and decreased sensation. Reduced skin temperature, pallor, and pulselessness are often late findings.
  - The intrinsic compartments are tested for pain with passive adduction and abduction of the fingers. The thenar compartment is tested by adduction of the thumb. The adductor of the thumb is tested by passive palmar abduction. The hypothenar compartment is tested by adduction of the small finger.
  - Normal intracompartment pressures are less than 10 mmHg; between 10 and 20 mmHg is considered high but not enough to cause muscle necrosis. An acute compartment syndrome is assumed if the measured interstitial tissue pressures are within 30 mmHg of the mean arterial pressure or 20 mmHg of the diastolic blood pressure.[2] Hand pressures are typically difficult to assess on the basis of direct measurement, given the extensive septation of the fascial compartments, underscoring the importance of clinical diagnosis. When in doubt, it is prudent to proceed with operative fasciotomy.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- As previously mentioned, noninvasive vascular imaging and physiologic assessment are essential to establishing the diagnosis of hand and digital ischemia as well as providing a physiologic corollary to subsequent arterial imaging studies obtained to outline the relevant anatomy. Noninvasive testing informs and should always precede anatomic imaging studies regardless of modality.
- Imaging provides essential identification of normal and variant arterial anatomy, recognition of the location and extent of obstructive and aneurysmal disease, and operative planning.
- The vascular anatomy of the hand includes the ulnar artery, radial artery, and sometimes a persistent median artery (5% of the population). The ulnar and radial arteries anastomose to form the superficial and deep palmar arches, with the ulnar artery being the main contributor to the superficial arch and the radial artery the main contributor to the deep palmar arch (**FIG 1**). There is significant variation in the vascular patterns of the superficial and deep palmar arches.
- The superficial palmar arch is completed by either the branches of the deep palmar arch, radial artery, or median artery in about 80% of patients. The deep palmar arch is completed by the superior branch of the ulnar artery, the inferior branch of the ulnar artery, or both in about 97% of patients.

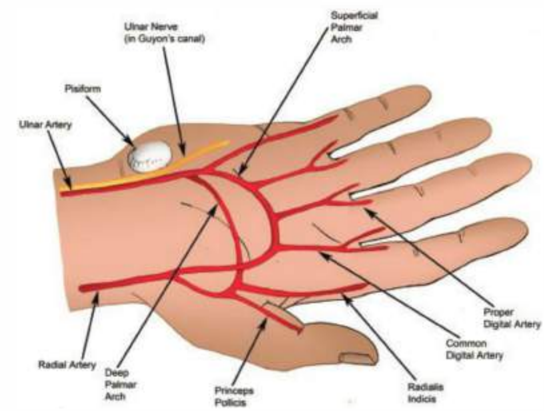

FIG 1 ● Anatomy of the hand illustration: schematic drawing of the vascular supply of the hand, demonstrating the ulnar artery as it passes Guyon's canal and becomes the superficial palmar arch, radial artery as it becomes the deep palmar arch, the common digital arteries, and the proper digital arteries.

- The main branches from the superficial palmar arch are the three common digital arteries, which go to the index-middle, middle-ring, and ring-small finger webspaces, as well as the proper digital artery to the ulnar aspect of the small finger. Each digit has a dual blood supply from the radial and ulnar proper digital vessels.
- The thumb has blood supply from the princeps pollicis artery, which variably arises from the radial artery, the deep palmar, or superficial palmar arch.
- Catheter-directed, contrast-enhanced, digital subtraction hand arteriography provides highly detailed anatomic information and represents the gold standard in vascular imaging (**FIG 2**). However, there are risks from this invasive procedure, which include contrast allergic reaction, vasospasm, contrast-induced nephropathy, thromboembolic events including digital embolization and stroke, and drug reactions precipitated by intraarterial injection of vasoactive agents including Priscoline and nitroglycerin. Hence, catheter-based arteriography is best suited to operative planning in patients already determined to need reconstructive surgery.

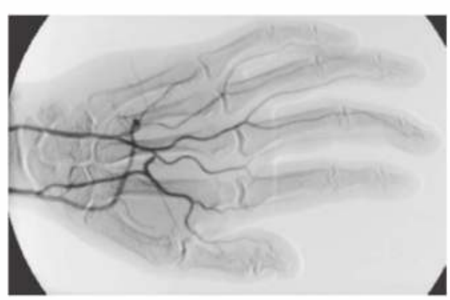

FIG 2 ● Hand angiogram: normal hand angiogram demonstrating complete superficial and deep palmar arches.

- Magnetic resonance arteriography (MRA) is another option for imaging that is noninvasive, eliminating risks of radiation, contrast reaction, and vasospasm. However, the resolution of MRA is not sufficient for detailed surgical planning.
- Computed tomographic arteriography (CTA) is also noninvasive, although contrast and (significant) radiation exposure are required for image acquisition. Similar to MRA imaging, the resolution of CTA is typically not sufficient to support detailed surgical planning.
- Measuring compartment pressures of the hand can be performed with the Stryker Intra-Compartmental Pressure Monitor (Kalamazoo, Michigan), which involves placing the device needle perpendicular to the skin and evaluating individual compartments including sites of maximum swelling of the thenar, hypothenar, and interosseous compartments. The compartment being measured should be at the level of the heart. In an intensive care unit setting, using an arterial pressure line connected to a strain gauge, zeroed at the level of needle entry into the hand, can also provide rapid and accurate compartmental measurements. A 20-gauge needle is inserted into the compartment and flushed, with measurement acquired after the flush bolus has disseminated in the compartment and the pressure spike from the flush returns to baseline.

SURGICAL MANAGEMENT

Preoperative Planning

- The overall goal is to restore distal blood flow to baseline/maximal levels, given anatomic constraints, available arterial conduit, central arterial perfusion pressure and cardiac output, and end-organ (hand) viability.
- Treatment of thromboembolic disease can include medical management and catheter-based chemical and mechanical thrombolysis, angioplasty, and stenting to maximize arteriolar outflow and arterial inflow, respectively. Upper extremity revascularization techniques are discussed in Part 6, Chapter 10.
- End-to-end primary vascular repair can be performed if arteries are tension free after mobilization, and the zone of injury is accurately identified to be uninvolved in the site of anastomosis. If there is any difficulty in approximating the vessels ends, then vascular grafts are preferred.
- In ulnar or radial artery thrombosis, reconstruction is preferred over ligation. Proximal reconstructions are attempted even in the setting of more distal occlusions, based on the rationale of augmenting collateral flow via direct or indirect means.[3]
- Determining venous or arterial graft harvest site is important for preoperative planning. Dorsal hand or foot veins provide the most appropriate size match for intrinsic arteries of the hand (and feet). Donor sites for arterial graft conduits include the deep inferior epigastric artery, subscapular artery, thoracodorsal artery, or descending branch of the lateral femoral circumflex artery. Typically, arterial grafts patency rates are superior to those obtained with venous grafts.[4]
- For chronic ischemia, medical management including pharmacologic treatment with vasodilators, topical nitroglycerin, calcium channel blockers, or botulinum toxin should be attempted first, prior to surgical management.[5] Evidence of gangrene, osteomyelitis, and so forth of the involved digit may require debridement or digital amputation.
- Periarterial sympathectomy in the hand, which involves stripping the adventitial layers from affected arteries, removes sympathetic nerve input to the media and has proven effective in promoting distal finger lesion healing in scleroderma patients. In scleroderma specifically, the thickened adventitia apparently contributes to decreased digital arterial flow.[6,7]

Positioning

- Hand surgery is usually performed with the patient in the supine position. The operated hand is placed on a hand surgery table, which is stabilized by two legs. Reconstructive surgery may be performed under tourniquet, depending on systemic comorbidities and the adequacy of arterial inflow. For tourniquet control, the upper arm is well padded with Webril (cotton) wrapped circumferentially, and then an 18-in (or appropriately sized) pneumatic tourniquet is secured around the upper arm (**FIG 3**). Alternatively, depending on inflow status, the tourniquet may be placed at the forearm or wrist. Finally, an impervious barrier (3M Steri-Drape 1000) is placed circumferentially just distal to the tourniquet to prevent see page of the sterile prep solution. The arm/hand are then sterilely prepped and draped.
- Intraoperatively, the arm is exsanguinated with an elastic bandage (Esmarch bandage) wrap and elevation immediately prior to tourniquet inflation. In adults, the tourniquet is typically inflated to 250 mmHg; in children, it is set 100 mmHg above the systolic pressure. The tourniquet inflation should last no more

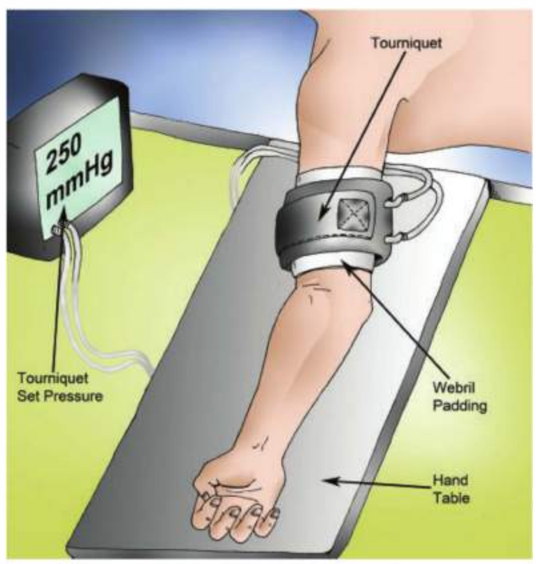

FIG 3 ● Positioning illustration: supine positioning of patient with arm being operated on placed out on hand table. Webril gauze is wrapped circumferentially around the arm and followed by tourniquet placement. Appropriate tourniquet pressure is set. Finally (not pictured) a 3M Steri-Drape 1000 is wrapped circumferentially.

than 2 hours and must be deflated for a 20-minute interval to allow reperfusion prior to reinflation, if needed. Consideration should be made to establishing systemic anticoagulation prior to tourniquet inflation when indicated.

- Appropriate concurrent sterile prep should be performed on graft harvest sites as necessary.
- Microsurgery prep includes ensuring that the operating scope is working properly and sterilely draped. Positioning is extremely important to reduce surgeon fatigue, which includes ensuring good table height, working height (with appropriate padding support of the wrists with stacks of surgical towels), and sitting position. Microsurgery instruments should be available as necessary, depending on the level of revascularization considered. 9-0 and 10-0 sutures are employed for more distal reconstructive procedures and digital reimplantation. For proximal radial and ulnar reconstruction procedures, at or immediately adjacent to the wrist, 2.5× to 3.5× surgical loupe magnification will provide adequate anatomic resolution and suture placement for operators with normal visual acuity.

ULNAR ARTERY RECONSTRUCTION

Placement of Incision

- Identify the ulnar artery aneurysm (FIG 4A), and incise the skin longitudinally over the ulnar artery as it crosses Guyon's canal. Extension across the midpalmar crease may be necessary to expose the distal ulnar artery as it curves radially to become the superficial palmar arch.
- The volar carpal ligament, the roof of Guyon's canal, is a continuation of the deep palmar fascia and fibers of the flexor carpi ulnaris and must be carefully incised for access to the ulnar artery and nerve.
- The ulnar nerve, particularly the motor branch, must be carefully protected.

Resection of Ulnar Aneurysm

- Once the deep palmar fascia is incised, the aneurysm is generally recognizable (FIG 4B AND FIG 5A). The aneurysm itself may be thrombosed or tortuous or elongated as a result of chronic posttraumatic remodeling. Microvascular clamps are placed on the ulnar artery proximal and distal to the aneurysm.
- Preserve the common digital arteries and other large branches distal to the thrombosed segment. Place microvascular clamps and vessel loops as needed on vessels that will require revascularization.
- Resect the affected artery and trim the ends sharply.
- The adventitia is excised as needed, and the intima inspected at the proximal and distal end of the anastomoses to ensure

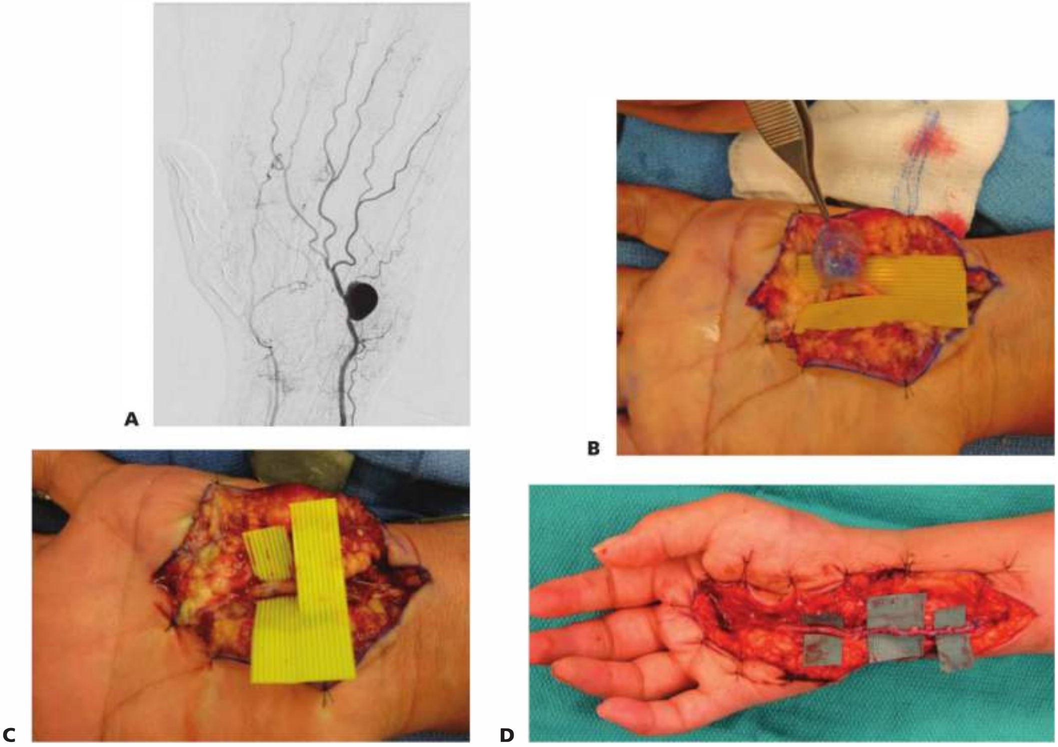

FIG 4 ● Ulnar artery reconstruction: **A.** Hand angiogram demonstrating a large ulnar artery aneurysm in Guyon's canal. **B.** Ulnar aneurysm segment is isolated proximally and distally. **C.** A direct end-to-end anastomoses was performed. **D.** In another patient, a long vein graft is used to extend from a more proximal ulnar artery.

that the entire disease segment is removed. Failure to remove the entirety of diseased artery may precipitate early graft thrombosis and recurrent digital embolization.

Vein Graft Interposition

- Occasionally, sufficient redundancy is present in the ulnar artery to allow direct primary repair (FIG 4C); in most cases, interposition vein grafting (FIG 4D) is required to complete the reconstruction without tension.
- When the superficial palmar arch and adjacent common digital arteries are involved, then a more complex "palmar arch" reconstruction may be necessary to restore perfusion to the dependant digits (FIG 5B), with end-to-side anastomoses of the common digital arteries into the distal extent of the vein graft.
- Vein harvest is typically chosen from the hand and foot veins. Length of vein harvest should be several centimeters longer to allow for trimming.
- Marking the superficial surface of the vein helps avoid twisting or kinking of the vein graft. Marking one end (typically distal) provides a reminder to reverse the graft prior to implantation. If needed, ends with valves are excised. Arterial graft may also be used when available and of suitable diameter and length.
- Longer grafts may also be used (FIG 4D) when more proximal arterial inflow is required.
- Microvascular anastomosis of vessel graft.
    - Anastomosis completion may require microsurgical technique, given that common digital arteries may be 1 to 2 mm in diameter.
    - Both ends of the vessels are held in place by an appropriately tensioned microvascular double-armed clamp.

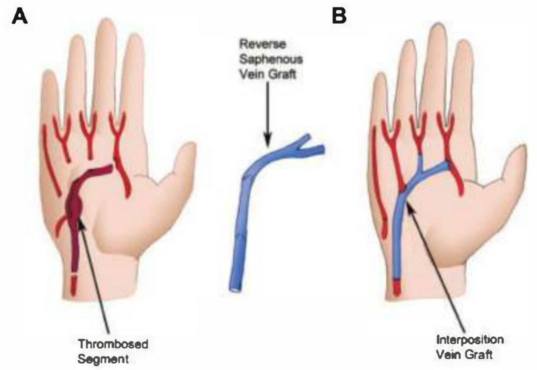

FIG 5 ● Ulnar artery reconstruction illustration. Exploration of the ulnar artery confirms findings of angiogram demonstrating **(A)** ulnar artery thrombosis to the origin of the common digital arteries. Reconstruction requires harvesting a Y branch of a saphenous vein graft, which is then reversed prior to interposition. **B.** End-to-side distal anastomosis, end-to-end anastomosis of the vein branch to the common digital artery, and end-to-side anastomosis to common digital artery are performed.

- After irrigation with heparinized saline, interrupted sutures are placed circumferentially using a triangulation technique.
- The proximal anastomosis is performed first, then flushed with heparin and clamped to allow the vein graft to extend to length before preparing and completing the distal anastomos(e)s.

SNUFFBOX RADIAL ARTERY RECONSTRUCTION

Placement of Incision

- At the level of wrist, the radial artery turns dorsally underneath the first extensor compartment (containing the abductor pollicis longus and extensor pollicis brevis), then runs between the first and third extensor compartments (extensor pollicis longus) in the area known as the "anatomic snuffbox." The diseased segment and distal targets should be confirmed by reference to the specific preoperative imaging studies (FIG 6A,B). A skin incision is made on the dorsum of the hand directly over the anatomic snuffbox parallel to the second metacarpal (FIG 7A).
- The superficial radial nerve is identified and preserved.

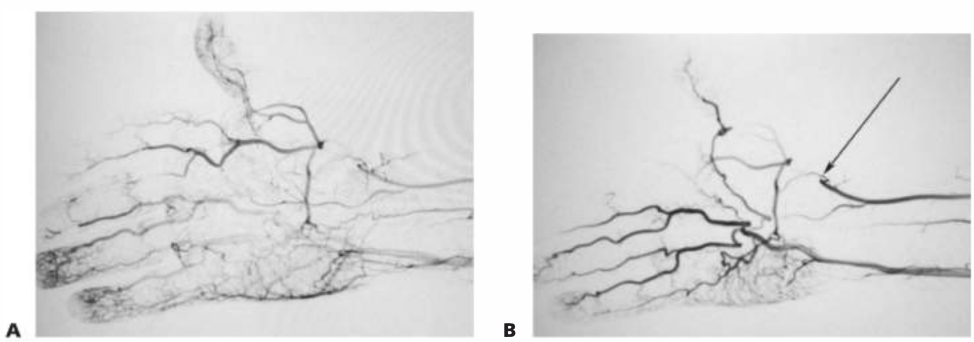

FIG 6 ● Snuffbox radial artery reconstruction angiograms: **A,B.** Angiograms demonstrating cutoff of radial artery (*arrow* demonstrates filling defect corresponding to occluded segment) at the level of the anatomic snuffbox.

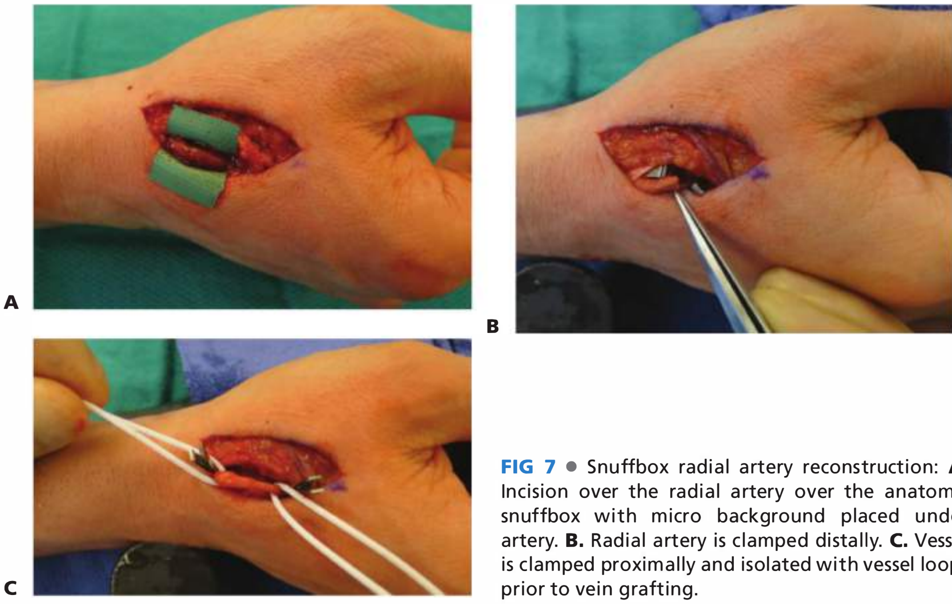

FIG 7 ● Snuffbox radial artery reconstruction: **A.** Incision over the radial artery over the anatomic snuffbox with micro background placed under artery. **B.** Radial artery is clamped distally. **C.** Vessel is clamped proximally and isolated with vessel loops prior to vein grafting.

Resection/Bypass of Diseased Segment

- This dissection is continued distally between the heads of the first dorsal interosseous muscle, allowing further mobilization of the distal radial artery and visualization of the origin of the deep palmar arch.
- Microvascular clamps are placed proximal and distal to the thrombosed segment of the radial artery.
- All branches from the thrombosed segment should be ligated and removed en bloc (**FIG 7B**).

Vein Graft Interposition

- The vein graft should be reversed and placed superficial to the extensor pollicis longus and extensor pollicis brevis (making the graft immediately beneath the skin) and then sutured end-to-end to the radial artery proximally and end-to-end to the deep arch distally (**FIG 7C**). See the "Ulnar Artery Reconstruction" section for further description on vein harvest and microvascular anastomosis technique.

HAND FASCIOTOMY

Placement of Incisions

- The 10 compartments of the hand include the thenar, hypothenar, adductor, and 4 dorsal and 3 volar interossei compartments. Four incisions are required to release all 10 compartments.
- The dorsal and volar interosseous compartments are decompressed with two dorsal incisions over the index finger and ring finger metacarpal (**FIG 8A**). These incisions are carried down to either side of the metacarpal to release the dorsal interossei. Dissection along the ulnar and radial aspects of the index metacarpal must be sufficiently deep (**FIG 8C**) to release the first dorsal palmar interosseous and the adductor compartments. Similarly, to release the remaining palmar interossei, deep dissection is required along the ulnar and radial aspects of the ring metacarpal. Meticulous release along the length of the metacarpal is essential to ensure adequate decompression.
- The thenar compartment is bound by thenar fascia and contains the abductor pollicis brevis, flexor pollicis brevis, and the opponens pollicis. This compartment is decompressed with a longitudinal incision along the radial/volar (**FIG 8A**) aspect of the thumb metacarpal.

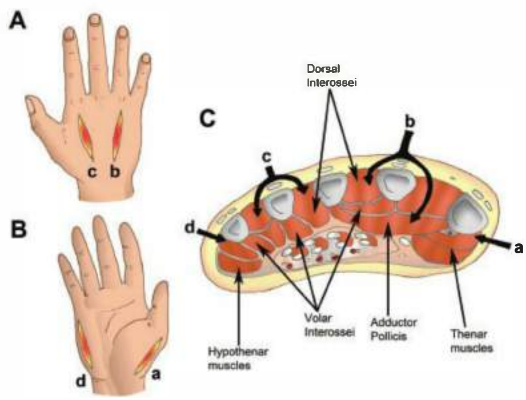

FIG 8 ● Hand fasciotomy illustration: fasciotomy incisions of the hand. **A.** Dorsal incisions over the index **(c)** and ring **(b)** finger metacarpal. **B.** Volar incisions over the hypothenar **(d)** and thenar **(a)** muscles. **C.** Cross section at the level of the metacarpals of the hand demonstrating that both dorsal and interosseous compartments and the adductor compartment to the thumb can be released through these four incisions with appropriate direction and depth as outlined **(a–d)**.

- The hypothenar compartment is bound by the hypothenar fascia and contains the abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi. This compartment is decompressed with a longitudinal incision along the ulnar/volar (**FIG 8B**) aspect of the small metacarpal.
- The finger can also have compartment syndrome if there is excessive swelling and depending on clinical assessment. Here, the fascial compartments are bound by Cleland's and Grayson's ligaments. The finger fasciotomy is performed by making midaxial incisions along the ulnar aspect of the index, ring, and long fingers and on the radial aspects of the thumb and small finger. Once incisions are made, blunt dissection is continued through Cleland's ligament (firm fascia bands that run from side of the phalanges to the skin and are dorsal to the neurovascular bundle), retracting the neurovascular bundles in a volar direction and remaining volar to the flexor tendon sheath.

Carpal Tunnel Release

- If any compartment pressure is elevated in the hand, then all compartments should be released including the carpal tunnel.
- A longitudinal palmar incision is made just distal to the volar wrist crease and extending distally for 3 to 4 cm in the proximal palm along the course of the radial aspect of the ring finger.
- The palmaris fascia is divided longitudinally to expose the underlying transverse carpal ligament, which is then incised under direct visualization.
- The incision is extended at least 2 cm into the forearm to ensure release of the deep antebrachial fascia.
- The carpal tunnel release incision is closed primarily with interrupted nylon sutures.

Wound Care

- Fasciotomy wounds are left open for a minimum of 48 hours or until swelling has resolved.
- Secondary closure with wet-to-dry dressings may occur over open incisions.
- Eventually, these wounds may need split-thickness skin grafting.
- The hand should be splinted in a safe position (70 to 90 degrees of metacarpophalangeal [MCP] flexion and proximal interphalangeal [PIP] joints straight).

PEARLS AND PITFALLS

- Although a thrombosed ulnar artery can be ligated, reconstruction of the ulnar artery can reconstitute normal flow and should be attempted.
- Hand vascular repair and grafting requires meticulous microvascular technique.
- The dorsal sides of the hand and foot have veins of similar size that are ideal for vein graft reconstruction.
- Periarterial sympathectomy is particularly effective in scleroderma because the vessels are encased in adventitial scarring.
- Early diagnosis and treatment for hand compartment syndrome is critical: When in doubt, release all compartments.

POSTOPERATIVE CARE

- Postoperative monitoring of the hand after vascular reconstruction is similar to finger replantations and can be performed with pencil Doppler monitoring or with pulse oximetry (**FIG 9**).
- Aspirin 81 mg is given for 6 weeks postoperatively after vessel reconstruction.
- For periarterial sympathectomy, immediate digital range of motion is encouraged, and cold temperature and vasoconstrictive drugs or substances (smoking, caffeine, etc.) are avoided for at least 6 weeks.
- For compartment syndrome, aggressive strengthening and range of motion should be started once wounds have stabilized.

OUTCOMES

- Radial artery reconstruction patency in a study of 13 patients found that all vein grafts were patent after mean follow-up of 22 months, with a significant decrease in pain; however, no difference in numbness was seen.[3] In another study of 145 patients, an overall patency of vein grafts of 85% over

FIG 9 • Hand postoperative monitoring: Revascularization of digits can be monitored with basic pulse oximetry at the tip of the digits.

an average follow-up period of 34 months was found as well as 100% with arterial grafts.[4]

- Long-term recovery after compartment syndrome release depends on the extent of injury and requires long-term hand therapy for recovery of hand function. Compartment release of the hand can result in normal function; however, contractures can develop, which may need eventual reoperation for contracture release.

COMPLICATIONS

- Infection
- Dehiscence of incisions and other wound healing complications
- Failure of revascularization
- Distal emboli
- Thrombosis at anastomosis
- Long-term patency
- Stiffness of the fingers
- Continued ischemia, pain, and ulcerations

Chapter 12

Exposure and Open Surgical Reconstruction in the Chest: The Thoracoabdominal Aorta

Germano Melissano Efrem Civilini Enrico Rinaldi
Roberto Chiesa

DEFINITION

- A thoracoabdominal aortic aneurysm (TAAA) involves the aorta at the diaphragmatic crura and extends variable distances proximally and/or distally from this point (**FIG 1**).[1] TAAAs can be classified in terms of their causes, the two most common being medial degeneration and dissection.
- Open treatment of TAAAs consists of graft replacement with reattachment of the main aortic branches: The inclusion technique was introduced by S. E. Crawford in the 70s and refined by subsequent surgeons in the following decades. TAAA repair, especially in extensive aortic disease, is associated with greater operative risk than repair of other aortic segments. The main sources of morbidity are spinal cord (SC) ischemia and renal as well as respiratory and cardiac complications.
- Experienced surgical centers now report lower mortality and morbidity rates for TAAA repair,[2] largely due to multimodal approaches to reduce surgical trauma and maximize organ protection.[3]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- To plan the best possible treatment strategy for each patient, our preferred modality is computed tomographic arteriography (CTA). The acquisition of computed tomography (CT) data in particular has benefited from spectacular progress, including multirow detectors, higher rotation and translation speeds with reduced scan times (single breath-hold), cardiac cycle synchronization, and better postprocessing capabilities.
- Digital Imaging and Communications in Medicine (DICOM) slices of adequate thickness (≤1 mm) should be postprocessed on a digital workstation using a multiplanar reformatting (MPR) tool to visualize a scan which angulation matches that of the aorta or the vessel under investigation. Postprocessing may be performed on a dedicated workstation (AquariusNet®, TeraRecon, Inc) or desktop computer with open source software (OsiriX and others) in a user-friendly and time/resources-efficient way (**FIG 2**).
- Beyond analysis of aortic diameter and the extent of pathologic involvement, reformatted images are particularly useful for evaluating the presence, extension, and characteristics of dissection and thrombus, particularly at proposed sites of clamp placement and the infradiaphragmatic aorta when direct aneurysm cannulation is considered for distal aortic perfusion. The exact location and geometry of aortic branches is obtained to reveal possible anatomic variations or anomalies, which are particularly common at the level of the renal arteries and arch vessels. Vessel patency is also routinely evaluated; in particular, obstruction of the superior and inferior mesenteric artery and the hypogastric arteries and dominance of one vertebral artery are assessed.
- Three-dimensional rendering tools such as maximum intensity projection (MIP), volume rendering, surface rendering, and so forth produce realistic imaging of the anatomic structures that may expand anatomic understanding, including, for instance, the most appropriate intercostal space to perform thoracotomy (**FIG 3**).
- Perioperative SC ischemia may precipitate paraparesis or paraplegia. Prior knowledge of the SC arterial supply informs both procedural planning and risk stratification.

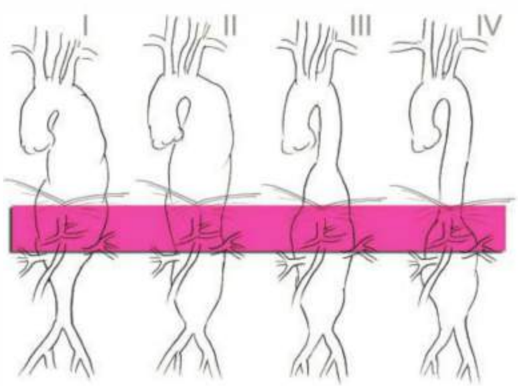

FIG 1 ● An aneurysm is defined as thoracoabdominal when the highlighted region is involved. Crawford's classification was developed to improve stratification of perioperative paraplegia risk. Subclassifications include the following: Extent I includes the thoracic and abdominal aorta, from the left subclavian artery to the level of the renal arteries; extent II includes the entire descending aorta from the level of the left subclavian artery to the aortic bifurcation; extent III includes aorta beginning at the T6 level extending to the bifurcation or lower; extent IV includes the entire abdominal aorta starting at the level of the diaphragm (T12) to the aortic bifurcation or lower.

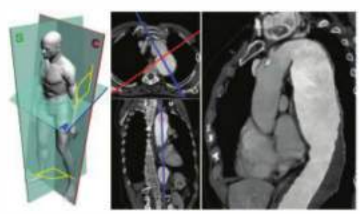

FIG 2 ● MPR tools allow the sagittal reconstruction to properly follow the major axis of the thoracic aorta. In this reformatted image, the entire thoracic aorta is included despite significant tortuosity.

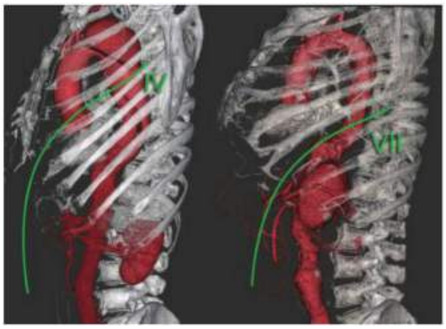

FIG 3 ● Beyond aortic imaging, the CT provides extensive anatomic information to guide exposure and surgical decision making.

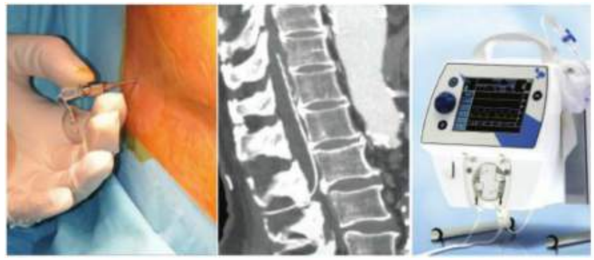

FIG 5 ● Once the dura has been punctured with the introducer needle, a drainage catheter is inserted 8 to 10 cm along the intradural space. The catheter is then connected to a pressure transducer, and the fluid is drained to keep the pressure below 10 cm H_2O. Automated systems are available for this purpose.

Recent advances in imaging techniques, especially noninvasive techniques, increased the likelihood that patient-specific risk criteria may soon be recognized and be widely available[4] (**FIG 4**).

SURGICAL MANAGEMENT

Preoperative Workup and Patient Optimization

- Preoperative transthoracic echocardiography is a satisfactory noninvasive screening method to evaluate both valvular and biventricular function. Stress testing identifies patients who require coronary catheterization and possible intervention.[5] Electrocardiographically (EKG) gated CT has recently emerged as a less invasive method of visualizing coronary anatomy. For severe, symptomatic coronary disease requiring percutaneous transluminal angioplasty prior to aneurysm repair, use of drug-eluting stents requiring prolonged double antiplatelet therapy should be avoided to reduce subsequent perioperative bleeding.
- The use of estimated glomerular filtration rate (eGFR), rather than serum creatinine levels alone, is recommended to assess renal function.[6] Based on the eGFR metric, chronic kidney disease has been shown to be a strong predictor of death following open or endovascular thoracic aneurysm repair, even in patients without other clinical evidence of preoperative renal disease.[7]

Pulmonary function evaluation with arterial blood gases and spirometry is used to evaluate the respiratory reserve of all patients undergoing open surgery of the descending aorta. In patients with a forced expiratory volume in 1 second (FEV_1) of less than 1 L and a partial pressure of carbon dioxide (PCO_2) greater than 45 mmHg, operative risk may be improved by cessation of cigarette smoking, treatment of chronic bronchitis (if present), weight loss, and participation in a supervised exercise program for a period of up to 6 months prior to surgery. However, in patients with aneurysm-related symptoms, this type of respiratory rehabilitation may not be practical or possible.

Positioning

- After inserting a cerebrospinal fluid drainage (CSFD)[8] catheter into the subarachnoid space between L2 and L3 or L3 and L4 (**FIG 5**), the patient is turned to a right lateral decubitus position, with the shoulders at 60 degrees and the hips flexed back to 30 degrees.
- Preparation should allow for access to the entire left thorax, abdomen, and both inguinal regions. Patient position is maintained with a moldable beanbag attached to a suction line for vacuum creation. A circulating water mattress is placed between the beanbag and the patient in order to modify body temperature as necessary (**FIG 6**).

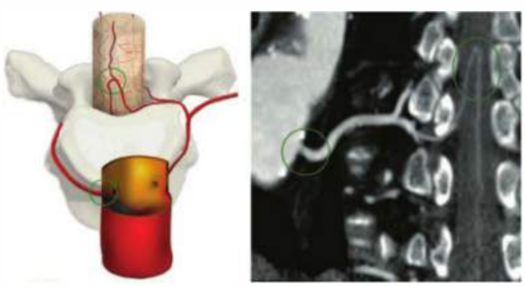

FIG 4 ● Using a customized curve plan, the whole path of the arterial feeder to the spinal cord (arteria radicularis magna) can be visualized from the aorta to the anterior spinal artery.

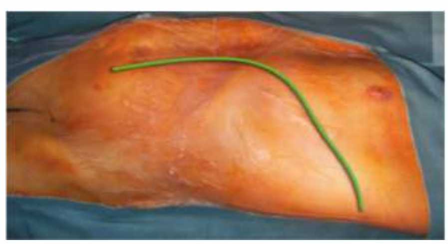

FIG 6 ● Prepping and draping for TAAA. Posterolateral aspect of the left thorax, the abdomen, and left groin are included in the sterile operatory field. Please note the gentle curvature of the line indicating the skin incision to avoid flap necrosis.

THORACO-PHRENO-LAPAROTOMY

- The thoracic incision varies in length and level, depending on exposure requirements. Usually, the 5th, 6th, or 7th intercostal space is employed according to the aneurysm anatomy. The posterior section of the ribs is gently spread to reduce thoracic wall trauma and fractures; anterolaterally, the incision curves gently as it crosses the costal margin to minimize subsequent tissue necrosis. The pleural space is entered after single right lung ventilation is initiated. Monopulmonary ventilation is maintained throughout thoracic aorta replacement (**FIG 7**).
- Paralysis of the left hemidiaphragm contributes significantly to postoperative respiratory failure; therefore, a limited circumferential rather than radial section of the diaphragm is routinely performed, sparing the phrenic center. Under favorable anatomic conditions, this approach reduces respiratory weaning time[9] (**FIG 8**).
- Special care must be taken when isolating the proximal aneurysm neck. The insertion of a large caliber esophageal probe makes it easier to distinguish the esophagus at this level. The vagus nerve and the origin of the recurrent laryngeal nerve must also be identified because they can also be damaged during isolation and clamping maneuvers (**FIG 9**). Identification and clipping of some "high" intercostal arteries can sometimes facilitate the preparation for the proximal anastomosis, thus reducing aortic bleeding.
- The upper abdominal aortic segment is exposed via a transperitoneal approach; after entering the peritoneum, medial visceral rotation is performed to retract the left colon, spleen, and left kidney anteriorly and to the right (**FIG 10**). Use of a transperitoneal approach allows direct assessment of the abdominal organs at the end of procedure. Extra care must be taken to avoid damage to the spleen, which is particularly prone to bleeding after capsular injuries regardless of size.

FIG 7 ● Thoraco-phreno-laparotomy in the 6th intercostal space. A circumferential incision of the diaphragm is carried out (dotted line).

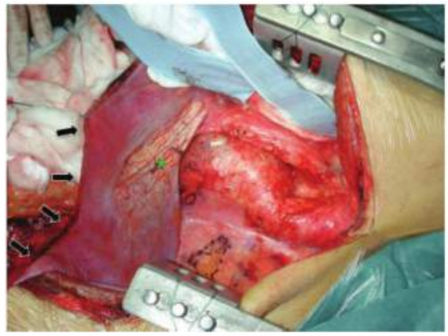

FIG 8 ● The diaphragm is circumferentially divided *(arrows)* for several centimeters near its peripheral attachment to the anterior chest wall sparing the phrenic center *(asterisk)*.

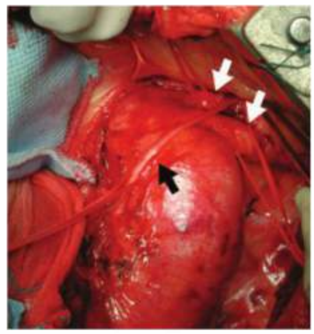

FIG 9 ● The vagus nerve *(black arrow)* and the origin of the recurrent laryngeal nerve are mobilized and identified with vessel loops to prevent injury during aortic clamping maneuvers or suture placement. When an aortic cross-clamping between left carotid and subclavian artery is required, these vessels are also identified and controlled with vessel loops *(white arrows)*.

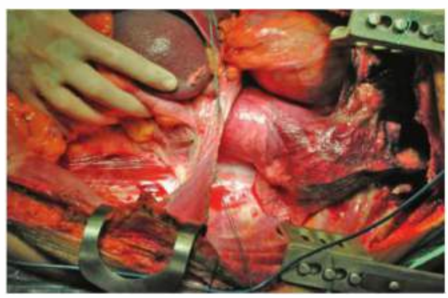

FIG 10 ● Medial visceral rotation: The left colon, the spleen, and the left kidney are retracted anteriorly and to the right to visualize the visceral and infrarenal aorta. Transperitoneal approach allows direct evaluation of the abdominal organs throughout the procedure.

DISTAL AORTIC PERFUSION

- Cross-clamping of the descending thoracic aorta produces immediate and significant increases in left ventricular afterload, myocardial oxygen consumption, and visceral and renal ischemia. Techniques incorporating distal aortic perfusion with left heart bypass (LHBP) have significantly improved outcomes in thoracic aortic surgery.[10] In preparation for LHBP and aortic cross-clamping, low-dose intravenous heparin is administered. If cessation of pump support is anticipated during the case, additional heparin should be administered at that time to provide full anticoagulation.
- The upper left pulmonary vein is usually cannulated for inflow of oxygenated blood, which is routed through a centrifugal pump (Bio-Medicus®) into the left femoral artery (**FIG 11**). A "Y" connector included in the circuit provides two occlusion/perfusion catheters (9 Fr) for selective visceral perfusion when necessary.

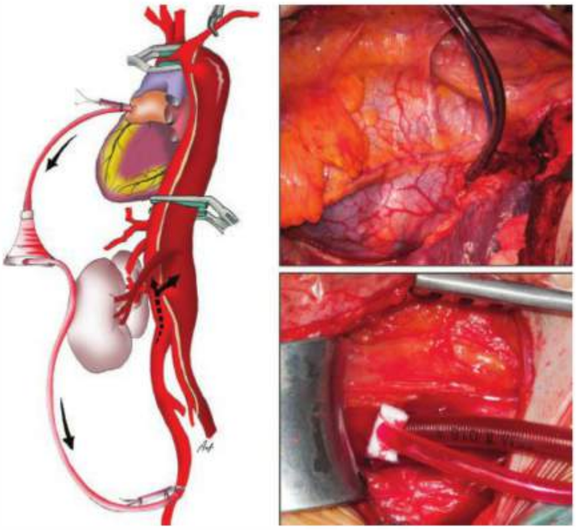

FIG 11 ● Schematic view of distal aortic perfusion. A 20-Fr cannula is inserted in left superior pulmonary vein for the arterial blood drainage **(up)**. Nonocclusive femoral cannula (14 to 18 Fr) allows synchronous proximal and distal perfusion from the femoral axis **(down)**.

AORTIC REPAIR

- Once the neck of the TAAA is isolated and controlled between clamps, the descending thoracic aorta is transected and separated from the esophagus (**FIG 12**). The graft is sutured proximally to the descending thoracic aorta using 2-0 polypropylene suture in a running fashion. The anastomosis is reinforced with Teflon felt (individual pledgets or single strip) (**FIG 13**). An additional aortic clamp is applied onto the abdominal aorta above the celiac axis before the proximal aortic clamp is removed (sequential cross-clamping).
- Intercostal artery reimplantation into the aortic graft plays a critical role in SC protection. Patent intercostal arteries from T7 to L2 are temporarily occluded to prevent backbleeding/maximize cord perfusion pressure[11] then selectively reattached to the graft by means of aortic patch or graft interposition (**FIG 14**). When ready, the distal clamp

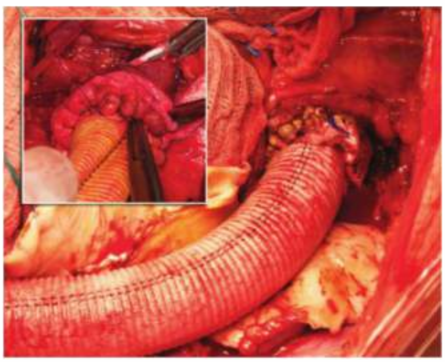

FIG 13 ● The proximal anastomosis routinely reinforced with a Teflon strip.

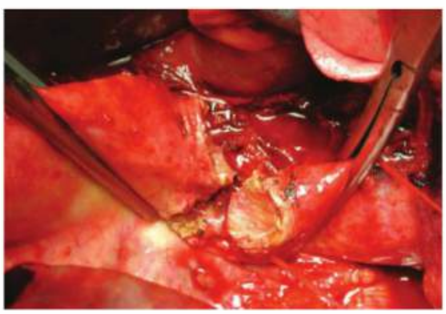

FIG 12 ● The proximal descending thoracic aorta is controlled and completely transected to avoid accidental injury to the adjacent esophagus.

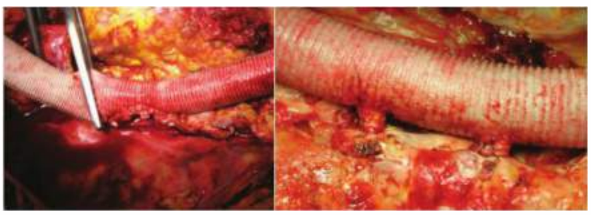

FIG 14 ● Critical intercostal arteries reattachment. Here visualized are two different techniques: On the **left**, an aortic island including the origin of several intercostal arteries is reattached to a fenestration created on the aortic graft; on the **right**, intercostal arteries are reattached selectively to the graft via 6/8-mm interposition grafts.

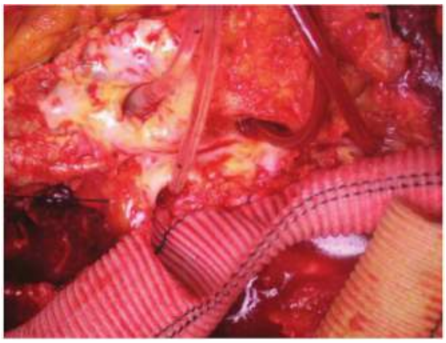

FIG 15 ● Visceral arteries perfusion with blood, renal perfusion with cold Custodiol® solution during branch artery reimplantation.

FIG 17 ● A modified technique to separately reattach the left renal artery is detailed here: The use of a hybrid tube graft that includes a self-expandable covered stent allows for a sutureless anastomosis. The advantages are the reduced ischemia time of the kidney and kink prevention of the graft after visceral derotation at the end of the aortic repair.

is moved below the renal arteries, and the aneurysm is opened across the diaphragm. The centrifugal pump maintains visceral perfusion (400 mL per minute) following insertion of the 9-Fr irrigation-perfusion catheters (LeMaitre Vascular) into the celiac trunk and the superior mesenteric artery. Cold perfusion of Custodiol[12] (histidine-tryptophane-ketoglutarate) is directed into the renal arteries (**FIG 15**). For visceral artery reimplantation, a fenestration is created in the graft and the visceral vessels are reattached as a single patch. Usually, the left renal artery is reconnected with an 8-mm polyester interposition graft. If visceral artery orificial stenosis is encountered, before placing the irrigation perfusion catheter, the stenosis may be resolved by direct placement of an appropriate-sized balloon-expandable stent within the artery[13] (**FIGS 16** and **17**). If creation of the visceral patch requires retaining a large segment of native aorta, we prefer to place a multibranched graft instead. This prosthesis, although somewhat more time consuming, significantly reduces the risk of recurrent aortic patch aneurysm (**FIG 18**). Finally, the distal end-to-end anastomosis with the distal aorta is performed, the graft flushed, and clamps removed (**FIG 19**).

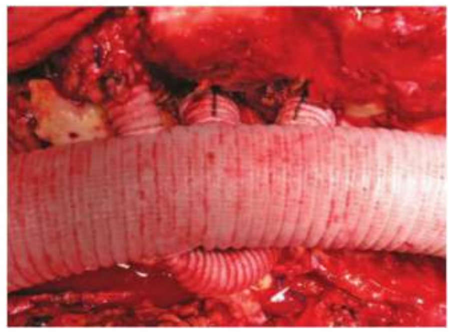

FIG 18 ● Visceral vessels and renal arteries are reattached separately in this patient with Marfan syndrome to reduce as much as possible the aortic native tissue and prevent recurrent aortic aneurysm formation.

FIG 19 ● End-to-end distal anastomosis at the aortic bifurcation.

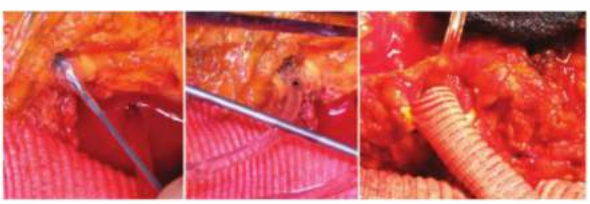

FIG 16 ● From left to right. In case of orificial stenosis, intraluminal stents are placed under direct visualization before insertion of the perfusion catheter and ultimate reimplantation.

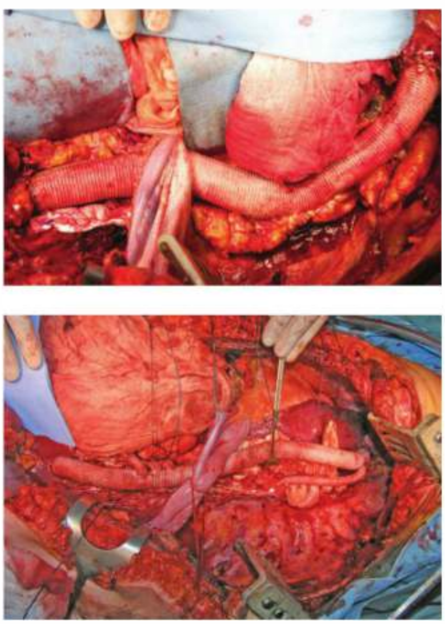
CLOSURE

- The entire aortic repair (**FIG 20**) is inspected. All exposed aortic branch pulses are palpated after derotation and replacement of the abdominal viscera. Any bleeding or kinking of the aortic branches is addressed at this juncture. The atrial and femoral cannulae are removed; the purse-string sutures are tied and reinforced. Anticoagulation is reversed with protamine. The crus of the diaphragm is reapproximated to restore the aortic hiatus (**FIG 21**) and the left hemidiaphragm loosely sutured with a running polypropylene suture. The left lung is temporarily inflated to check for air leakage.
- A closed-suction abdominal drain is placed next to the aortic graft in the left retroperitoneal space, and two chest tubes are placed in the posteroapical and basal pleural space. Absorbable pericostal sutures are placed to approximate the ribs (**FIG 22**), and two steel wires are used to stabilize the costal margin. The lung is inflated, and the correct expansion of all the segments is carefully checked; the pericostal and diaphragmatic sutures are tightened and ligated. The steel wires are twisted and buried in the cartilaginous costal margin. The abdominal fascia is closed with a running suture. The abdominal and thoracic drains are connected to suction. The serratus and latissimus dorsi muscles are approximated with separate absorbable sutures. Subdermal layer is sutured, and the skin is closed with staples (**FIG 23**).



A

FIG 20 ● Final repair of a type II TAAA. **A.** Standard inclusion technique. **B.** Selective reimplantation with multibranched graft.

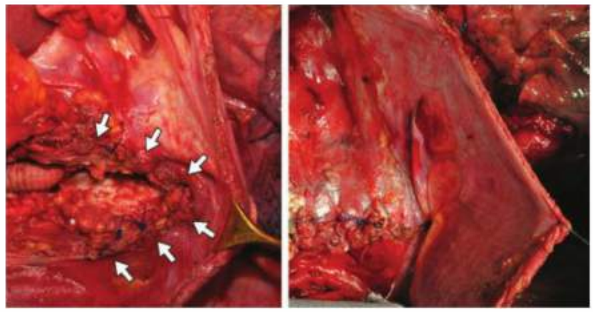

FIG 21 ● The pillars of the diaphragm (arrows) are approximated with absorbable sutures to reshape the aortic hiatus.

FIG 22 ● The thoracic wall is repaired with pericostal sutures. The left lung is inflated and checked for air leakage; two chest tubes are positioned to drain the upper and lower thoracic space.

FIG 23 ● The abdominal and thoracic walls are sutured; skin is closed with staples.

PEARLS AND PITFALLS

Indications	■ Aortic diameter and aneurysm morphology ■ Signs and symptoms of acute aortic syndrome
Preoperative planning	■ Level of intercostal incision ■ Graft selection ■ Identification of accessory renal arteries and other visceral anomalies (e.g., horseshoe kidney) ■ Potential need for multibranch graft vs. Carrel patch
Surgical access	■ Avoid skin flap necrosis. ■ Rib section ■ Limited phrenotomy (circumferential diaphragmatic incision) ■ Transperitoneal approach ■ Careful and limited lung manipulation ■ Nonocclusive femoral cannulation
Technical adjuncts for organ protection	■ Spinal cord drainage ■ Left heart bypass ■ Sequential aortic clamping ■ Critical intercostal artery reattachment ■ Visceral perfusion from left heart bypass cannulas ■ Renal perfusion with cold Custodiol® or similar solution ■ Direct stenting of renal and visceral orificial lesions as needed

POSTOPERATIVE CARE

- The main focus of immediate postoperative management is the early detection of neurologic or cardiovascular complication as prompt intervention may prevent substantial long-term morbidity. As soon as baseline blood pressure and body temperature are restored, sedation is lightened regardless of ventilatory status. When SC or cerebral neurologic injury is suspected, CT imaging is performed immediately to address the possibility of intracranial or intradural SC hematoma. In case of paraparesis or paraplegia, mean arterial pressure is chemically maintained above 80 mmHg, CSFD is drained in order to lower the cerebrospinal fluid pressure below 10 mmHg, and methylprednisolone (1 g bolus followed by 4 g per 24 hours continuous infusion) and 18% mannitol (5 mg/kg, four times a day) are administrated.
- If malperfusion develops in the lower limbs, renal or visceral circulation, efforts should be made to restore normal circulation immediately. For a precise visualization of visceral organ perfusion, emergency arteriography (catheter-based or CT) is required.
- Blood pressure fluctuations, including recalcitrant hypertension, is common in the early postoperative period, especially in the chronically hypertensive patient; prompt attention should be paid to regulating the mean arterial pressure in a physiologic range. Immediate intervention may be required to reduce the risk of anastomotic bleeding, especially in the setting of dissection.
- In uncomplicated cases, drainage tubes are removed at 36 to 48 hours postoperatively, whereas the intrathecal CSFD catheter is removed usually after 72 hours. A prolonged requirement for ventilatory support is not unusual, especially after emergency operations, in patients with significant blood loss and after longer periods of circulatory arrest (if necessary for concurrent arch or ascending aortic reconstruction). In case of severe chronic kidney disease, transient temporary renal replacement therapy may also be necessary in the early postoperative period.

COMPLICATIONS

- Bleeding
- Multiorgan failure
- Dialysis
- Paraplegia
- Stroke
- Death
- Aneurysm recurrence

Chapter 13

Thoracic Aortic Stent Graft Repair for Aneurysm, Dissection, and Traumatic Transection

Brant W. Ullery Jason T. Lee

DEFINITION

- In 1994, Dake and colleagues,[1] at Stanford University, were the first to report the use of custom-designed thoracic aortic stent grafts for the treatment of descending thoracic aortic aneurysms in patients deemed high risk for conventional open surgery. Each of these devices was deployed through peripheral arterial access, successfully excluding the aneurysm from systemic pressurization. This groundbreaking minimally invasive technique thereby avoided many of the physiologic insults associated with open surgery, including the need for thoracotomy, aortic cross-clamping, reperfusion injury, and acute hemodynamic changes.
- Results from the first multicenter U.S. Food and Drug Administration–sponsored trial for thoracic aortic stent grafts demonstrated significantly less perioperative mortality, respiratory failure, renal insufficiency, and spinal cord ischemia in patients after thoracic endovascular aortic repair (TEVAR) compared to a matched cohort of patients undergoing open descending thoracic aortic aneurysm repair.[2]
- After two decades of surgeon experience and endovascular technologic advancement, TEVAR has evolved to serve as a primary treatment strategy for an increasingly diverse group of acute and chronic aortic pathologies including thoracic aortic aneurysms, dissections, and traumatic transections.

DIFFERENTIAL DIAGNOSIS

- Depending on the type and extent of pathology, TEVAR may include the use of fenestrated or branched stent grafts, advanced snorkel/chimney/periscope techniques, or the need for hybrid debranching procedures. The decision to treat thoracic aortic pathology with stent grafts is based on individual patient comorbidity burden, detailed analysis of thoracic aortic anatomy, and physician experience.
- Acute thoracic aortic pathologies often present with chest pain and therefore must be considered in the workup for acute coronary syndrome. The ubiquitous use of computed tomography (CT) scanning for pain, shortness of breath, trauma, and to "rule out" many pathologies has led to an increase in the recognition of thoracic aortic pathology potentially benefitting from TEVAR technology.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Thoracic aortic aneurysms (TAAs) are defined as localized or diffuse dilation of 50% or more relative to the diameter of the adjacent normal-sized aorta. Common risk factors for aneurysmal degeneration include smoking, hypertension, chronic obstructive pulmonary disease, atherosclerosis, and connective tissue diseases. Indications for repair of descending TAAs are similar to those for conventional open repair: maximum aortic diameter greater than 6 cm, rapid aneurysmal growth (>5 mm of growth over 6 months), or symptoms such as persistent chest or back pain, rupture, or dissection. In most patients with TAA, the aneurysms were diagnosed following routine imaging ordered for other reasons and are therefore most commonly asymptomatic.
- Aortic dissection occurs when an intimal tear in the aorta causes blood to flow between the layers of the wall of the aorta and most often presents as tearing chest pain that radiates to the back. Potential etiologic factors leading to aortic dissection include poorly controlled hypertension, connective tissue disorders, trauma, or vasculitis. Medical management of uncomplicated type B thoracic aortic dissection serves as the current standard of care. These practice guidelines stem from the results of the INvestigation of STEnt grafts in patients with type B Aortic Dissection (INSTEAD) trial, the first prospective, multicenter randomized trial comparing optimal medical therapy (e.g., blood pressure control) to TEVAR for uncomplicated type B dissection.[3] This trial demonstrated no significant improvement in 2-year survival or adverse event rates with TEVAR despite favorable aortic remodeling, although recently reported 5-year data suggest improved long-term survival in patients undergoing TEVAR. In contrast, for patients with complicated type B dissections involving rupture, malperfusion (e.g., visceral or limb ischemia), or refractory back pain despite optimal medical management, TEVAR is indicated. The goal of TEVAR in this setting is to cover, or exclude, the primary entry tear and reexpand the true lumen while promoting thrombosis of the false lumen.
- Traumatic aortic transection results from a high-velocity or deceleration injury to the aorta. The tethering of the aorta by the ligamentum arteriosum makes this site most susceptible to shearing forces during sudden deceleration. A high index of suspicion is necessary to help make the diagnosis. Trauma workups most often involve whole-body CT scanning, which allows rapid triage for possible treatment. CT-A commonly demonstrates an irregular outpouching beyond the takeoff of the left subclavian artery at the aortic isthmus, which corresponds to the presence of an aortic pseudoaneurysm caused by the traumatic event. Extent of blunt traumatic aortic injury and the corresponding physiologic insult may range from clinically occult intimal injury to life-threatening complete transection and rupture (**FIG 1**).[4] Early diagnosis and endovascular treatment is generally recommended for those presenting with a traumatic aortic transection, particularly when there is a contour abnormality visualized on cross-sectional imaging.

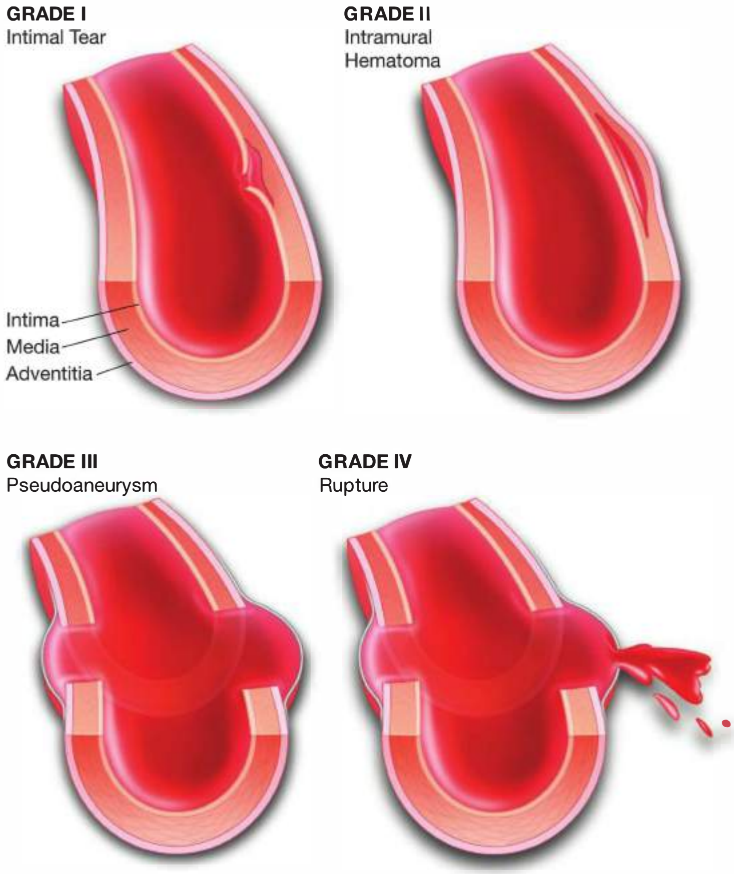

FIG 1 ● Society for Vascular Surgery classification of blunt traumatic aortic injury. (Adapted from Lee WA, Matsumura JS, Mitchell RS, et al. Endovascular repair of traumatic thoracic aortic injury: clinical practice guidelines of the Society for Vascular Surgery. *J Vasc Surg*. 2011;53:187–192.)

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Transesophageal echocardiography (TEE) may serve as a useful imaging tool, particularly in the setting of acute thoracic aortic pathology. TEE can confirm the presence of aortic dissection, distinguish between types A and B dissections, identify involvement of supra-aortic vessels, and assess for contained rupture.
- High-resolution computed tomography angiography (CT-A) with three-dimensional reconstructive software allows for the most complete anatomic analysis, including details regarding aneurysm morphology, diameter, dissection flap characterization, thrombus burden, calcification, angulation, and branch vessel orientation.
- Familiarity and routine usage of three-dimensional workstations and the ability to customize measurements provide an accurate road map to guide endovascular strategy, device selection, and stent graft sizing.

SURGICAL MANAGEMENT

Preoperative Planning

- Patients scheduled for elective TEVAR undergo routine preoperative cardiac evaluation. Based on cardiovascular risk profile, symptomatology, and presence of electrocardiogram abnormalities, selected patients undergo further evaluation in the form of an exercise stress test, dobutamine stress echocardiography, or Persantine thallium stress testing. Coronary angiography is pursued in cases involving extensive or symptomatic coronary artery disease.
- Aortic transections or symptomatic dissections and aneurysms should have early and aggressive blood pressure control using intravenous beta-blocker or calcium channel blocker medications. After obtaining a reliable clinical examination, refractory chest, back, or abdominal pain should be treated with narcotic analgesics.
- Renal protective strategies should be employed preoperatively to minimize the risk of contrast-induced nephropathy. Intravenous hydration is initiated preoperatively and, in the setting of baseline renal insufficiency, may warrant early hospital preadmission and concomitant administration of Mucomyst and bicarbonate infusion.
- Suspected blunt aortic injury should prompt a referral to a level I trauma center in order to facilitate early evaluation by a vascular specialist and other pertinent members of a multidisciplinary trauma team.
- General anesthesia is routinely performed in TEVAR cases. Prophylactic lumbar cerebrospinal fluid (CSF) drainage is

considered in every case based on the relative risk of spinal cord ischemia, hemodynamic status, and acuity of clinical presentation. Arterial monitoring is performed via a right radial artery approach. Peripheral intravenous lines are typically adequate; however, more intensive central venous monitoring may be required in cases involving unstable traumatic transections, patients with significant baseline cardiovascular comorbidities, or any case involving hemodynamic instability.

- Preoperative imaging should be heavily scrutinized for the adequacy of iliofemoral access anatomy. An iliac conduit may be required in cases involving small-caliber, tortuous, or heavily calcified access vessels. Anticipated use of a conduit should prompt consideration of an autotransfusion or cell saver machine to be available during the procedure.
- Numerous variables have been identified as risk factors for the development of spinal cord ischemia after TEVAR. Given that hypoperfusion represents the primary etiology of spinal cord injury following TEVAR, commonly cited risk factors involve those relating to the extent of impairment or exclusion of the collateral perfusion to the spinal cord. The European Collaborators on Stent/Graft Techniques for Aortic Aneurysm Repair (EUROSTAR) investigators reported results from the largest multicenter registry to date (N = 606).[5] In the EUROSTAR registry, the incidence of spinal cord ischemia was 2.5% and independent risk factors included left subclavian artery coverage without revascularization (odds ratio [OR], 3.9; p = .037), concomitant open abdominal aortic surgery (OR, 5.5; p = .037), and the use of three or more stent grafts (OR, 3.5; p = .043).
- Based on the principle that spinal cord perfusion pressure is approximated by the difference between the mean arterial pressure (MAP) and CSF pressure, placement of a prophylactic lumbar drain has the potential to increase spinal cord perfusion pressure by decreasing CSF pressure and may be beneficial in select patients at high risk for spinal cord ischemia. Percutaneous drainage of CSF is performed by inserting a silastic catheter 10 to 15 cm into the subarachnoid space through a 14-gauge Tuohy needle at the L3–L4 vertebral interspace. The open end of the catheter is attached to a sterile closed circuit reservoir and the lumbar CSF pressure is measured with a pressure transducer zero-referenced to the midline of the brain. Lumbar CSF can be drained continuously or intermittently in the operating room to achieve target CSF pressures of 10 to 12 mmHg. Postoperatively, intermittent or continuous CSF drainage can be continued in the intensive care unit for CSF pressures exceeding 10 mmHg or at the first sign of lower extremity weakness. In the absence of neurologic deficits, the lumbar CSF drainage catheter can be clamped 24 hours postprocedure followed by continued monitoring of CSF pressure together with serial neurologic assessments. The CSF drain can then be removed at 48 hours after operation. Although prophylactic or therapeutic lumbar CSF drainage has an established record of safety, complications have been reported to occur in approximately 1% of patients, which may include neuraxial hematoma, subdural hematoma, catheter fracture, meningitis, intracranial hypotension, chronic CSF leak, and spinal headache.

Selection and Sizing of Thoracic Stent Graft

Landing zones

- Proximal and distal landing zones must be of sufficient length (usually at least 2 cm) to enable safe and accurate deployment bracketing the area of thoracic aortic pathology, which often includes the subclavian artery proximally or the celiac artery distally.
- Intentional coverage of the left subclavian artery is sometimes required due to a very proximal extent of aortic pathology, especially transections. Left subclavian artery revascularization may be required in select cases. The celiac artery rarely requires intentional coverage.
- Significant tortuosity, circumferential mural thrombus, and extensive calcification can compromise the proximal or distal landing zone, thereby predisposing to inadequate fixation and subsequent development of endoleak or migration. Site of proximal and distal landing zones should be selected in order to minimize the impact of these anatomic features, even if it requires extending the length of aortic coverage.
- A variety of anatomic measurements are taken from preoperative CT-A imaging to assist in the sizing and selection of the thoracic stent graft (**FIG 2**). Interventionalists should be proficient in accurate sizing and measuring of key thoracic aortic locations that influence device selection and ultimately determine patient outcomes.

Sizing of stent grafts

- The degree of stent graft oversizing can vary based on the indication for intervention. Stent grafts are generally oversized by 10% to 20% based on the aortic diameter at the proximal and distal fixation sites for aneurysmal disease. Insufficient oversizing for the treatment of TAAs may predispose to inadequate exclusion and the potential for endoleak or migration. Aggressive oversizing, on the other hand, increases the risk for stent graft collapse, graft thrombosis, access arterial injury, and potential for peri- or postprocedural iatrogenic retrograde type A dissection.
- Chronic type B dissections are frequently characterized by a thick, nonmobile dissection flap, or septum, that separates true and false lumens into concave or convex discs of flow lumen. Such dissection flaps have limited compliance; therefore, minimal or no oversizing may be required in order to achieve a suitable proximal or distal seal.
- Aortic transections frequently occur in young trauma patients with normal or minimally diseased aortas. As such, minimal oversizing is needed to achieve an adequate seal and only recently did device manufacturers create devices meant for smaller diameter aortas. Note also that underrescucitated patients on admission will have smaller aortic diameters on their CT-A.
- Currently available stent grafts range in diameter from 22 to 46 mm. Given the traditional 10% to 20% rule of device oversizing, these devices are designed to safely treat aortas with landing zones ranging from 19 to 43 mm in diameter.

Access vessel anatomy

- Current thoracic aortic stent grafts require large-caliber delivery systems, ranging from 18 to 26 Fr in outer diameter. Small,

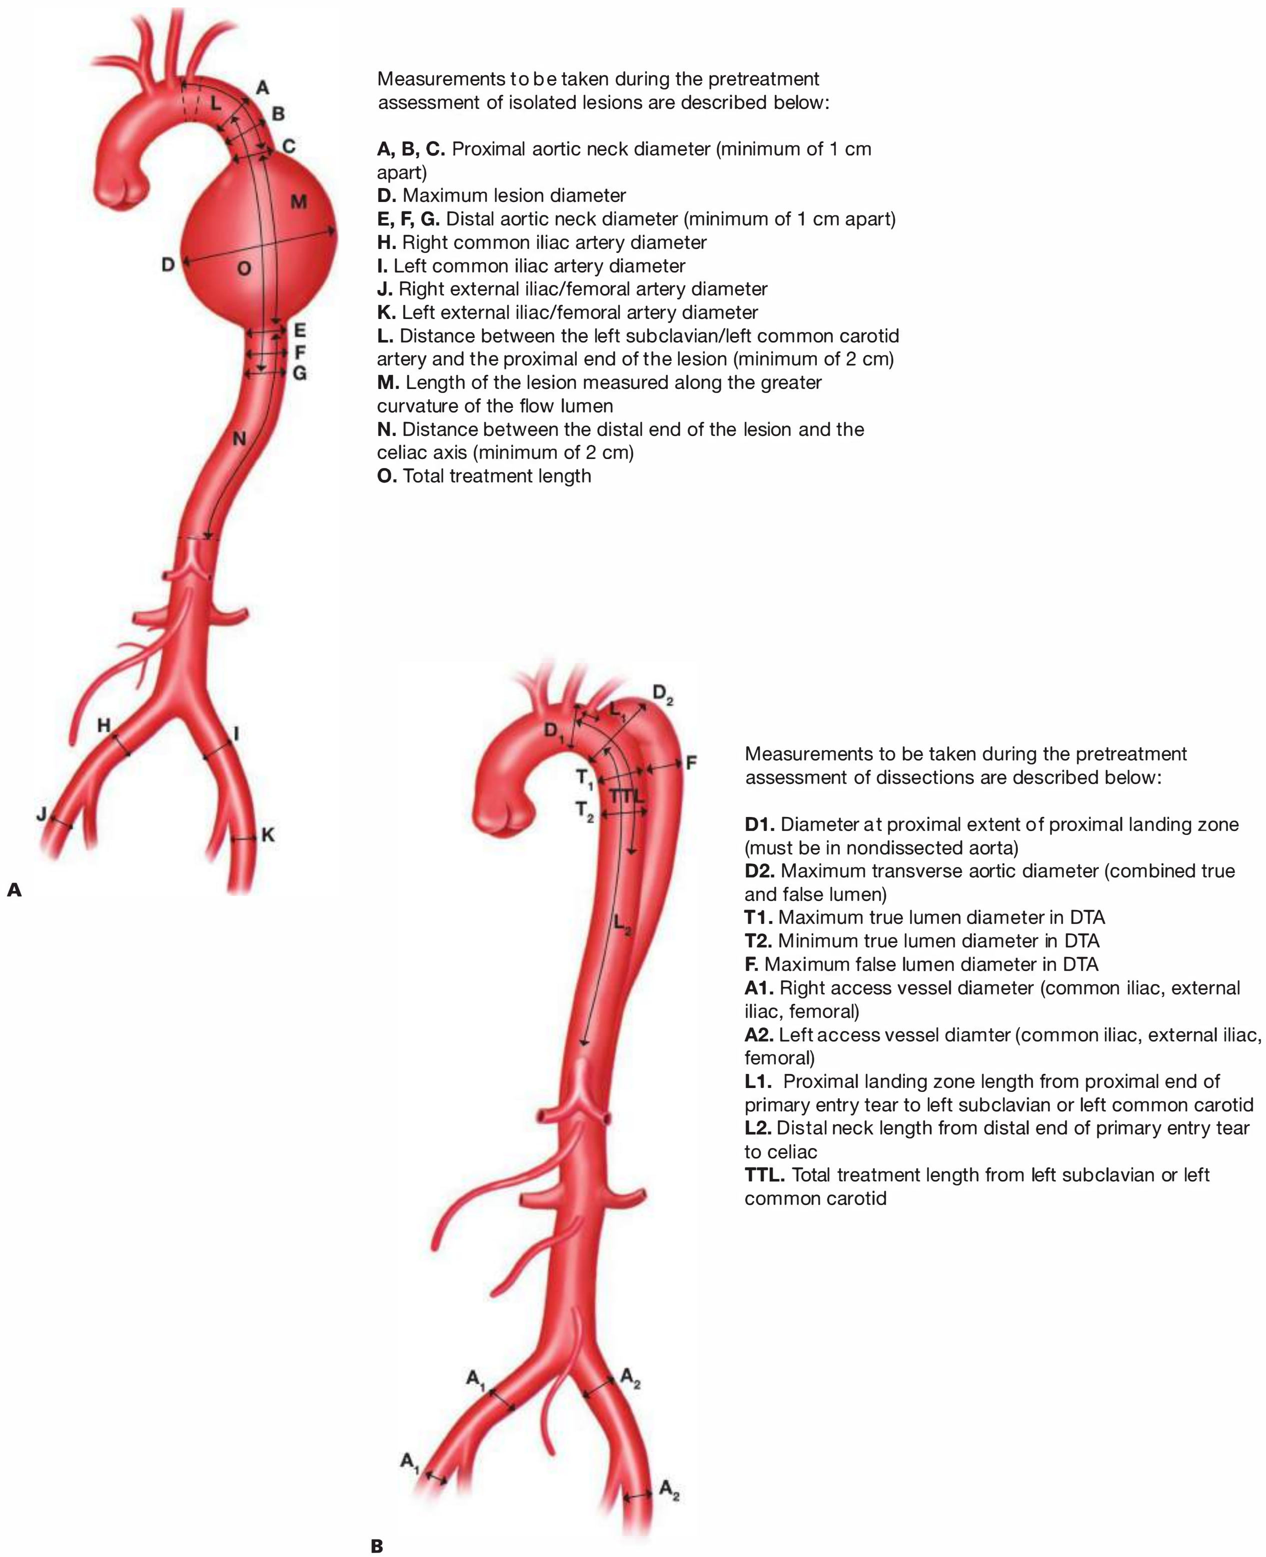

FIG 2 ● Anatomic measurements to assist in thoracic stent graft device sizing and selection for the treatment of aneurysms **(A)** and dissections **(B)**. DTA, descending thoracic aorta.

tortuous, and heavily calcified iliofemoral arteries may prohibit sheath advancement and predispose to access site–related complications, including groin hematoma, dissection, or rupture.

- Careful evaluation of access vessel anatomy on preoperative imaging should be performed in order to assess the caliber, tortuosity, thrombus burden, and extent of calcification of the iliofemoral arteries. Such anatomic information will serve as the basis for deciding laterality of femoral access as well as to determine the need for an iliac conduit.
- Serial dilation may be attempted for patients with small iliofemoral vessels. Iliac atherosclerotic lesions may be pretreated with balloon angioplasty and/or stent grafting in order to facilitate sheath advancement and introduction of the thoracic stent graft components.
- Iliac conduits serve as a safe and reliable technique to circumvent issues related to suboptimal access vessel anatomy. From either flank incision, a retroperitoneal exposure provides visualization of the common iliac artery or distal abdominal aorta. A 10- or 12-mm Dacron graft is commonly used as the conduit of choice. The conduit can be modified by creating a patch at the distal end in order to further facilitate the delivery of large-caliber sheath and enable additional degrees of torqueability (**FIG 3**). This modification involves creating a patch by cutting the Dacron graft along its long access, thereby enlarging the transition zone from the graft to artery.

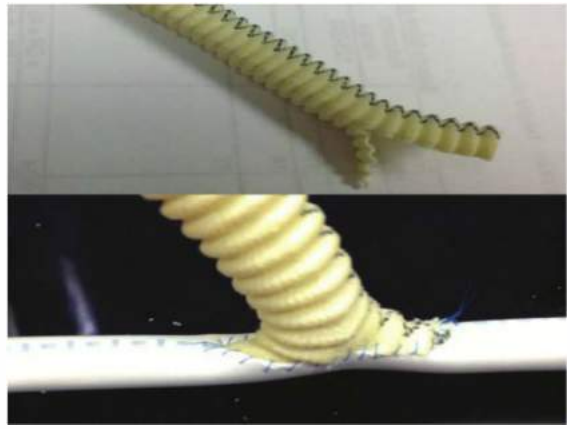

FIG 3 • **A.** 10-mm Dacron conduit bisected longitudinally to create a sewing patch. **B.** Dacron iliac conduit sewn to native iliac artery allows easy mobility of the conduit at multiple angles of entry for large-caliber device or sheath. (From Lee JT, Lee GK, Chandra V, et al. Comparison of fenestrated endografts and the snorkel/chimney technique [published online ahead of print April 27, 2014]. *J Vasc Surg*. doi:10.1016/j.jvs.2014.03.255.)

TECHNIQUES

EARLY PROCEDURAL CONSIDERATIONS

Positioning

- The C-arm is typically configured in the "head" position. The left arm may be abducted to 75 to 90 degrees and circumferentially prepped into the field if an embolization or snorkel/chimney procedure involving the left subclavian artery is anticipated. The chest, abdomen, and bilateral groins should be prepped. As frequently only one groin access is required for the performance of a routine TEVAR, laterality of the operator position may vary based on surgeon preference or anticipated access site location.

Establishing Vascular Access

- The ipsilateral femoral artery is accessed either percutaneously or from an open exposure. Secondary access may be obtained from the contralateral femoral artery or brachial artery as needed for a 5-Fr sheath and flush catheter. Surgical exposure is obtained from a small oblique incision at the level of the inguinal ligament. The common femoral artery is exposed, with proximal control obtained at the level of the external iliac artery and distal control at the level of the femoral bifurcation or proximal superficial femoral and profunda femoral arteries. Heavy calcification may require preemptive endarterectomy and patch angioplasty in order to facilitate safe sheath placement.
- The femoral artery is punctured using a standard micropuncture set, and if arterial access is obtained percutaneously, a sheathogram is performed to confirm adequate puncture site location (mid–common femoral artery). A standard length Bentson wire is inserted into the aorta through micropuncture sheath and exchange for a 7-Fr sheath is then performed using Seldinger technique. Wire exchange is then done for a 260-cm stiff Lunderquist wire. The Lunderquist wire should have a flexible, curved proximal end that should be advanced under fluoroscopy across the aortic arch to abut the aortic value. The location of the distal end of the Lunderquist wire should be marked on the operating table and this wire position should be maintained throughout the procedure.
- Over the stiff Lunderquist wire platform, the 7-Fr sheath is removed and serial dilators are advanced to gradually enlarge the subcutaneous tract and arteriotomy site in order to accommodate either the stent graft device itself or a larger 18- to 26-Fr introducer sheath required for device delivery.
- After placement of the larger sheath, systemic heparin is administered at a dose of 100 units/kg (goal activated clotting time of >250 seconds). Concomitant traumatic injuries, particularly intracranial hemorrhage, may alter the dose or decision to administer heparin.

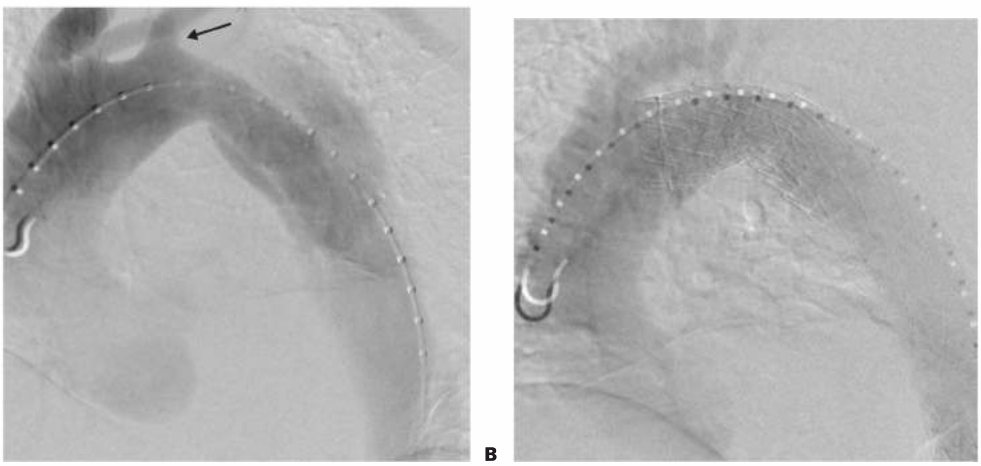
INITIAL AORTOGRAM

- A 5-Fr 100-cm Omniflush or pigtail catheter is inserted into aorta and advanced to the level of the aortic arch. This catheter may be advanced via a contralateral 5-Fr sheath or it may be inserted into an additional ipsilateral 5-Fr sheath placed distal to the arteriotomy for the main body delivery sheath.

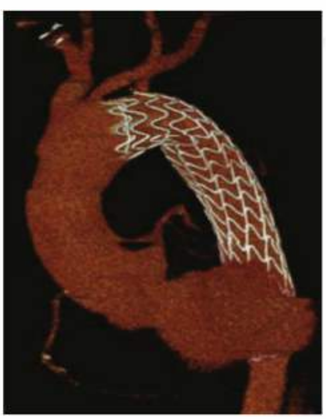
- If satisfied with stent graft sizing based on available preoperative imaging, the thoracic aortic stent graft may be advanced over the Lunderquist wire and be positioned in the proximal to midportion of the thoracic aorta prior to initial aortogram.
- Optimal angiographic imaging of the aortic arch is obtained by placing the fluoroscopic C-arm in a left anterior oblique orientation, often 35 to 65 degrees, and can be optimized by referencing the preoperative CT-A. The location of the supra-aortic vessels, particularly the left subclavian artery, should be noted and marked on viewing monitors (**FIG 4A**).
- Intravascular ultrasound (IVUS) may be used an adjunct in cases involving dissection to assist in the identification of true and false lumens, as well as to gain additional information on aortic diameter, branch vessel location, and morphology of proximal and distal landing zones. IVUS also aids in limiting intravenous contrast exposure in those patients with baseline impaired renal function.
- If necessary to guide distal extent of stent graft placement, the celiac artery is best imaged from a full lateral projection. Additional structures to note are large, patent intercostal arteries at the level of the aortic hiatus. Efforts should be made to avoid covering these if at all possible during the course of the repair.

Device Deployment

- Precise proximal positioning of the stent graft is facilitated by either marking the location of the left subclavian artery on the viewing screen and/or using the road-mapping feature. The distal radiopaque line of the endotracheal tube seen on fluoroscopy at about 45 degrees left anterior oblique can sometimes correlate to the position of the left common carotid artery, thereby serving as a convenient landmark in cases requiring left subclavian artery coverage.
- Immediately prior to stent graft deployment, systemic arterial blood pressure is reduced below 100 mmHg to reduce risk of caudal migration.
- The stent grafts are generally deployed in a proximal-to-distal sequence. However, a distal-to-proximal sequence may be preferred in cases involving precise deployment near the celiac artery or in aortas with significant diameter taper and a larger proximal landing zone compared to the distal landing zone (where devices of different diameter may need to be stacked up on each other).
- Deployed endografts will naturally extend toward the outer curvature of the aorta and precision deployment is facilitated by gently providing forward traction on the wire toward the outer curve during deployment. This



A B



C

FIG 4 ● **A.** Initial thoracic aortogram performed with C-arm in a 45-degree left anterior oblique orientation in a case involving a type B aortic dissection. Note how clearly the origin of the subclavian *(arrow)* is seen to accurately decide if there is adequate proximal neck length. **B.** Aortogram following deployment of thoracic stent graft with coverage of the ostium of the left subclavian artery. **C.** Postoperative three-dimensional imaging demonstrating successful exclusion of the proximal entry dissection tear.

maneuver also facilitates straightening out of the transverse arch, which can be helpful in minimizing the "bird-beaking" effect at the proximal graft margin, where the device may not fully oppose to the "inner" aortic wall. Bird beaking, when present, can predispose to proximal type I endoleaks, endograft collapse, and potential aortic occlusion.

- Additional graft components are added, when necessary, by exchanging the first device over the Lunderquist wire. A minimum overlap of 5 cm between pieces is recommended to ensure adequate apposition and minimize risk of junctional (type III) endoleak.

Balloon Molding

- Balloon molding is often required in cases involving TAAs. Under fluoroscopic guidance, a noncompliant molding balloon (Coda [Cook Medical, Bloomington, IN, USA] or Tri-Lobe [W. L. Gore, Flagstaff, AZ, USA]) is advanced up to the proximal edge of the stent graft and balloon molding is performed in a proximal-to-distal sequence. Balloon molding should be performed at the proximal and distal fixation sites, as well as at areas of stent graft overlap in those cases requiring multiple stent grafts.
- Aggressive ballooning can cause component fracture and aortic injury, and care must be taken during inflation with constant visualization and knowledge of the tension applied to the balloon.
- Balloon molding is not typically required in cases involving aortic dissection or transection, particularly in cases where no obvious endoleak is visualized. Balloon molding may increase risk for iatrogenic retrograde type A conversion if performed in a region of friable or fragile aorta and is generally not recommended during dissection cases.

COMPLETION AORTOGRAM

- After stent graft deployment, the pigtail catheter is withdrawn along the outside of the deployed device(s) over a wire to below the level of the stent graft. The catheter is then readvanced over a wire within the stent graft lumen and positioned at the level of the aortic arch.
- Additional aortograms may be performed at this time as necessary in order to ensure adequate stent graft position and patency of the supra-aortic and celiac arteries and to assess for the presence of endoleaks.

REMOVAL OF SHEATH AND ARTERIOTOMY CLOSURE

- In cases involving percutaneous access, the two previously placed Perclose ProGlide devices are used to close the arteriotomy site(s) (see Part 6, Chapter 23 for details). If open surgical exposure was obtained, proximal and distal vascular control is obtained in the respective groin. All wires and sheaths are removed. The arteriotomy is closed transversely using a polypropylene suture in either a running continuous or interrupted fashion. Antegrade and retrograde flushing maneuvers should be performed prior to completion of the arteriotomy closure.

LEFT SUBCLAVIAN ARTERY REVASCULARIZATION

- Endovascular procedures that require coverage of the left subclavian artery have the potential to increase the risk of spinal cord injury by compromising blood flow to the ipsilateral vertebral artery, an important collateral pathway for arterial flow to the anterior spinal artery. Subclavian artery revascularization therefore serves as an additional strategy to decrease the risk of spinal cord ischemia in select patients deemed high risk.
- Techniques to revascularize the left subclavian artery include transposition of the subclavian onto the left carotid artery or left carotid–subclavian bypass grafting with subsequent embolization of the left subclavian artery proximal to the bypass graft (**FIG 5**). These revascularization procedures may be performed as part of a staged repair or at the time of TEVAR.
- The existing clinical evidence to support the efficacy of routine left subclavian artery revascularization remains controversial; there are advocates for routine revascularization, selective revascularization, or no revascularization. A meta-analysis of published studies showed a trend toward increased risk of spinal cord ischemia when the left subclavian artery was covered, suggesting a potential benefit for left subclavian artery revascularization, but the finding was not statistically significant.[4–6]

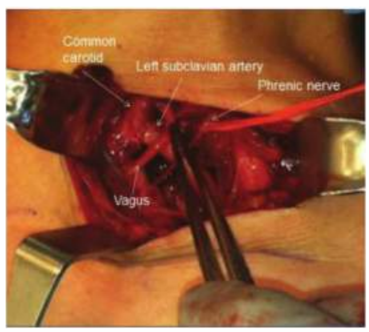


FIG 5 ● Left subclavian artery transposition is performed by ligating the left subclavian artery proximal to the vertebral artery and moving it cephalad in order to perform an end-to-side anastomosis between the left subclavian and left common carotid arteries. Alternatively, a Dacron graft can be used as a left carotid–subclavian bypass.

SPECIAL CONSIDERATIONS BASED ON AORTIC PATHOLOGY

Aortic Dissection

- The primary goal of TEVAR for the treatment of dissection is coverage of the proximal entry tear (**FIG 6A,B**). Stent graft sizing is based on the diameter of the adjacent nondissected thoracic aorta. Minimal or no oversizing of the stent graft is recommended.
- In acute type B dissections, the septum is relatively mobile and compliant. Therefore, the diameter of the small true lumen in the dissected portion often returns to normal diameter following successful exclusion of the proximal entry tear.
- Chronic dissections have thicker, less compliant septa, which may limit expansion of the true lumen despite adequate entry tear coverage. Often, these patients have chronic false lumen aneurysmal dilation, and entry tear and fenestration covering serve simply to decrease false lumen pressurization and promote thrombosis.
- IVUS serves as a useful adjunct in dissection cases, both in terms of initial identification of true and false lumen, as well as assisting in precise positioning of the device.

Aortic Transection

- Traumatic aortic injuries are typically located along the inner curve of the proximal descending thoracic aorta (**FIG 7**). Given the proximal location, left subclavian artery coverage is sometimes needed.[4]
- In the absence of concomitant hemorrhage or brain injury, routine heparin is recommended.
- Trauma patients are frequently hypovolemic and, as a result, may have an underdistended aorta on preoperative cross-sectional imaging. Initial cross-sectional imaging can underestimate true aortic morphology at the region of the subclavian by as much as 10% to 20%. In such settings, IVUS may assist in more accurate stent graft sizing performed in vivo.[7]

A B

FIG 6 ● **A.** CTA reconstruction demonstrating complex thoracoabdominal aortic dissection with proximal entry tear located in the proximal descending thoracic aorta. **B.** Initial aortogram documenting position of the supra-aortic arteries. PEARLS AND PITFALLS

Indications	■ TEVAR follows general recommendations for elective repair of descending thoracic and thoracoabdominal aortic aneurysms and should be offered to good anatomic risk patients with aneurysms >6 cm. ■ Patient selection should take into account the need for regular interval clinical and radiologic follow-up in order to monitor for stent graft–related complications and endoleaks.
Preoperative workup	■ High-quality imaging and ability to configure three-dimensional reconstructive software are essential for successful preoperative planning and device selection. ■ Pre- and perioperative hydration is a central part in the protection from contrast-induced nephropathy. ■ Patients should be stratified according to baseline risk of spinal cord ischemia. A prophylactic lumbar drain should be considered in those at high risk.
Patient setup	■ A hybrid endovascular suite provides optimal opportunity for accurate imaging and capability to perform necessary open surgical exposure or repair of access-related complications. ■ Anticipated adjunct procedures, including left subclavian artery embolization or revascularization, may require prepping the left neck and/or arm into the surgical field.
Thoracic aneurysms	■ Oversizing of stent grafts by 10% to 20% and balloon molding is generally recommended in order to maximize proximal and distal fixation. ■ Proximal and distal landing zones should be relatively free of stenosis, calcification, and thrombus to maximize durability of this minimally invasive technology.
Type B dissection	■ Accurate identification of true and false lumen is essential prior to deployment of the stent graft. IVUS may be a useful adjunct in this setting to confirm true or false lumen position. ■ Aggressive oversizing of stent grafts is not recommended in patients with aortic dissection. Balloon molding is generally reserved only for those with type I or III endoleak on completion angiography and not against the region where there is a mobile septum.
Traumatic transection	■ Routine heparin is recommended unless contraindicated by concomitant intracranial or solid organ injury. ■ Similar to dissections, aggressive oversizing and balloon molding is not routinely performed during the treatment of transections.

POSTOPERATIVE CARE

- Patients are typically extubated immediately following the procedure unless prohibited by concomitant physiologic insults (e.g., hemodynamic instability, trauma patient).
- Intensive care unit monitoring is required for patients who require a lumbar drain for 24 to 48 hours. Immediate and frequent neurologic assessments are critical in the early perioperative period to assess for spinal cord ischemia. Raising MAP goals are an additional way to minimize risk of cord ischemia.
- Durability of TEVAR is reliant on routine imaging to evaluate for stent graft–specific complications postoperation. Follow-up chest CT-A and plain x-rays are typically obtained at 1, 6, and 12 months and at intervals thereafter. Consideration should be made between balancing risks for cumulative lifetime iodinated contrast and radiation exposure versus the necessity for serial graft monitoring. In stable patients, chest x-rays may suffice to confirm device position, with CT scanning reserved for those with migration suggested by CT or evidence of progressive aortic enlargement or onset of recurrent symptoms such as chest pain.

OUTCOMES

- The largest published series, which has reported 1-year follow-up, included 443 patients treated with TEVAR for a variety of indications, both emergent and elective, as follows: TAA (n = 249), thoracic aortic dissection (n = 131), traumatic aortic injury (n = 50), and false anastomotic aneurysm (n = 13).[8] Technical success was achieved in nearly 90% of patients, with an all-cause mortality among patients treated for aortic aneurysm and aortic dissection of 20% and 10%, respectively.
- No randomized trials comparing TEVAR to open surgery have been published to date. However, multiple nonrandomized comparisons suggest equivalent or better outcomes with TEVAR. In a single-center, retrospective study of over 700 patients who underwent either TEVAR or open surgery, mortality was not significantly different at 30-day (5.7% vs. 8.3%, respectively) or 1-year (15.6% vs. 15.9%, respectively) follow-up.[9] Two smaller studies demonstrated a reduction in 30-day perioperative mortality with TEVAR compared with open surgery (1.9% vs. 5.7%).[10,11]

COMPLICATIONS

- Stroke continues to be a common complication following TEVAR and is associated with significant in-hospital mortality. Recent clinical series have reported an incidence of stroke after TEVAR to range from 2% to 8%.[12,13] The underlying mechanisms contributing to acute ischemic stroke after TEVAR and the temporal relationship of stroke to the procedure are not completely understood. However, the constellation of preoperative risk factors, neurologic examinations, and patterns of brain infarction observed in these patients has led most investigators to conclude that cerebral embolization and ischemic events are the primary mechanisms for perioperative stroke in TEVAR.[5,13,14] Embolic events are related to instrumentation of the aortic arch in patients with severe atheromatous disease, whereas ischemia is a result of the planned or inadvertent endovascular coverage of supra-aortic vessels.

- Spinal cord ischemia and subsequent acute or delayed paraplegia represents the most devastating complication of TEVAR. The pathogenesis of spinal cord injury after TEVAR is likely multifactorial but still poorly understood. The deployment of thoracic stent grafts results in rapid complete exclusion of varying lengths of segmental collateral vessels without the ability to surgically reimplant or revascularize the intercostal arteries. Stent deployment and catheter manipulation can predispose patients to dislodgement of thrombotic or atheromatous debris from the aortic wall into segmental vessels, with subsequent distal embolization and occlusion of arteries supplying the spinal cord. Moreover, endovascular coverage of the left subclavian artery may compromise spinal cord perfusion in patients with a dominant left vertebral artery, solitary vertebral artery, carotid artery disease, or an incomplete circle of Willis. Access site injuries to the iliofemoral vessels may further increase the risk of spinal cord ischemia by compromising collateral flow to the anterior spinal artery through the hypogastric and pelvic vascular plexus. Lastly, pharmacologic measures aimed at decreasing arterial blood pressure to enhance accuracy of device deployment in cases involving difficult aortic anatomy may lead to hypotension similar to that observed in open surgery.
- Due to the large sheath sizes required for the delivery of thoracic stent grafts, small-diameter, tortuous, or heavily calcified access vessels can predispose to iliofemoral arterial injury. Postoperative CT-A often documents arterial dissections and injury that can be followed with noninvasive duplex and managed expectantly until patients have claudication-like symptoms.
- Endoleaks are a relatively common finding after TEVAR, affecting nearly 15% of patients in the early or late postoperative periods. Type I or III endoleaks typically require additional stent placement or balloon molding in order to improve proximal, distal, or junctional fixation. Most type II endoleaks observed on completion angiogram or early follow-up cross-sectional imaging will resolve spontaneously. Persistent type II endoleaks, especially those with aneurysm sac expansion or failure to adequately seal a proximal entry tear or transection, warrant additional intervention. Retrograde flow from intercostal or left subclavian arteries can be treated using coil embolization or vascular plug placement.

Chapter 14

Exposure and Open Surgical Management at the Diaphragm

Peter H. U. Lee Ramin E. Beygui

DEFINITION

- Thoracoabdominal aneurysms and complicated descending aortic dissections are the two most likely reasons for requiring surgical exposure of the diaphragm in vascular surgery. The need to expose the aorta both above and below the diaphragm requires an extended incision spanning the left thorax to the abdomen, the length and exact location of which depends on the location of the targeted aortic pathology. Often, the diaphragm must be divided, necessitating an awareness of the regional anatomy as well as various surgical management considerations.

DIFFERENTIAL DIAGNOSIS

- Thoracoabdominal aneurysm: The Crawford classification categorizes thoracoabdominal aneurysms according to the extent of the aneurysm and is the most widely used[1] (**FIG 1**). The classification is as follows: type I, from the left subclavian artery to just above the renal arteries; type II, from the left subclavian artery to the infrarenal aorta; type III, from the mid-descending thoracic aorta to below the renal arteries; type IV, from the diaphragmatic aorta to the iliac bifurcation; and type V (modified classification by Safi et al.[2]): from the mid-descending thoracic aorta.
- Descending (type B) aortic dissection: Two classifications systems are commonly used to describe the extent of aortic dissections (**FIG 2**). Stanford type A dissections involve the ascending aorta with or without involving the descending aorta, whereas type B dissections only involve the descending aorta beyond the left subclavian artery. The DeBakey classification includes type I, which involves both the ascending and descending aortas; type II, which involves only the ascending aorta; and type III, which involves only the descending aorta.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients who are referred for surgery for a thoracoabdominal aneurysm present with no symptoms. However, when they do have signs and/or symptoms, they may present with pain in the chest, abdomen, or lower back; a mass in the abdomen, which may be pulsatile, or rigid abdomen; and evidence of atheroembolism distally. The aforementioned symptoms, with signs of hypovolemic shock, may indicate a ruptured aneurysm.
- Uncomplicated descending aortic dissections are generally managed medically. However, if the dissection is complicated, such as when it is associated with significant symptoms or leads to visceral or distal malperfusion, rapid surgical intervention is warranted.
- A more complete discussion regarding indications for intervention in aortic dissections and thoracoabdominal aortic aneurysm can be found in a number of relevant reference textbooks.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging is used to determine the proximal and distal extent of repair required. It impacts the type of exposure required (i.e., thoracotomy vs. laparotomy vs. thoracoabdominal incision) as well as the level of incision.
- If the exposure is for the repair of thoracoabdominal aortic pathology, all patients require adequate preoperative imaging, ideally consisting of a computed tomography aortography (CTA) with or without 3-D reconstruction. Magnetic resonance aortography (MRA) may also provide the necessary information, but this generally requires more time, is more expensive, and requires more extensive postprocessing. However, MRA is the study of choice when CTA is contraindicated or unsafe, such as in patients with a contrast allergy or renal insufficiency. Catheter-based invasive aortography has generally been supplanted by CTA and MRA as the primary preoperative imaging

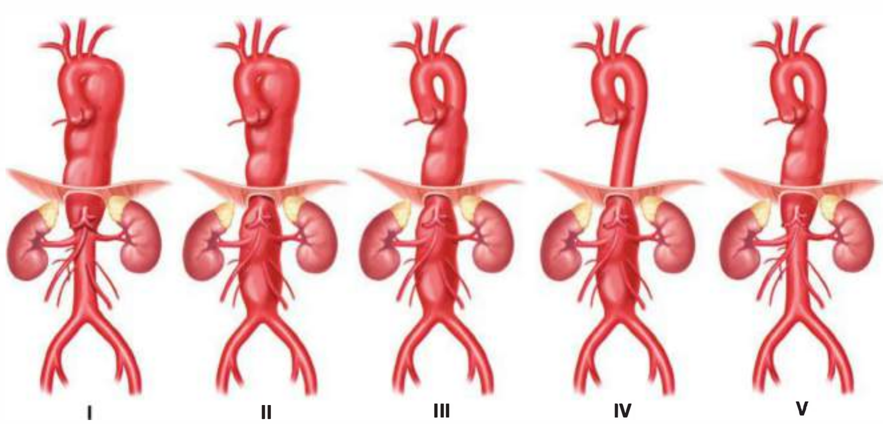

FIG 1 ● Modified Crawford classification.

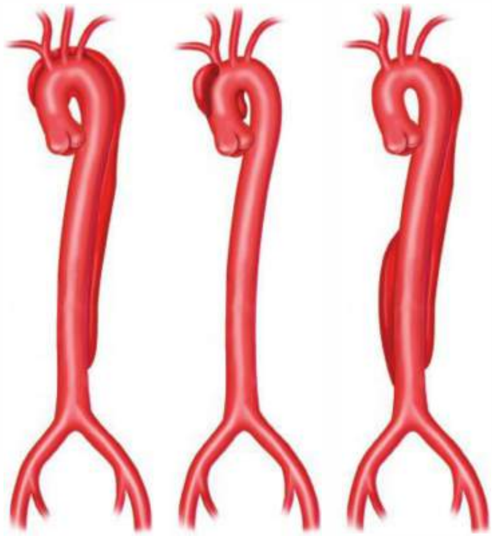

FIG 2 ● Stanford/DeBakey classification.

modality of choice, as it is more cumbersome and does not provide a complete assessment of the aneurysm, including thrombus volume and adjacent anatomic structures.

- If the surgery is elective, as in the case of an incidentally found aneurysm, extensive preoperative evaluations are necessary to minimize postoperative morbidity and mortality.
- Thorough evaluations of the cardiac, pulmonary, and renal systems are necessary, especially because these systems are most commonly affected when there are complications. Depending on the risk factors and prior history, further testing may be required and patients should be referred to appropriate specialists for proper evaluation. A good neurologic evaluation is also warranted, particularly if the patient has a prior history or symptoms suggestive of a lower extremity weakness or spinal injury.

SURGICAL MANAGEMENT

Preoperative Planning

- Determine the possible need for adjuncts such as cardiopulmonary bypass and neurophysiologic monitoring. In some instances, pulmonary artery catheters may be warranted for monitoring cardiovascular hemodynamics.
- Assess the need for spinal cord protection, including the use of lumbar drainage of cerebrospinal fluid (CSF), distal aortic perfusion, epidural cooling, and distal aortic perfusion.
- Given the expected amount of blood loss, a Cell Saver and rapid infuser should be available.
- Double lumen endotracheal tube should be used for single-lung ventilation of the right lung. Bronchial blockers are not reliable adjuncts for this purpose.

Positioning

- Initially, place the patient supine on a deflated beanbag (**FIG 3**). Roll the left chest upward and toward the right and place a shoulder roll under the right axilla and a bump under the left scapula while also gently pulling and securing the right arm over to the right side. Ideally, the upper back should be rotated about 60 degrees to the table with the pelvis remaining flat, such that the trunk is twisted to the right. Position the patient with the break located halfway between the left costal margin and the left iliac crest. Jackknife the table and then inflate the beanbag. Be sure to support and secure the arms ("airplane" splint for the left arm) and pad all pressure points on the body and extremities.
- Prep the left chest with the following boundaries: the axilla superiorly, the spine posteriorly, and the sternum and abdomen beyond the right of midline anteriorly. Keep the groins in the field for surgical access to the femoral vessels for possible cannulation if necessary.

FIG 3 ● Positioning.

PLANNING THE INCISION

- This chapter deals with distal thoracic aortic pathology requiring exposure of the diaphragm where a simple thoracotomy incision would not be adequate. Such more limited pathologies are described elsewhere.
- The proximal extent of the pathology and the anticipated location of the proximal clamp determine the level of the thoracic portion of the incision.
  - If the proximal clamp is to be placed between the aortic arch and just beyond the left subclavian artery, the chest is entered through the 4th or 5th intercostal spaces (e.g., Crawford types III and V aneurysms).

  - If the proximal clamp is to be placed just above or at the diaphragm, the 8th or 9th interspace should be entered (e.g., Crawford type IV aneurysms).
- Consider the possible use of parallel or "double" thoracotomy incisions if exposure of both the proximal and distal extent of the thoracic aorta is needed. In this case, the skin incision is placed between the levels of the two interspaces anticipated to be entered.
- The length and location of abdominal incision is determined by distal extent of the aortic pathology.
  - A modified thoracoabdominal incision that does not extend to midline is adequate if limited exposure of the abdominal aorta to the level of the celiac artery is required.
  - Extend the incision to the midline for exposure of the visceral aorta.
  - The incision should be extended down the abdominal midline for more extensive exposure of the infrarenal abdominal aorta (types II, III, and IV) to the aortic bifurcation or common iliac arteries (**FIG 4**).

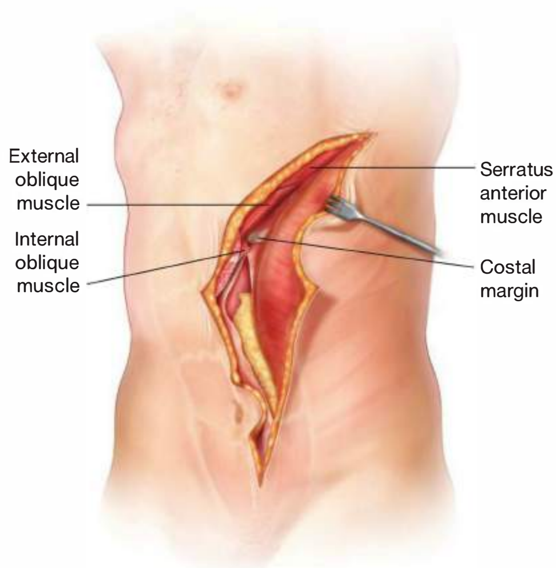

FIG 4 ● Thoracoabdominal incision.

THE INITIAL INCISION AND EXPOSURE

- Mark where the incision is to be made including finding the appropriate interspace and the extent of the abdominal incision as described earlier.
- Start with the thoracic incision over the appropriate interspace and then extend it across the costal margin. Depending on the degree of the abdominal exposure required, extend this incision obliquely to the midline of the abdomen. The midline incision can then be extended to the level of the symphysis pubis, if necessary.
- The abdominal incision is carried through the subcutaneous tissues, the external abdominal oblique aponeurosis, and the anterior rectus sheath.
- Split the external abdominal oblique muscle in the direction of its fibers.
- Divide the underlying internal oblique and transversus abdominus muscles between the costal margin and lateral edge of the rectus sheath.
- Divide left rectus muscle.
- The thoracic incision should provide adequate exposure posteriorly and should be extended to the erector spinae fascia.
- Expose the intercostal muscles by incising through the subcutaneous tissues and the external oblique fascia.

ABDOMINAL EXPOSURE

- Develop the abdominal portion of the incision before entry into the left pleural cavity
- The aorta may be exposed by an extraperitoneal or transperitoneal approach.
  - Extraperitoneal: This approach is ideal for repairing thoracoabdominal aneurysms, especially those involving the upper abdominal aorta (**FIG 5**).
    - Develop the plane between the transversalis fascia and the parietal peritoneum.
    - Separate the peritoneum from the lateral and posterior abdominal walls as well as from the diaphragm superiorly.
- Transperitoneal: This approach provides better exposure for visceral artery revascularization when required, especially when bypass is required to the right renal artery.
- Additional details of these approaches can be found elsewhere and are beyond the scope of this chapter.

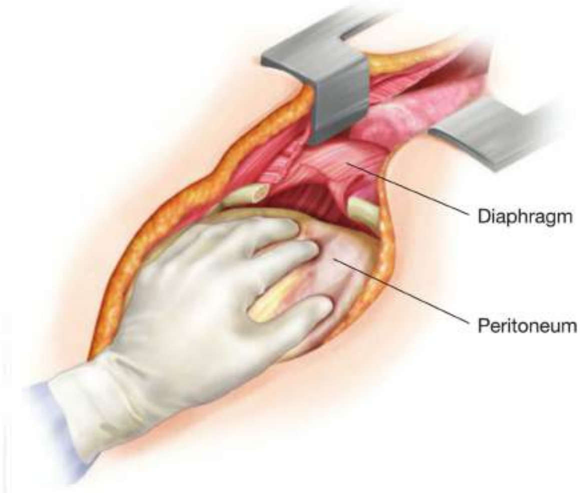

FIG 5 ● Abdominal aortic exposure via extraperitoneal approach.

THORACIC EXPOSURE

- Develop a plane superficial to the ribs and intercostal muscles.
- Hold ventilation to the left lung and allow it to collapse.
- Enter the left chest by opening the intercostal space along the superior edge of the lower rib, making sure not to injure the lungs.
- To maximize the exposure, it may be necessary to perform a subperiosteal resection of the rib above or below the interspace entered, depending on the target location.
- Additional exposure can be obtained from "notching" an adjacent rib. This is accomplished by excising a 2-cm segment of the rib posteriorly
- If two interspaces are being entered, develop an adequate plane anterior to the ribs. The skin and overlying muscles can be retracted to accommodate both thoracic interspace exposures.
- Use a self-retaining retractor to maintain exposure.
- Be aware that there can be extensive adhesions within the pleura that may predispose to lung injury. Usually, these adhesions can be mobilized bluntly if thin but may need bovie cautery or scissors if more substantial.

EXPOSURE AND DIVISION OF THE DIAPHRAGM

- Release any adhesions that may be present, mobilize the lung by dividing the inferior pulmonary ligament, and retract the lung cephalad to expose the diaphragm.
- Next, join the left thoracic cavity and the retroperitoneum or abdomen by dividing the diaphragm.
- The diaphragm can be incised partially or completely (**FIG 6**).
  - Partial incision: Incise the muscular portion of the diaphragm and preserve the central tendinous portion. This approach minimizes respiratory complications.
  - Complete division: This approach provides the best exposure of the aorta. This extends the incision from the divided costal margin to the aortic hiatus. Division can be accomplished either radially or circumferentially. Be sure to leave approximately 2 to 3 cm of diaphragm from the internal costal margin to aid in the later closure of diaphragm. The circumferential approach also theoretically minimizes disruption of the phrenic nerve and is generally preferred.

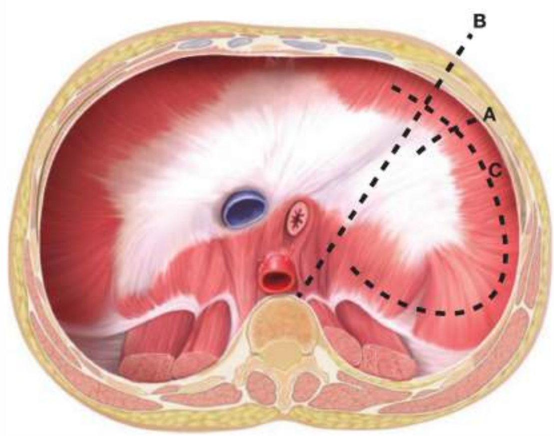

FIG 6 ● Division of the diaphragm.

CLOSURE

- After completion of the core surgical procedure, close the diaphragm.
- Take patient out of flexed position and close the diaphragm with heavy running suture.
- Place chest tubes.
- Reapproximate the interspace with multiple simple or figure-of-eight heavy (no. 1) nonabsorbable suture.
- Close the incision in layers, including the muscle with running Vicryl as well as the deep dermal layer. Close the skin with subcuticular sutures or staples.

PEARLS AND PITFALLS

Indications	■ Preoperative CTA or MRA is mandatory to determine the suitability of the aortic pathology for surgical repair.
Placement of incision	■ The placement of the incision should be carefully considered preoperatively based on imaging and the extent of the pathology. A single thoractomy incision can be placed even if two intercostal spaces need to be entered. To minimize morbidity, begin with a smaller incision because it can always be extended when necessary.
Injury to phrenic	■ A circumferential division of the diaphragm can provide the best exposure while also minimizing the risk of injury to the phrenic nerve.
Closure	■ When carrying out a circumfrential division of the diaphragm, leave 2 to 3 cm of diaphragm from the internal costal margin for the repair of the diaphragm when closing.

POSTOPERATIVE CARE

- Monitor in the surgical intensive care unit as necessary for the extent of the aortic reconstruction required.
- Remove chest tubes when drainage is adequately low.
- Continuous spinal cord protection and neurologic monitoring immediately postoperatively; continue CSF drainage for ~3 days.
- Follow-up imaging with CTA to establish a baseline
- Standard postoperative incision and wound care

OUTCOMES

- It is proposed that pulmonary dysfunction associated with thoracoabdominal aortic surgery is to a large part associated with diaphragmatic dysfunction. Stickley and Giglia[3] recommend a new technique using a gastrointestinal stapler to divide the diaphragm. This technique is proposed to be "rapid, hemostatic, and aids with reapproximation at the completion of the case" and that "this method of diaphragm division is quicker and less traumatic and has the potential to decrease the incidence of postoperative pulmonary dysfunction."
- Huynh et al.[4] conclude that renal failure, spinal cord deficit, and pulmonary complication were the major determinants of length of stay (LOS) in patients for thoracoabdominal aortic aneurysm (TAAA) repair. Their study has shown that the preservation of diaphragmatic function and the use of the adjunct distal aortic perfusion and CSF drainage may reduce hospital LOS.

COMPLICATIONS

- Bleeding; take back
- Phrenic nerve palsy or paralysis
- Diaphragmatic hernia
- Pulmonary complications, respiratory failure
- Wound complications
- Paralysis; spinal cord ischemic injury, associated with thoracoabdominal aortic surgery
- Stroke/transient ischemic attack (TIA), associated with thoracoabdominal aortic surgery
- Multiorgan failure, associated with thoracoabdominal aortic surgery
- Death, associated with thoracoabdominal aortic surgery

Chapter 15

Retroperitoneal Aortic Exposure

Matthew Mell

IMAGING AND OTHER DIAGNOSTIC STUDIES

General Considerations

- Retroperitoneal aortic exposure may be desirable for a variety of vascular conditions, including abdominal aortic aneurysms, aortoiliac occlusive disease, and mesenteric or left renal artery occlusive disease.
- Retroperitoneal exposure may be preferred for patients with a hostile abdomen from previous intraabdominal infection, surgery, or radiation.
- Compared with transabdominal aortic exposure, retroperitoneal exposure may be associated with shorter postoperative ileus, decreased pulmonary complications, decreased pain, and lower incidence of late complications including small bowel obstruction or aortoenteric fistulae.[1]
- Retroperitoneal aortic exposure can be converted, when necessary, to thoracoabdominal exposure with excellent visualization of the superior mesenteric artery (SMA), left renal artery, celiac axis, and descending thoracic aorta.[2]
- Examination of intraabdominal contents is possible through a retroperitoneal approach by simply opening a peritoneal window as necessary.

Preoperative Imaging

- Prior to aortic reconstruction, detailed anatomic imaging derived from modern, multirow detector computed tomographic arteriography (CTA) will greatly facilitate surgical planning. Image acquisition should extend from the normal proximal aorta to the common femoral artery bifurcations bilaterally. Runoff imaging may also aid decision making depending on clinical circumstances.
- Data derived from submillimeter imaging slices may be readily reformatted into multiplanar and 3-D reconstructions, with excellent resolution of the peripheral mesenteric and renal vasculature.
- Noncontrast images should also be obtained to help assess the degree of mural calcification present in diseased proximal aorta. Recognition of extensive mural calcification may modify the location chosen for clamp placement, or prohibit safe clamping entirely in diseased segments.
- CTA may require larger contrast dose than that required for catheter-based contrast aortography. Contrast volumes required for CTA may be reduced significantly by modifying the field of view or imaging parameters required for the procedure. Consultation with the responsible radiologist will ensure optimal imaging of the necessary arterial anatomy with minimal contrast and radiation exposure.
- Contrast-based aortography, either CT or catheter-based, may be contraindicated for patients with reduced creatinine clearance or an anaphylactic reaction to contrast. Milder allergic responses (hives, rash) may be successfully tempered by premedication with steroids and antihistamines, depending on the relative indication for contrast administration and the patient's overall medical condition. Adverse effects of intravenous or intraarterial contrast administration on creatinine clearance may be partially ameliorated by preprocedural oral or intravenous hydration and administration of N-acetylcysteine (Mucomyst). Although sometimes considered a reasonable alternative under these circumstances, gadolinium-based contrast administration for magnetic resonance arteriographic indications is also contraindicated in patients with a creatinine clearance less than 60 mL per minute. When contrast administration is absolutely out of the question, CT images acquired without contrast may provide adequate anatomic imaging to proceed with surgery, with the caveat that anomalies such as a retroaortic left renal vein may be present and unrecognized until exposed at surgery.

SURGICAL MANAGEMENT

Instrumentation

- In addition to standard vascular instrumentation, additional equipment may aid in exposure of the aorta and its visceral branches from the retroperitoneal approach:
  - Beanbag and airplane for positioning
  - A fully articulated operative table, capable of flex and reflex at the level of the umbilicus
  - Self-retaining, table-mounted retractor (e.g., Bookwalter, Omni, or other)
  - Finochietto chest retractor
  - Nos. 3, 4, and 5 Fogarty occlusion balloons
  - Cold renal perfusion
  - Arterial cannulas for renal perfusion

Positioning

- The patient is placed supine on a beanbag and all lines and tubes are placed. For exposure of the infrarenal aorta and iliac arteries, the left shoulder is lifted and protected with the beanbag and padding. The left arm can be abducted or rotated to the patient's right with a padded airplane retractor for support. The table break and the kidney bar are used to open up the retroperitoneal space between the 12th rib and the iliac crest as the incision is developed. For this reason, it is essential that the patient be positioned with the umbilicus on the table break. An oblique incision is made from below the umbilicus to the tip of the 11th rib. With this location, the incision can be extended into the 10th intercostal space and the chest entered if additional proximal exposure is required (**FIG 1**). When additional iliac artery or pelvic exposure is anticipated, the incision should be initiated distal to the umbilicus. Either way, in patients with considerable

abdominal girth and redundant pannus, landmarks should be confirmed to ensure that the incision is not placed too far distally on the abdomen, as juxtarenal aortic control can be extremely difficult when the incision is placed too far distally on the abdomen.

- For thoracoabdominal exposure, the patient is placed in the right lateral decubitus position using a beanbag and axillary role for support. The left arm is protected with adequate padding and an airplane-type retractor. It is important to secure the left arm such that the scapula rolls anteriorly, providing exposure of the posterior lateral chest. The incision will be made overlying the 8th intercostal space and extended toward the umbilicus.

FIG 1 • Patient position for thoracoabdominal exposure with incision in the 8th intercostal space (dotted line). Positioning is supported with a beanbag and right axillary roll.

- The incision is carried through the external oblique, internal oblique, and transversus abdominis muscles. The retroperitoneal space is then entered laterally near the tip of the 11th rib by identifying the characteristic yellow preperitoneal fat. The retroperitoneal space is then developed from lateral to medial using a sponge stick or hands for blunt dissection. Anteriorly, the peritoneum tends to be more adherent at the level of the rectus sheath; care should be taken to avoid entering the peritoneal cavity in this area. The psoas fascia is encountered as the dissection is developed posteriorly in the course of this dissection, which leads directly to the left iliac vessels and ureter. Dissection is continued proximally anterior to the ureter; the ureter is either left in situ to limit injury or gently retracted medially with silastic slings as the retroperitoneal space is developed.
- Superiorly, the kidney is identified as the dissection is continued anterior to Gerota's fascia—a potential space exists between descending colon and Gerota's fascia in the retroperitoneum, which is progressively developed in a cephalad direction from the psoas muscle, adjacent to the aorta. Once the renal vein is visualized in this space, the superior margin of the dissection is complete. If suprarenal aortic control and exposure is required, this same dissection plane should be developed posterior to the kidney, elevating the kidney and ureters along with the peritoneal contents and retracting all to the right to expose the subdiaphragmatic visceral aorta.
- Self-retaining retractor systems are best deployed either after the psoas muscle is identified or following exposure of the renal vein or elevation of the left kidney. Deploying the retractor system earlier will interfere with the dissection necessary to access the appropriate retrocolic space. Following placement of the initial padded retractor blade along the medial margin of the wound, circumferential retraction is secured by placement of additional blades, typically opposite each other to prevent undue tension on the retraction system, with sequential replacement with deeper blades and additional retraction until the entire periaortic retroperitoneum is exposed.
- The aorta and iliac arteries are then dissected free of surrounding tissue. Circumferential aortic control is an essential safety element of all aortic procedures, and care should be taken to gently and patiently create a space between the inferior vena cava (IVC), aorta, and vertebral bodies posteriorly to pass an umbilical tape around the aorta with a right-angle clamp. Circumferential control of the common iliac arteries, on the other hand, is not necessary in all circumstances. Sufficient medial and lateral dissection to allow for placement of a Wylie hypogastric clamp around the common iliac artery will usually suffice. Avoidance of attempts at circumferential iliac control will reduce the risk of right iliac vein injury. When circumferential control is required, patience is necessary to gradually separate the right common iliac artery from the distal IVC and left common iliac vein. When a venous injury is encountered during this maneuver, division of the common iliac artery may be necessary to gain adequate exposure for control. Alternatively, an occlusion balloon may be introduced from the right common femoral or external iliac veins will tamponade the venous

bleeding until sufficient exposure is gained to repair the wound. Finally, a covered self-expanding endograft may also be deployed over a wire to gain control. Again, readjustment of the retractor system with each consecutive stage of exposure will optimize operative efficiency. Frequently, to optimize distal exposure, the proximal retractor blades need to be temporarily relaxed and vice versa.

- This exposure provides adequate exposure to the infrarenal aorta (and inferior mesenteric artery if reimplantation is anticipated), right and left common and left external iliac arteries. The right external iliac artery is not well visualized from this approach, although tunneling to the right femoral artery is readily achieved for aortofemoral bypass grafting when necessary. Care should be taken to develop the tunnel immediately anterior to the iliac arteries to avoid injury to the right ureter or trapping the ureter between the graft limb and adjacent artery. When right external iliac artery exposure is required during a left retroperitoneal exposure, a counterincision may also be placed in the right lower quadrant, although patient positioning and retractor system placement may limit the potential use of this maneuver.
- For procedures requiring more proximal, visceral aortic exposure, the latissimus dorsi is identified and dissected from surrounding superficial and deep tissues and retracted laterally. The 8th intercostal space is opened posteriorly to the paraspinal muscles and anteriorly to the costal margin, which is divided. As the retroperitoneal space is developed, the peritoneum is bluntly separated from the inferior surface of the diaphragm. The diaphragm is divided in a circumferential manner 1 to 2 cm from its attachments to the chest wall to avoid injury to the phrenic nerve (**FIG 2**). The median arcuate ligament is identified and divided. Proximal aortic control can now be obtained under direct vision, again following strategic placement of self-retaining retractor blades, taking care to identify and avoid injury to the esophagus.

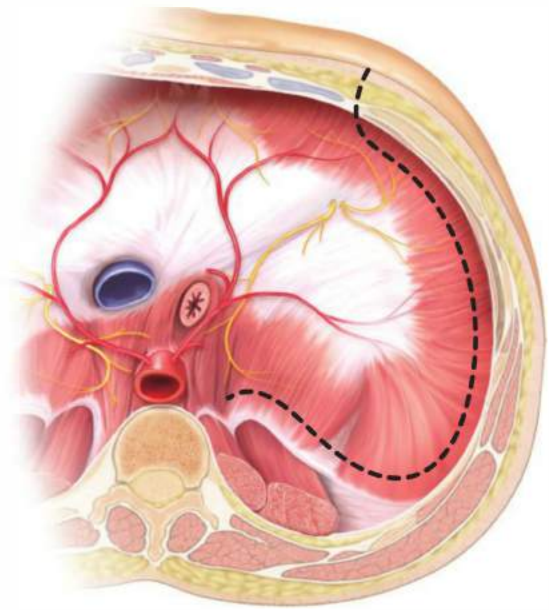

FIG 2 ● The diaphragm is incised circumferentially (dotted line) to protect the phrenic nerve and thereby preserve diaphragmatic function. A one-to two centimeter cuff of diaphragm is left attached to the chest was to aide in closure.

- Dissection of the plane posterior the Gerota's fascia allows for exposure of the left renal artery, which is an important landmark in further dissection of the visceral aorta. Once the origin of the left renal artery is identified and the median arcuate ligament has been divided, the visceral aorta and origins of the celiac axis and SMA can be isolated with sharp dissection. With the left kidney rotated anteriorly, the SMA can be exposed over a distance of approximately 5 cm (**FIG 3**).

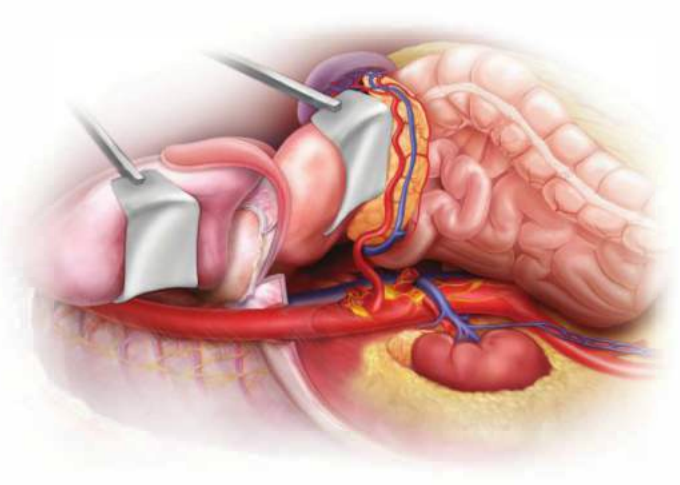

FIG 3 ● Exposure of the visceral aorta with the left kidney lifted to expose the left renal artery and the entire posterior-lateral aorta. Note that the left renal vein rolls off the aorta.

Additional exposure can be obtained by rotating the kidney posterior to expose the SMA as it courses behind the pancreas (**FIG 4**).

- Following vascular repair, the retroperitoneal space should be inspected for hemostasis. The ureter should be inspected, and any suspected injury or leak can be investigated with intravenous methylene blue. If needed, the peritoneum can be opened for inspection of abdominal contents.
- Removing the table break or lowering the kidney bar if used will aid in approximating tissue layers without tension.
- If divided, the diaphragm can be reapproximated with a continuous running absorbable suture. The suture can be secured at the anterior costal margin and will help approximate these structures as well.
- If the thorax was entered, a large-bore chest tube is placed dependently and secured with U stitches.
- A large Blake or Jackson-Pratt drain can be placed in the retroperitoneal space to avoid early postoperative fluid collections.
- The muscular layers are closed with continuous absorbable sutures and the subcutaneous tissue and skin closed with standard techniques.

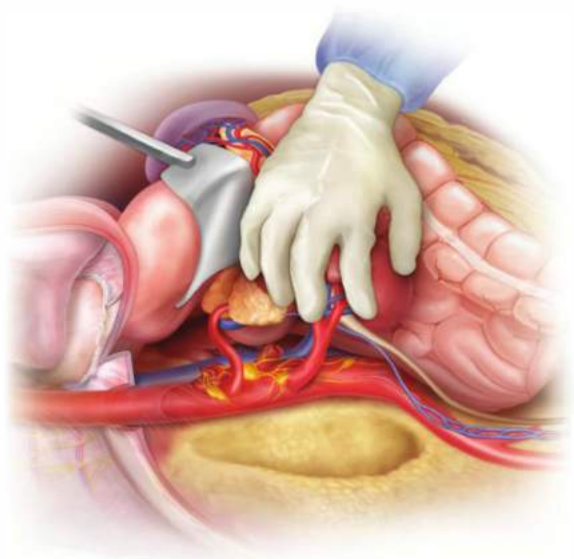

FIG 4 ● Exposure of the visceral aorta with the left kidney left *in situ*. This approach allows for additional exposure of the proximal superior mesenteric artery.

PEARLS AND PITFALLS

- Choosing the most appropriate procedure for any given patient with mesenteric or renal artery occlusive disease is dependent on a multitude of factors, especially with the widespread availability of percutaneous interventions. Open surgical procedures continue to remain an excellent alternative for patients with multivessel disease, with coexisting aortoiliac occlusive or aneurysmal disease, and with disease too extensive to be adequately treated with wire-based techniques. When selecting from the variety of open procedures, patient comorbidity, body habitus and its impact on adequate exposure, quality of the inflow and outflow vessels, and ability to safely clamp vessels should all be taken into consideration. Having a working knowledge of all alternatives is important, as occasionally, intraoperative findings dictate a deviation from the preoperative plan.
- Intraoperative management is similar to that for other abdominal vascular procedures. When the dissection is complete, patients are given heparin at a dose of 100 units/kg prior to clamping vessels, achieving a target activated clotting time (ACT) of 200 to 250 seconds. For cases where renal perfusion is interrupted, 0.25 to 0.5 g/kg of mannitol is given prior to cross-clamping. As soon as possible, the kidney is perfused with 300 to 400 mL of saline cooled to 4°C. This may be done at the renal artery ostium immediately after a renal endarterectomy, or directly into the renal artery at the level of the distal anastomosis. Renal artery cannulas, which come in a variety of sizes, are used for perfusion. Using a size that most closely matches the diameter of the renal vessel assures that the perfusate will go into the kidney and not spill onto the operative field.
- When revascularization is complete, heparin is reversed with protamine while checking for hemostasis. The patency of revascularization may be checked with intraoperative duplex imaging. Confirmation of an adequate endpoint is especially important when endarterectomy has been performed, as intimal flaps may present as a delayed vessel occlusion and end-organ loss.

POSTOPERATIVE CARE

- In addition to the standard postoperative strategies for patients undergoing aortic surgery, including serial hematocrit and hemoglobin, electrolytes, creatinine, and lactic acid, it is important to monitor renal and intestinal function. Patients undergoing renal revascularization commonly have an obligatory diuresis for the first 12 hours after surgery. This phenomenon may be due to residual effects of operative mannitol as well as a response to transient renal ischemia. During this time, urine output is not reflective of the patient's overall volume status, and crystalloid should be given at rates sufficient to maintain central filling pressures. Also, serum creatinine should be serially measured. It is common for the serum creatinine to increase slightly in the first 1 or 2 postoperative days, but increases of more than 20% or 30% warrant further investigation, especially if associated with oliguria. Sudden changes in renal function that are unexplained or unresponsive to corrective measures warrant duplex imaging to determine renal perfusion.

- Patients after mesenteric revascularization often develop hyperactive peristalsis, sometimes while the incision is still open. Under these circumstances, serial examination for bowel sounds in the first 24 hours can provide clues to the continued patency of the revascularization. Serial lactate levels are also checked. Although immediate postoperative lactate levels are elevated, they should return to normal as the patient is warmed and resuscitated. Coagulation parameters may also be elevated initially in response to blood loss and transient hepatic ischemia. These parameters should be monitored and corrected for active bleeding; normal values are usually present by the first postoperative day.

COMPLICATIONS

General Considerations

- As with all aortic surgery, potential complications after visceral artery revascularization include myocardial infarction, respiratory failure, and postoperative bleeding. Additionally, renal failure is always a potential complication during visceral revascularization, although its incidence is low.[3–5] Potential causes of renal failure include generalized hypoperfusion from cardiac dysfunction or hypovolemia, prolonged intraoperative ischemia, or thrombosis of the repair. Progressive or unexpected renal failure should initiate a prompt workup including duplex imaging of the kidneys to identify potentially treatable causes. Thrombosis with absence of flow to the kidney is generally irreversible unless identified immediately.
- Intestinal ischemia is the major concern after mesenteric revascularization. Signs and symptoms may include severe abdominal pain, continued acidosis, and hematochezia. Ischemia may be secondary to vessel or graft thrombosis or may result from distal embolization during or following the repair. Patients with evidence of peritonitis should be promptly reexplored, and those treated initially for acute mesenteric ischemia should have a planned second look at 12 to 24 hours if there was any question of intestinal viability at the time of the original operation. Arterial duplex may confirm the viability of the repair but cannot rule out embolization as a cause for postoperative intestinal ischemia. At exploration, nonviable intestine can be resected, and issues with the revascularization can be addressed.

Graft or Vessel Twisting or Kinking

- When performing a bypass to the SMA, it is important to retract the mesentery in a caudal direction to adequately assess graft length. Inadequate positioning will result in excessive graft length and potential kinking and thrombosis once the peritoneal contents are reduced to the abdomen and the incision is closed. Additionally, for retrograde bypass, the graft should be placed with enough slack to allow the distal endpoint to be in-line with the SMA with caudal retraction of the intestines. This positioning will prevent both kinking of the graft and tenting and narrowing of the anastomosis. Bypass to the renal arteries should similarly be constructed with appropriate graft length as it will lay in the retroperitoneum after retraction is released. For cases of arterial reimplantation, it is important to maintain orientation of the target vessel to prevent twisting during construction of the anastomosis. Additionally, the anastomotic site should be chosen in a similar coronal plane to prevent kinking once the end organs assume their natural position.

Injury during Endarterectomy

- Identifying the appropriate endarterectomy plane is usually straightforward in the aorta, renal arteries, and SMA. The celiac artery can be challenging, as it may be thin-walled, and plaque removal may injure the arterial wall. Limited injuries can be repaired with interrupted 4-0 or 5-0 Prolene sutures supported with Teflon pledgets, but larger injuries or those with severely attenuated vessel walls may not be successfully repaired with this technique. If the integrity of the artery is in doubt, it may be safer to transect it and perform a bypass from the aorta to the transected celiac artery using an 8-mm or 10-mm graft. The celiac artery stump can be oversewn with pledgeted 3-0 Prolene suture placed into healthy aorta. Unacceptable endpoints after renal endarterectomy are best treated with conversion to a bypass.

Inadequate Distal Endarterectomy Endpoint

- Plaque extending to the infrapancreatic SMA may be difficult to entirely remove with standard thoracoabdominal exposure. Intraoperative duplex can confirm an adequate endpoint, and if there is any uncertainty, the abdominal cavity can be entered and the SMA exposed by dividing the ligament of Treitz. This maneuver will provide exposure of the SMA as it emerges from behind the pancreas, usually at a place distal to the diseased segment. Inspection by palpation or with duplex ultrasound can evaluate the repair. Incomplete endarterectomy or intimal flaps can be managed through an arteriotomy at this location. A reasonably sized SMA can be transected and the retained plaque removed; reapproximation with interrupted sutures will secure the intima distal to the endarterectomy. Exposing the endpoint in a smaller vessel is most safely performed with a lateral arteriotomy and subsequent patch angioplasty closure to prevent narrowing.
- Problematic endarterectomy endpoints in the celiac artery or renal arteries may be best managed with placement of a bypass graft. Conversion to bypass will require enough exposure of the target vessel to allow for revascularization distal to the diseased segment. Either end-to-end or end-to-side reconstruction is acceptable and should be performed, making certain that the intima is secured with the suture line.

Chapter 16

Hybrid Revascularization Strategies for Visceral/Renal Arteries

Benjamin W. Starnes

DEFINITION

- The term "hybrid" in vascular surgery traditionally refers to the use of *both* traditional open surgical and endovascular techniques for remedy of the vascular condition (**FIG 1**).
- Two hybrid approaches are described in this chapter.
  - Complete visceral debranching and endovascular tube graft repair
  - Partial visceral debranching and physician-modified fenestrated endovascular repair

DIFFERENTIAL DIAGNOSIS

- Paravisceral aortic aneurysms may develop due to the following conditions:
  - Degenerative aneurysm
  - Aortic dissection
  - Mycotic aneurysm
  - Paraanastomotic juxtarenal aneurysm
  - Connective tissue disorders (Marfan's syndrome)
  - Behçet syndrome

PATIENT HISTORY AND PHYSICAL FINDINGS

- The majority of patients are asymptomatic and the diagnosis is made with imaging done for other reasons. Some patients will complain of mild to moderate abdominal and low back pain. Severe and unrelenting pain should raise the index of suspicion for a mycotic process which, if confirmed, would make hybrid approaches prohibitive.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Contrast-enhanced, axial thin-slice computed tomography arteriography (CTA) is the current standard for imaging paravisceral aneurysms. Detailed information can be gathered regarding the precise origin of the celiac, superior mesenteric artery (SMA), and renal arteries (**FIG 2**).
- Other important findings on CTA should be as follows:
  - Size and quality of access vessels for delivery of endovascular devices (>7 mm)
  - Location of left renal vein
  - Aberrant anatomy (e.g., replaced right hepatic artery)
  - Quality of gastroduodenal artery for possible celiac artery ligation or sacrifice
  - Renal cortical thickness

SURGICAL MANAGEMENT

- Indications for repair include aortic aneurysms of more than 5.5 cm, symptoms, or evidence of rapid expansion (>0.5 cm per 6 months).

Preoperative Planning

- As formal open repair would often include a bicavitary incision (chest and abdomen, as in a formal thoracoabdominal repair), the standard preoperative assessment should focus on the patient's fitness to undergo major vascular surgery. This includes assessment of heart, lung, and kidney function and reserve.

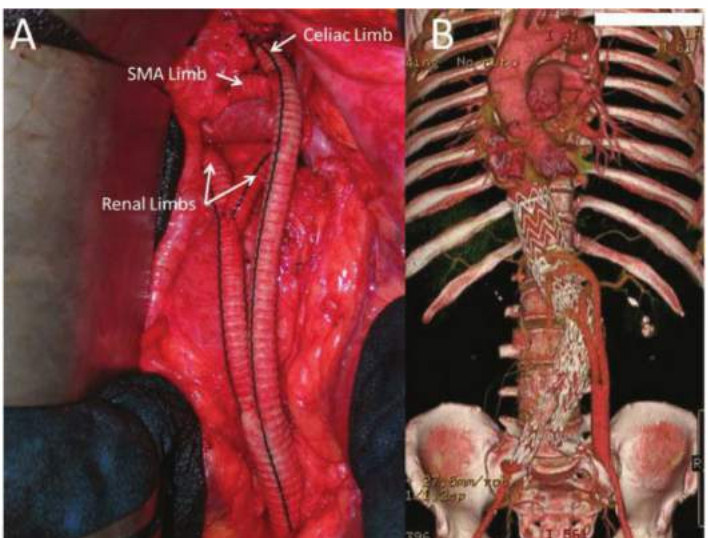

FIG 1 ● "Hybrid repair" refers to the use of both traditional open surgical and endovascular techniques to manage the same problem. SMA, superior mesenteric artery. **A.** Intraoperative photo. **B.** Post operative CTA after completed repair.

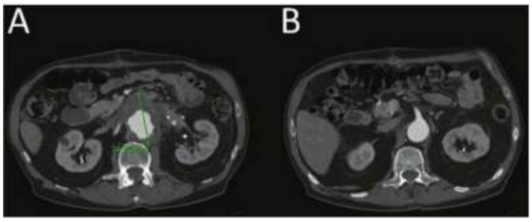

FIG 2 ● CTA axial images depicting **(A)** a 7.4-cm paraanastomotic juxtarenal aortic aneurysm and **(B)** a healthy aortic segment in the region of the SMA.

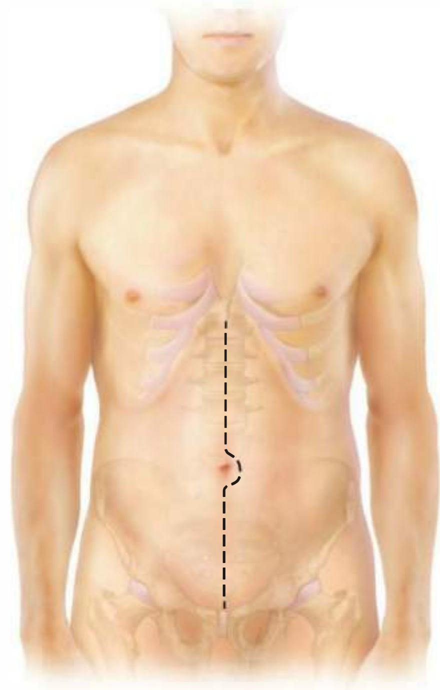

FIG 3 ● Depiction of positioning and intended incision in the midline.

Positioning

- Proper and precise positioning should be as follows (**FIG 3**):
  - Patient supine on standard operating room table or imaging table
  - Hair properly clipped over entire abdomen and both groins
  - Both arms tucked (option to have right arm at 90 degrees if planning brachial access)
  - Foley under one leg and padded

COMPLETE VISCERAL DEBRANCHING AND ENDOVASCULAR TUBE GRAFT REPAIR—STAGE 1

First Step—Exposure

- Standard midline laparotomy and positioning of retractor system
- Upon entry into the abdomen, the falciform ligament is divided between clamps and ligated. The triangular ligaments above the liver are divided to facilitate adequate exposure/retraction while minimizing risk of hepatic capsular injury, anticipating systemic anticoagulation later in the procedure.
- A nasogastric tube is positioned in the stomach to provide temporary decompression. The common hepatic artery is identified following division of the gastrohepatic ligament and traced back to origin of celiac artery. Once identified, the target artery is encircled with a silastic vessel loop. Space is created along the left side of the aorta with blunt/finger dissection, beginning at the level of the celiac artery, to create the retrograde bypass tunnel posterior to the pancreas (**FIG 4**).
- The colon and omentum are lifted in a cephalad direction, the small bowel swept to the patient's right and packed in moist towels. Self-retaining retractors (Omni or Bookwalter) should be positioned at this juncture to maintain exposure, with care taken to appropriately pad the retractor blades as necessary.
- The third and fourth portions of the duodenum are mobilized to the right following division of the ligament of Treitz, exposing the anterior surface of the aorta. The inferior mesenteric vein is ligated and divided as well and the dissection continued along the proximal aorta until the left renal vein is clearly identified (**FIG 5**).
- Widely mobilize the left renal vein sharply and encircle with a moist umbilical tape. The self-retaining renal vein retractor blade is used to retract the left renal vein cephalad as necessary to facilitate further exposure.
- The origin of the renal arteries is identified by careful posterolateral dissection around the aorta, just cephalad of the overlying renal vein. Exposure on the right is complicated somewhat by the overlying inferior vena cava/left renal vein confluence. At least 2 cm of renal artery should be exposed bilaterally. Encircle the renal arteries with silastic vessel loops. On the left, finger dissect bluntly along the aorta in a cephalad fashion to complete the retropancreatic tunnel for the celiac limb of the bypass graft.
- The SMA is identified next by palpation within the base of the small bowel mesentery, directly anterior to the pancreas. Doppler ultrasonography may assist identification when the pulse is faint. Once identified, a 3-cm segment of SMA is isolated as proximal as possible to the root of the mesentery. Beginning with the middle colic artery, multiple mesenteric arteries quickly branch from the SMA as it emerges from the pancreas, underscoring the need for proximal identification and isolation. The SMA is controlled with vessel loops.

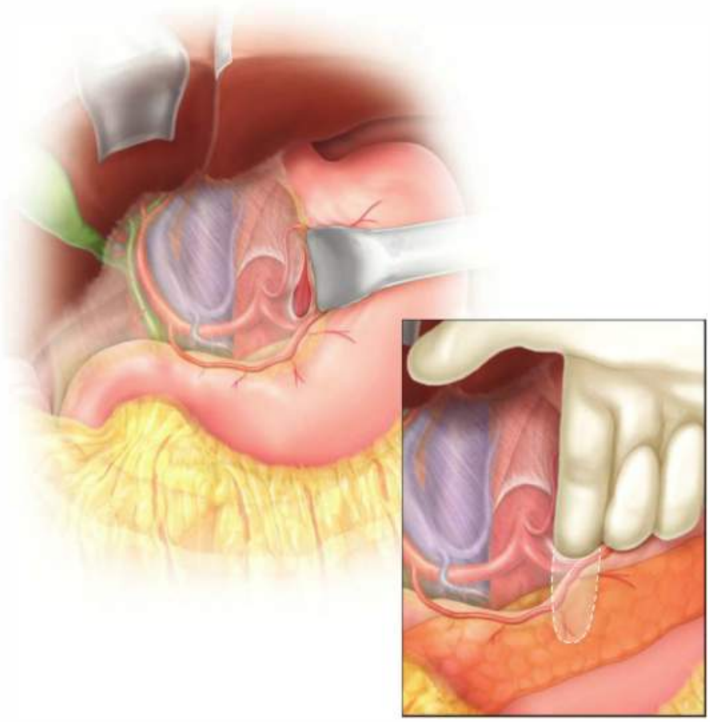

FIG 4 ● Drawing of exposure of the celiac artery through the lesser sac. Note the blunt finger dissection along the left side of the aorta and behind the pancreas.

- The next step is to prepare the donor artery for hybrid bypass. The specific artery—most commonly the common or external iliac arteries—should be selected from the preoperative imaging study. The retroperitoneum is opened directly over the selected donor artery, which is exposed while protecting the adjacent ureter. Alternatively, donor artery exposure may be achieved via medial-visceral rotation, developing the entire retroperitoneal plane on the left. The latter approach provides the added benefit of exclusion of the graft from the viscera and abdominal contents once the viscera are returned to their original position. This maneuver adds significantly more time to

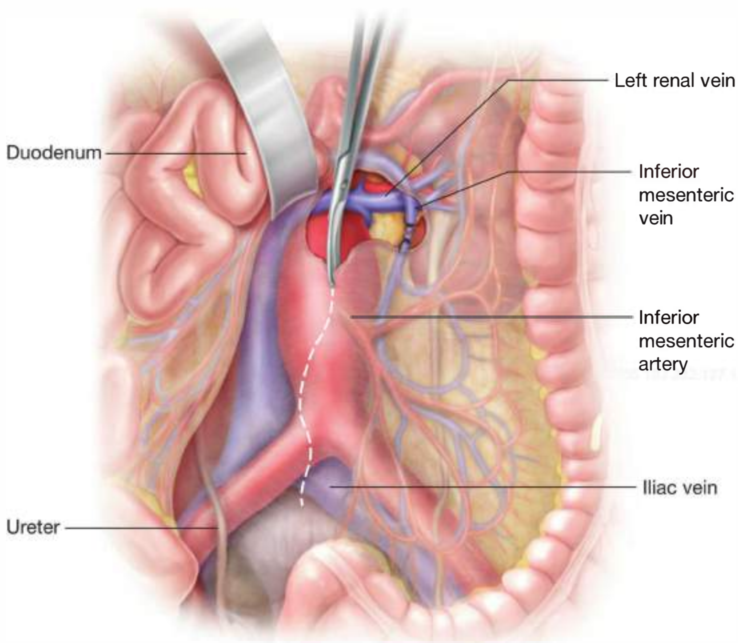

FIG 5 ● Drawing of exposure of the left renal vein and anterior surface of the aortic aneurysm. Dashed line depicts intended incision line to avoid nervi erigentes.

the case, however, and contributes to increased blood loss. Graft coverage can also be obtained without developing the entire retroperitoneal plane, either via direct tunneling along the preferred course of the graft or creation of an omental tongue affixed directly to the graft.

Second Step—Anticoagulation

- Systemic anticoagulation is achieved with a bolus injection of unfractionated heparin, 50 units/kg. Monitoring activated clotting time is a useful method of maintaining adequate anticoagulation during the procedure.

Third Step—Multivisceral Bypass

- Trifurcated grafts exist for the purpose of facilitating multivessel hybrid revascularization, but the use of these are limited by the tendency of the middle limb to occlude when "squeezed" between the outside limbs during graft routing and abdominal closure. In most circumstances, a standard 12 × 7 bifurcated, collagen-impregnated knitted polyester graft provides excellent conduits for bilateral renal revascularization, with a separate 8-mm limb connected to the celiac and SMA. Examples of bypass graft configurations are shown in **FIGS 6** and **7**.
- The proximal (iliac/inflow) anastomosis is completed first with running 4-0 or 5-0 polypropylene suture.
- The next anastomosis to be completed should be one anticipated to be the technically most difficult, given exposure and graft routing issues. Most commonly, this is the right renal artery. This is divided following placement of a large clip at the origin. The appropriate graft limb is pulled to length and anastomosed end-to-end with 5-0 polypropylene suture. The limb and artery are flushed just prior to completion of the graft, after which the clamps are released to reperfuse the kidney. Following this sequence, warm renal ischemia time is generally less than 12 minutes. The stump of the right renal artery is then suture ligated; avoid clip dislodgement. Note: Excessive traction on the confluence of the left renal vein and vena cava may cause caval injury and massive hemorrhage during preparation and completion of the right renal artery anastomosis. Retractor positioning needs to account for potential venous injury during exposure and significantly relaxed following completion of the anastomosis.

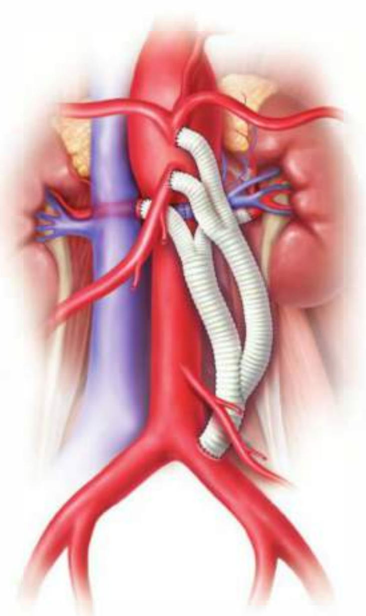

FIG 6 ● Drawing of a four-vessel debranching based off of the left common iliac artery. Note that the left renal vein was divided in this case, and subsequently repaired, for better exposure of the renal arteries.

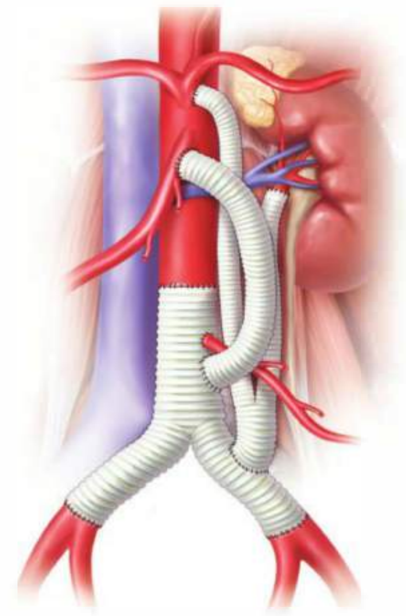

FIG 7 ● Aortobiiliac and subsequent debranching for a patient with a solitary left kidney and infrarenal aneurysm.

- The left renal anastomosis is completed in nearly identical fashion, minus many of the exposure limitations present on the right.
- The SMA graft is carefully sized to length so that it follows a "C"-shaped configuration without kinking. Inflow can be obtained either from the many bodies of the graft or either of the completed renal limbs. The SMA-graft anastomosis is completed end-to-side with interrupted or running 5-0 polypropylene suture. The end-to-side arteriotomy length is 1.5 to 2 times the width of the bypass graft (12 to 16 mm). Alternatively, end-to-end anastomotic configuration may reduce the likelihood of graft kinking depending on final configuration. Following completion of the anastomosis, the proximal SMA is ligated with a large clip or circumference suture. Again, ischemia time should be under 10 to 12 minutes.
- Typically, following SMA and renal graft completion, repositioning of the retraction system is necessary to reobtain and optimize celiac artery exposure. Prior to reexposing

the celiac, a vascular clamp is repassed through the retropancreatic tunnel left of the aorta. This position is then maintained until the transverse colon and mesocolon are reduced to their usual location. This reexposes the "looped" celiac and common hepatic arteries previously isolated in the lesser sac. The clamp tip exiting the retrohepatic tunnel is identified, and a moist umbilical tape is pulled through the tunnel. Following this, the celiac limb is tied to the umbilical tape, which is then pulled cephalad behind the pancreas and into position for either end-to-end or end-to-side anastomosis. Care again needs to be taken to optimize limb routing and length to minimize risk for kinking.

- After coverage of remaining exposed graft limbs with omentum or parietal peritoneum as appropriate, standard abdominal closure is performed.

COMPLETE VISCERAL DEBRANCHING AND ENDOVASCULAR TUBE GRAFT REPAIR—STAGE 2

First Step—Percutaneous Access

- Following the "debranching" procedure described in stage 1, endovascular aneurysm repair (EVAR) may be performed either at the same setting or within several weeks of the initial procedure. The risk of potential aneurysm rupture associated with a staged approach needs to be balanced with the additional operative risk inherent in the longer anesthetic time required to complete both stages in one sitting. For the EVAR procedure itself, standard percutaneous access to an appropriately sized access vessel is obtained using Seldinger technique and a wire advanced into the aorta under fluoroscopic guidance. In our practice, this is most commonly obtained percutaneously, using ultrasound guidance and preplacement of polypropylene suture prior to dilation of the access sites (also known as the "preclose" Perclose® technique (Abbott Vascular Inc, Redwood City, CA).[1] An 11-Fr standard sheath is placed into the common femoral artery and flushed with heparinized saline. Wire advancement from the femoral artery to the aortic arch must be visualized radiographically throughout its course, as the wire may preferentially enter the debranching graft and cause end-organ injury or hemorrhage without real-time position monitoring and guidance.

Second Step—Stiff Wire Exchange

- After wire advancement to the transverse aortic arch, standard wire exchange technique is used to position a 0.035-in stiff (e.g., Lunderquist®, Cook Medical, Bloomington, IN) wire through the abdominal and thoracic aorta. Optimal final wire positioning is at/just distal to the left subclavian artery orifice.

Third Step—Intravascular Ultrasound

- An 8.2-Fr Visions® catheter (Volcano Therapeutics, Irvine, CA) is used to confirm appropriate proximal and distal landing zones for endovascular graft placement. The optimal graft size and configuration is determined by analysis of CTA images reformatted and visualized on a dedicated 3-D image workstation (AquariusNet®, TeraRecon, Inc, San Mateo, CA). Graft diameter should be oversized by 10% to 15% for this application.
- During advancement of the device, the origin of the debranching graft can also be visualized either through fluoroscopic confirmation of a metallic clip placed during the debranching procedure or under intravascular ultrasound (IVUS) real-time guidance. Using IVUS, the position of the IVUS catheter is marked on the fluoroscopic monitor when the catheter itself recognizes the orifice of the debranched graft. Alternatively, a contrast power injection can be performed through an appropriately positioned arteriographic catheter with 30 mL of contrast injected at 15 mL per second to confirm the proximal and distal landing zones.

Fourth Step—Endograft Deployment

- The endovascular graft is deployed following device-specific instructions for use (IFU), covering the native origins of the visceral vessels and excluding the aortic aneurysm. The femoral arteriotomy is then closed.

PARTIAL VISCERAL DEBRANCHING AND PHYSICIAN-MODIFIED ENDOVASCULAR REPAIR—STAGE 1

First Step—Exposure

- Standard midline laparotomy and positioning of retractor system.
- Upon entry into the abdomen, the falciform ligament is divided between clamps and ligated. The triangular ligaments above the liver are divided to facilitate adequate exposure/retraction while minimizing risk of hepatic capsular injury, anticipating systemic anticoagulation later in the procedure.
- A nasogastric tube is positioned in the stomach to provide temporary decompression. The common hepatic artery is identified following division of the gastrohepatic ligament and traced back to origin of celiac artery. Once identified, the target artery is encircled with a silastic vessel loop. Space is created along the left side of the aorta with blunt/finger dissection, beginning at the level of the celiac artery, to create the retrograde bypass tunnel posterior to the pancreas.
- The colon and omentum are lifted in a cephalad direction, the small bowel swept to the patient's right and

packed in moist towels. Self-retaining retractors (Omni or Bookwalter) should be positioned at this juncture to maintain exposure, with care taken to appropriately pad the retractor blades as necessary.

- The third and fourth portions of the duodenum are mobilized to the right following division of the ligament of Treitz, exposing the anterior surface of the aorta. The inferior mesenteric vein is ligated and divided as well and the dissection continued along the proximal aorta until the left renal vein is clearly identified.
- Widely mobilize the left renal vein sharply and encircle with a moist umbilical tape. The self-retaining renal vein retractor blade is used to retract the left renal vein cephalad as necessary to facilitate further exposure.
- The origin of the renal arteries is identified by careful posterolateral dissection around the aorta, just cephalad of the overlying renal vein. Exposure on the right is complicated somewhat by the overlying inferior vena cava/left renal vein confluence. At least 2 cm of renal artery should be exposed bilaterally. Encircle the renal arteries with silastic vessel loops. On the left, finger dissect bluntly along the aorta in a cephalad fashion to complete the retropancreatic tunnel for the celiac limb of the bypass graft.
- The SMA is identified next by palpation within the base of the small bowel mesentery, directly anterior to the pancreas. Doppler ultrasonography may assist identification when the pulse is faint. Once identified, a 3-cm segment of SMA is isolated as proximal as possible to the root of the mesentery. Beginning with the middle colic artery, multiple mesenteric arteries quickly branch from the SMA as it emerges from the pancreas, underscoring the need for proximal identification and isolation. The SMA is controlled with vessel loops.
- The next step is to prepare the donor artery for hybrid bypass. The specific artery—most commonly the common or external iliac arteries—should be selected from the preoperative imaging study. The retroperitoneum is opened directly over the selected donor artery, which is exposed while protecting the adjacent ureter. Alternatively, donor artery exposure may be achieved via medial-visceral rotation, developing the entire retroperitoneal plane on the left. The latter approach provides the added benefit of exclusion of the graft from the viscera and abdominal contents once the viscera are returned to their original position. This maneuver adds significantly more time to the case, however, and contributes to increased blood loss. Graft coverage can also be obtained without developing the entire retroperitoneal plane, either via direct tunneling along the preferred course of the graft or creation of an omental tongue affixed directly to the graft.

Second Step—Anticoagulation

- Systemic anticoagulation is achieved with a bolus injection of unfractionated heparin, 50 units/kg. Monitoring activated clotting time is a useful method of maintaining adequate anticoagulation during the procedure.

Third Step—Multivisceral Bypass

- Trifurcated grafts exist for the purpose of facilitating multivessel hybrid revascularization, but the use of these are limited by the tendency of the middle limb to occlude when squeezed between the outside limbs during graft routing and abdominal closure. In most circumstances, a standard 12 × 7 bifurcated, collagen-impregnated knitted polyester graft provides excellent conduits for bilateral renal revascularization, with a separate 8-mm limb connected to the celiac and SMA. Examples of bypass graft configurations are shown in **FIGS 6** and **7**.
- The proximal (iliac/inflow) anastomosis is completed first with running 4-0 or 5-0 polypropylene suture.
- The next anastomosis to be completed should be one anticipated to be the technically most difficult, given exposure and graft routing issues. Most commonly, this is the right renal artery. This is divided following placement of a large clip at the origin. The appropriate graft limb is pulled to length and anastomosed end-to-end with 5-0 polypropylene suture. The limb and artery are flushed just prior to completion of the graft, after which the clamps are released to reperfuse the kidney. Following this sequence, warm renal ischemia time is generally less than 12 minutes. The stump of the right renal artery is then suture ligated; avoid clip dislodgement. Note: Excessive traction on the confluence of the left renal vein and vena cava may cause caval injury and massive hemorrhage during preparation and completion of the right renal artery anastomosis. Retractor positioning needs to account for potential venous injury during exposure and significantly relaxed following completion of the anastomosis.
- The renal anastomosis is completed in nearly identical fashion, minus many of the exposure limitations present on the right.

PARTIAL VISCERAL DEBRANCHING AND PHYSICIAN-MODIFIED ENDOVASCULAR REPAIR—STAGE 2[2]

First Step—Creation of a Fenestrated Graft for the Celiac and Superior Mesenteric Artery

- The appropriate endovascular device is chosen according to standard IFU sizing guidelines, typically incorporating 10% to 15% oversizing. The sterile graft is unsheathed on a dedicated sterile table in the operating room and marked with the relative locations (length from proximal end and clockface measurements) of the celiac and SMA fenestrations as previously determined via TeraRecon® workstation analysis. Minor adjustments are allowed to minimize strut overlap of planned fenestration locations. Fenestrations in the polyester endograft fabric are created with a disposable ophthalmic cautery to minimize fraying. The fenestrations are outlined and reinforced with 15-mm gold Amplatz Gooseneck®

FIG 8 ● Photograph of a thoracic endograft with two fenestrations created for the celiac (struts present) and SMA (strut free), prior to resheathing and deployment.

snares (ev3 Endovascular, Inc, Plymouth, MN). These are hand sewn into place using 4-0 Prolene suture in a double row circumferentially (FIG 8). Diameter-reducing ties were then used to constrain the device along its posterior border (opposite the SMA and or celiac fenestration at 6 o'clock) by rerouting the existing proximal trigger wire through and through the graft material at the midportion of each of the top two Z stents. The constraining ties are then tied down into place over the trigger wire. The entire graft is then wetted with heparinized saline and then reloaded into the existing sheath.

Second Step—Percutaneous Access

- Standard percutaneous access to an appropriately sized access vessel is obtained using Seldinger technique. The initial guidewire is advanced into the aorta under fluoroscopic guidance. In our practice, this is most commonly obtained percutaneously, using ultrasound guidance and preplacement of polypropylene suture prior to dilation of the access sites (also known as the "preclose" Perclose® technique (Abbott Vascular Inc, Redwood City, CA).[1] An 11-Fr standard sheath is placed into the common femoral artery and flushed with heparinized saline. Wire advancement from the femoral artery to the aortic arch must be visualized radiographically throughout its course, as the wire may preferentially enter the debranching graft and cause end-organ renal injury, rupture of Gerota's fascia, and retroperitoneal hemorrhage without real-time position monitoring and guidance.

Third Step—Stiff Wire Exchange

- A standard 4- or 5-Fr catheter is used to perform a wire exchange to a stiff 0.035-in Lunderquist® wire (Cook Medical, Bloomington, IN). The wire is positioned so that its tip is just distal to the left subclavian artery.

Fourth Step—Marking of the Target Vessels and Graft Deployment

- A contrast power injection can be performed with 10 mL of contrast injected at 25 mL per second to mark the precise origins of the celiac and SMA (FIG 9). The modified graft is positioned over the target vessels, oriented, and deployed.

Fifth Step—Cannulation of the Target Vessels

- An 18-Fr sheath is advanced from the contralateral groin and into the distal graft over a stiff wire. Two

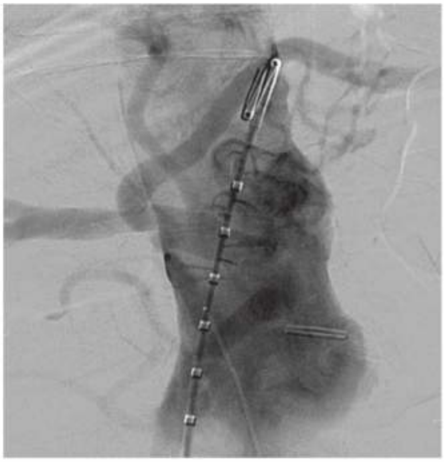

FIG 9 ● Note the double densities depicting the origins of the celiac and SMA on this flush aortogram.

7-Fr Raabe® sheaths (Cook Medical, Bloomington, IN) are advanced together through the 18-Fr sheath. Working through these sheaths, the SMA and celiac vessels are selected through the fenestrations using standard catheter and guidewire techniques, with the sheaths ultimately advanced into the target vessels over stiff wires.
- After sheath advancement and confirmation of target vessel acquisition, the main body is distended flush with the surrounding aorta with a moulding balloon (e.g., Coda®, Cook Medical, Bloomington, IN). This inflation represents the final opportunity to distend the endograft in the region of the visceral stents. Lateral positioning of the image intensifier guides stent placement into the SMA and celiac arteries (typically 8- to 9-mm stents; FIG 10). FIG 11 shows follow-up computed tomography (CT) imaging of a patient 1 year after successful treatment with this technique.

Sixth Step—Access Site Closure

- The access sites are closed with the previously placed sutures.

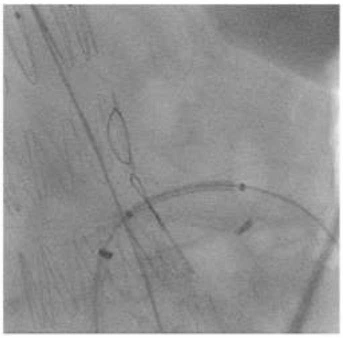

FIG 10 ● Lateral image depicting placement of a covered balloon-expandable stent into the SMA prior to deployment.

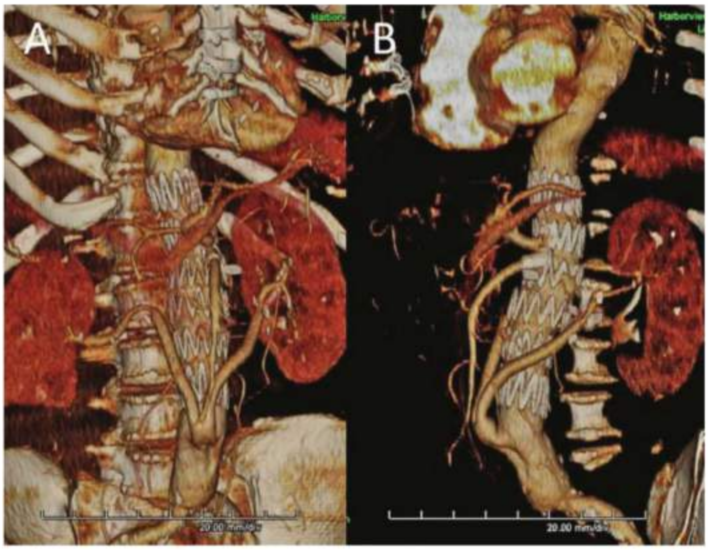

FIG 11 ● **A,B.** Follow-up CT images of a patient successfully treated with partial visceral debranching and physician-modified endovascular fenestrated repair.

PEARLS AND PITFALLS

Choice of operating room (OR) table	■ Use standard OR tables for open surgical procedures and imaging tables for image-guided or hybrid procedures. Advanced planning is essential to optimize outcome. Never sacrifice exposure!
Exposure of common iliac artery	■ Identify and protect the ureter.
Placement of wires after debranching procedure	■ Pass guidewires under continuous fluoroscopic guidance following debranching. An advancing aortic wire may preferentially enter and traverse the debranching graft, causing end-organ injury, disorientation, and possible endograft maldeployment if not recognized.
Timing of stent graft balloon moulding during fenestrated EVAR	■ Always seat the endograft with balloon inflation prior to placement of visceral bridging stents. Instrumentation or distention of the fenestrated endograft following branch vessel stenting may compromise stent positioning, integrity, and patency.

POSTOPERATIVE CARE

- Open aortic debranching procedures are not benign; almost all patients will require intensive care postprocedure. Spinal drainage is used selectively for aortic coverage extending more than 10 cm cephalad to the celiac artery. Postoperative anuria or persistent acidosis/rising lactate require immediate investigation to prove branch vessel patency.

OUTCOMES

- Contemporary hybrid debranching procedures for complex abdominal aortic aneurysmal disease are associated with a 13% operative mortality rate, 2% permanent paraplegia rate, and 1% stroke rate.[3]
- Hybrid approaches offer the advantage of versatility, avoidance of extensive operative exposures, and potentially offer a broader range of therapies to a patient population that would not otherwise be considered for aortic surgical repair.

COMPLICATIONS

- Access-related complications
- Hemorrhage requiring transfusion
- Paraplegia
- Stroke
- Renal failure
- Death

Chapter 17

Snorkel/Chimney and Periscope Visceral Revascularization during Complex Endovascular Aneurysm Repair

Jason T. Lee   Ronald L. Dalman

DEFINITION

- Although routine endovascular aneurysm repair (EVAR) has gained widespread acceptance as the procedure of choice for patients with suitable aortic neck anatomy, the optimal approach to the juxtarenal aortic aneurysm (JAA), often with challenging anatomy at the visceral neck, remains controversial.[1] Although open repair is an effective and durable option for patients with JAA, particularly in centers of excellence for low physiologic risk patients,[2] endovascular techniques including fenestrated and branched EVAR (FBE) have emerged as effective, potentially less invasive alternatives.[3]
- In the United States, however, lack of widespread availability of FBE has allowed other techniques to emerge, and in this chapter, we describe the increasingly popular "snorkel" or "chimney" technique, defined as a parallel stent graft adjacent to the endograft main body to maintain perfusion to renal and visceral branches during EVAR and placed from a cranial direction, and the "periscope" technique, where the parallel stent graft is placed from the caudal direction.
- First described by Greenberg and associates,[4] the snorkel strategy can be employed either as a bailout from accidental coverage of vital side branches during deployments requiring close approximation of the main body to the branch artery in question, or the intentional cranial relocation of the EVAR seal zone for JAAs.[5–8]

DIFFERENTIAL DIAGNOSIS

- The challenge for the vascular specialist in treating JAAs revolves around an increasing number of choices for intervention, including traditional suprarenal repair, hybrid type debranching procedures, fenestrated and branched devices in clinical trials or certain centers, and snorkel/chimney/periscope techniques. The choice is most often based on patient physiologic parameters, physician experience with the multitude of techniques, and a very individualized approach to complex aortic anatomy.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients present electively and essentially without symptoms for consideration of repair of their JAA, as it is most often discovered during radiographic workup for vague abdominal discomfort, back pain, or as part of a screening program. A pulsatile, nontender abdominal mass can be elicited on careful abdominal exam. Any signs of persistent abdominal or back pain or hemodynamic instability or compromise should suggest the possibility of an acute aortic pathology and prompt more urgent workup and treatment. Careful attention during the history and physical examination to cardiac and renal comorbidities aids in risk-stratifying the patient for potential repair of their JAA. Because most patients are asymptomatic and aneurysms are repaired to prevent future rupture, some reasonable quality of life must be present for the patient to enjoy the survival advantage.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- High-quality computed tomography angiography (CT-A) on a modern 64-slice scanner able to produce at least 2-mm–thin cuts is a requirement for treatment with snorkel techniques. These imaging algorithms allow the creation of virtual models of the aneurysm for the surgeon to better appreciate the relationship of branches and potential areas of technical challenge (**FIG 1**). Patients with compromised kidney function who cannot undertake iodinated contrast are poor candidates for snorkel procedures, as noncontrast scans fail to elucidate thrombus volume, branch artery patency, and luminal diameter in the preoperative planning that is paramount to success.
- Access to a three-dimensional (3-D) workstation/program and familiarity with reconstruction software by the implanting surgeon for manipulation of the images and creating centerline pathways should be mandatory to most accurately plan device orientation, selection, and sizing (**FIG 2**).
- Because the snorkel technique usually involves access of the brachial artery for delivery of the parallel visceral stent grafts, visualization of the arch and proximal subclavian is

FIG 1 ● 3-D reconstruction of juxtarenal aneurysm with infrarenal neck length of 5 mm.

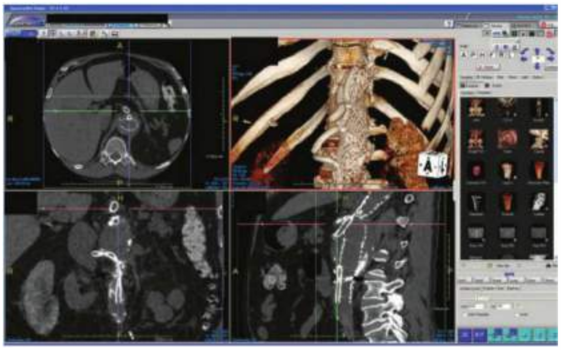

FIG 2 ● TeraRecon workstation view highlighting ability to manipulate images in multiple user-defined planes.

most conveniently obtained by including the chest in the standard CT-A of the abdomen and pelvis. The presence of a challenging type III arch, where the subclavian inserts below the inner curve of the aortic arch, makes the procedure more challenging and many times prohibitive due to concerns about arch manipulation, cerebral emboli, and deliverability of stent grafts (**FIG 3**). If the patient has already undergone an adequate CT-A abdomen and pelvis and one wishes to avoid the additional contrast load of repeating the study, a noncontrast chest computed tomography (CT) can be performed to visualize the arch but then should be combined with arterial duplex and waveforms of the upper extremities to ensure patency of the axillosubclavian arterial system.

- For patients with chronic kidney disease, high-grade renal stenosis, atretic kidneys, or multiple visceral and renal vessels involved in the endovascular plan for snorkeling, nuclear medicine split renal function tests can help determine if it is reasonable to sacrifice one of the renal arteries. This can be done in order to simplify the snorkel strategy and keep the number of cranially oriented stent grafts to two, which may have an influence on overall morbidity and mortality from the procedure.[1,7,8]

FIG 3 ● Type III aortic arch with origin of subclavian artery being lower than inner curve of aortic arch. The ability to advance a snorkel sheath from the left arm is severely compromised in this configuration and generally not recommended if alternative repair methods are available.

SURGICAL MANAGEMENT

Preoperative Planning

- All patients considered for snorkel/chimney or periscope techniques should have undergone an extensive informed consent discussion related to off-label use of endograft components for treatment of their complex aneurysm. Alternatives often discussed include open surgery with suprarenal clamping, hybrid debranching, referral to a center with access to fenestrated or branched devices, or no surgery at all. Once the decision is made to proceed with the snorkel strategy, we prefer a two-surgeon approach with one performing the femoral access portion and one the brachial access portion. Both surgeons should have reviewed on the 3-D workstation the anatomy, the endovascular plan, and the sequence for deployment.
- Access to a hybrid endovascular suite is highly recommended, although not mandatory, for successful completion of these procedures. Fixed imaging provides improved accuracy, reliability, and reproducibility of the anatomy throughout the sequence of the snorkel procedure. Knowledgeable operating room and cath-angio staff should be assigned to these cases and available endografts and wires/catheters as well as backups should all be arranged ahead of time to provide the safest working environment for the patient as well as the operative team.
- Choosing the main body endograft, its configuration, and size has been described by numerous authors who all report excellent results overall with a wide variety of devices and formulas.[9] In general, we often "oversized" to about 25% to 30% instead of the typical 15% to 20% for standard EVAR to account for the additional fabric infolding to accommodate the snorkel stent(s).
- Given the amount of dye often used as well as renal artery manipulation during the most complex of snorkel cases, we prefer to admit the patient the evening before or several hours prior to surgery for additional intravenous hydration when possible.
- General anesthesia is preferred, with consideration for preoperative lumbar drainage based on risk of spinal cord ischemia. Arterial monitoring, when necessary, is achieved via the right arm. Adequate venous access can consist of either large-bore peripheral intravenous lines (IVs) or a central line. There is usually not a need for autotransfusion or cell saver setups unless an iliac or axillary conduit is planned where there is more potential for early blood loss during the procedure.

Positioning

- The hybrid room can be set up as either "head" position (**FIG 4**) or "right side, table rotated" depending on the type of imaging equipment. With the right arm tucked, the left arm is prepped circumferentially and placed on an armboard at about 75 to 90 degrees while the chest and abdomen down to the groins are prepped. Surgeon A, who will stand at the patient's right hip, has control of the C-arm and imaging functions and is in charge of obtaining femoral access and delivery of devices from the groins. Surgeon B stands above the outstretched left arm, with an additional sterile table extending off the left hand to allow for wires and catheters to remain sterile and available for arm access during the procedure. The monitor is placed at a slight angle toward the foot of the bed to allow both surgeons to visualize, or a slave monitor can be employed.

FIG 4 ● Endovascular suite setup for snorkel/chimney EVAR with left arm prepped and outstretched, C-arm at right-sided/table rotated position to allow for lateral imaging, and monitors at foot of bed. Surgeon A stands at patient's right hip and controls C-arm. Surgeon B stands above patient's left arm to deliver wires and catheters from side table.

SNORKEL/CHIMNEY ENDOVASCULAR ANEURYSM REPAIR

Arm Access

- A 5-cm transverse incision slightly below the left axilla over the palpable brachial pulse affords several centimeters of longitudinal exposure of the high brachial artery (FIG 5A). Staying proximal to the deep brachial artery takeoff allows a large enough caliber of brachial artery for typical delivery of two 7-Fr sheaths for a double renal snorkel procedure. At least 7 to 8 cm of healthy brachial artery should be dissected free and slung with vessel loops to allow accurate puncture of the vessel. The two punctures should be placed at least 2 cm apart, and not next to each other, to facilitate later simpler, individual primary closure.
- For cases when larger delivery sheaths may need to be inserted or in cases where potentially up to three or four snorkel stents need delivery, then an infraclavicular incision and exposure of the axillary artery for possible 10-mm Dacron conduit placement is recommended (FIG 5B). When this is planned, a 20-Fr or 22-Fr sheath can be inserted to get around the arch and then three 6-Fr or 7-Fr sheaths can be used to cannulate the visceral vessels.
- For the simplest of all snorkel cases, when just one renal artery needs stenting, a lower brachial incision can be made to allow insertion of a single 7-Fr sheath (FIG 5C).

Renal/Visceral Cannulation and Sheath Advancement

- A 5-Fr micropuncture access is obtained under direct visualization into the brachial artery. A Bentson wire is advanced, under fluoroscopic guidance, most often into the ascending aorta. The use of an Omniflush catheter and glidewire (either a 260-cm Rosen or Amplatz [Cook Medical, Bloomington, IN]) combination, to direct the wire toward the visceral aorta, allows a wire exchange for a stiffer platform. Over this stiffer platform, two 7-Fr 90-cm Pinnacle Destination sheaths (Terumo Medical, Somerset, NJ) are positioned near the visceral target branches to facilitate cannulation attempts (FIG 6A).
- Through the 7-Fr sheaths, the targeted renal and visceral branches are cannulated using 260-cm–length hydrophilic guidewires and a 125-cm JB1 catheter (Cook Medical, Bloomington, IN). An angiographic run can be performed from a flush catheter advanced from femoral access to aid in renal cannulation (FIG 6B). Thorough knowledge of the preoperative anatomy, derived from reformatting from the 3-D workstation facilitates

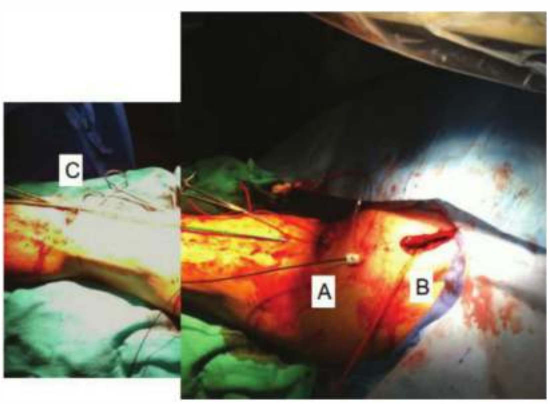

FIG 5 ● **A.** Skin incision via a high brachial incision near the axilla exposes the proximal brachial artery, often giving adequate size for double puncture. **B.** Infraclavicular incision to expose the axillary artery necessary when three or four snorkel/chimney sheaths needed. A 10-mm or 12-mm Dacron conduit can be sewn into the axillary artery in this position. **C.** Small incision over palpable brachial artery near antecubital crease can be used when only single snorkel/chimney sheath necessary.

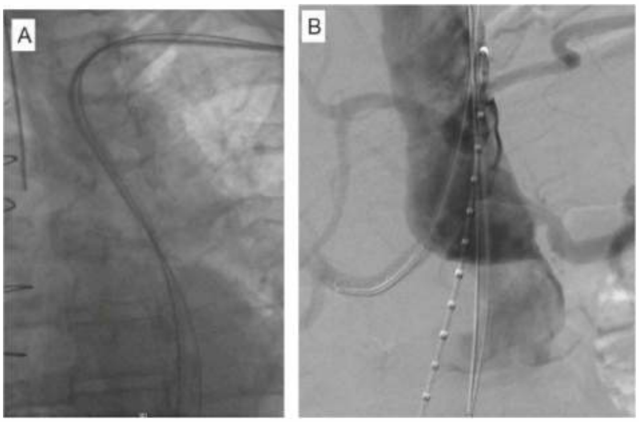

FIG 6 ● **A.** Two 7-Fr Terumo sheaths placed from arm access down descending thoracic aorta ready to be positioned near visceral aortic region. **B.** Right renal artery cannulated with glidewire and JB1 catheter. Omniflush catheter from below reveals in an angiogram the position of the left renal artery to be cannulated next.

this portion of the procedure, guiding optimal angulation of the C-arm.

- Once cannulated, the sheaths are advanced coaxially into the target artery orifice. When necessary, or in cases where there is a slight turn to the horizontal rather than downward angled, the soft hydrophilic guidewire needs to be exchanged for a 260-cm J-tip Rosen wire (Cook Medical, Bloomington, IN) or Amplatz Superstiff (1-cm tip) to facilitate sheath advancement into the target renal artery. Confirmation angiography, through the sheath, is performed to ensure patency of the renal arteries, cannulation of the main renal artery, and avoidance of accidental side branch cannulation.

Positioning of Main Body Endograft and Snorkel Stent Grafts

- Standard femoral access for EVAR is employed for snorkel technique. This is well described in other chapters. Briefly, a small transverse incision, below the inguinal ligament, can be used to expose the common femoral artery to the bifurcation for delivery of endograft components. The percutaneous approach involves the "preclose" technique and employs two Perclose ProGlide devices (Abbott Vascular, Santa Clara, CA) oriented at 10 o'clock and 2 o'clock positions.[10]
- The main body endograft can then be delivered up the chosen femoral side to the paravisceral aorta at the same time as the iCAST (Atrium Medical, Hudson, NJ) or Viabahn (Gore Medical, Flagstaff, AZ) stents are advanced through the snorkel sheaths out to the target renal arteries (**FIG 7A**). The typical length of the iCAST is 59 mm, with the diameter sized appropriately to seal in the target renal artery, most often 5, 6, or 7 mm. For Viabahn stents, similar diameters are used in 50- or 100-mm lengths as appropriate. To prevent theoretical compression of the Viabahn stent by the main body of the endograft, the Viabahn can be reinforced from the inside with a bare-metal, balloon-expandable stent along the areas of overlap with the main body. The positioning of the snorkel stent requires that at least 10 mm of fixation into the renal artery be present and that the proximal extent of the graft is above the fabric of the main body endograft.
- In a lateral projection angiography, the superior mesenteric artery (SMA) is visualized (when performing the typical double renal snorkel) and the main body fabric edge placed immediately below the origin of the SMA (**FIG 7B**).

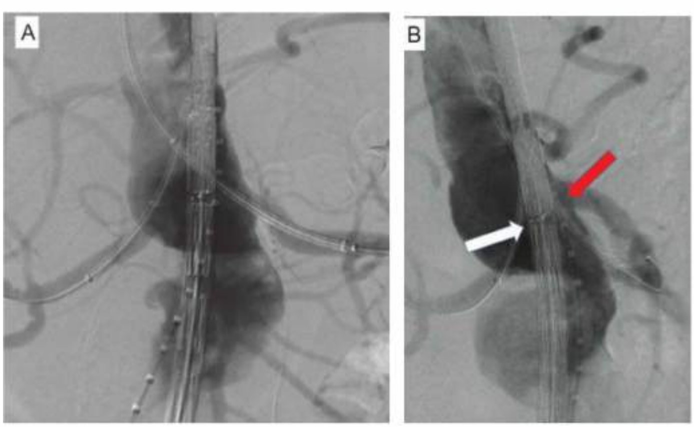

FIG 7 ● **A.** In the anterior-posterior view, both snorkel iCAST stents in position from arm approach along with main body endograft being put into position. **B.** Lateral view angiogram shows takeoff of SMA *(red arrow)* and positioning of the main body endograft fabric edge *(white arrow)* immediately below SMA.

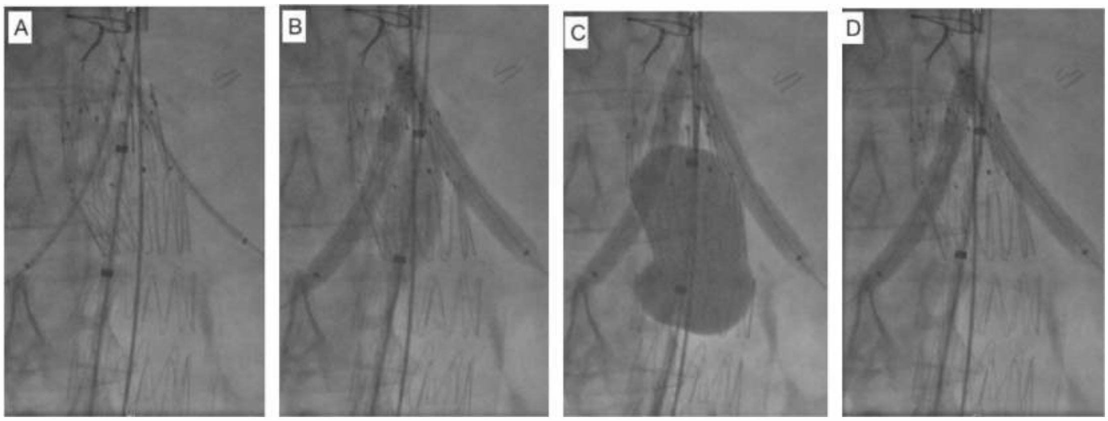

FIG 8 ● **A.** Main body endograft deployed in anteroposterior (AP) view with snorkel stents in position. **B.** After cannulation of contralateral gate and advancement of proximal molding balloon into aortic stent, the two snorkel stents are fully inflated. **C.** The molding balloon is then maximally inflated to profile and to minimize gutters. **D.** The molding balloon is completely deflated prior to snorkel stent balloon deflation.

- At this point, final small adjustments can be made as well as further angiography to ensure that the snorkel stents are in good position. To avoid the issue of the iCAST stent being unstable off its balloon, we often leave the 7-Fr sheaths in place to protect them until final deployment.

Sequence of Stent Graft Deployment and Balloon Molding

- The main body endograft is deployed at the target location with its fabric edge being immediately below the SMA edge (**FIG 8A**). Depending on the endograft system used, deployment proceeds down to the contralateral gate opening. From the contralateral femoral access, cannulation of the gate is confirmed and a noncompliant molding balloon (32- or 40-mm Coda balloon; Cook Medical, Bloomington, IN) is placed up to the level of the renal vessels.
- The 7-Fr sheaths are slowly withdrawn from the brachial approach so the tip is just proximal to the edge of the renal snorkel stents and deployment of the iCAST occurs, most often simultaneously and to a nominal pressure of eight atmospheres (**FIG 8B**). At the same time that the iCAST stents are being deployed by balloon inflation, slower inflation of the Coda occurs to slowly mold the main body fabric around the snorkel stents to minimize gutter formation.
- Only when the renal snorkel stents are maximally inflated can the Coda balloon go up to full main body endograft diameter (**FIG 8C**). This step cannot be overemphasized, as deflation of the snorkel stents while the Coda is inflated is likely to crush the balloon-expandable covered stents.
- With the renal snorkel stents still maximally inflated, the Coda balloon can finally be let down after a few seconds of balloon molding to complete the sequence (**FIG 8D**). After the proximal molding balloon is completely deflated, the renal snorkel balloons are deflated to allow perfusion of the kidneys.

Completion of Distal Components

- Prior to losing wire access to the renal vessels, a proximal aortogram is performed to look for a large type I endoleak or poor perfusion of either targeted kidney. If this is satisfactory, the distal components of the endograft can be advanced and deployed in the usual fashion.
- Repair of the access sites, particularly the brachial site, requires careful interrupted 6-0 or 7-0 Prolene sutures, and adequate hand and foot perfusion is verified prior to completion of the case.
- Postoperative CTA demonstrates the typical appearance of the snorkel stents adjacent to the main body endograft with minimal gutters (**FIG 9A**), and the 3-D reconstruction shows excellent alignment and configuration of the snorkel EVAR components (**FIG 9B**).

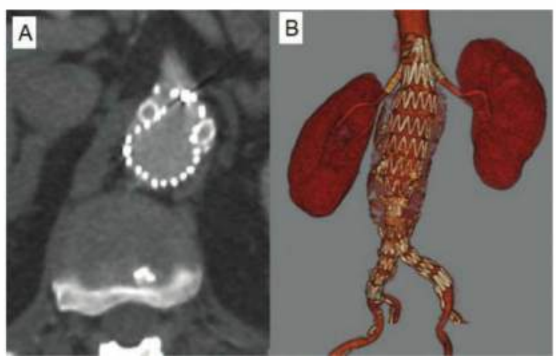

FIG 9 ● **A.** Postoperative CTA axial view showing molding of main body endograft around two widely patent snorkel stents. **B.** 3-D reconstruction demonstrating excellent perfusion of both kidneys and no evidence of endoleak.

PERISCOPE ENDOVASCULAR ANEURYSM REPAIR/THORACIC ENDOVASCULAR AORTIC REPAIR

Femoral Access for Introduction of Main Body Endograft

- Periscope EVAR/thoracic endovascular aortic repair (TEVAR) builds on the concept above of parallel endografts but places the visceral stents from a femoral approach, requiring blood flow to go through the main body stent graft, then turn around and return cranially to the visceral or renal vessel.[11]
- The femoral access for periscope, in contradistinction to snorkel/chimney strategies, often involves the use of larger caliber thoracic or fenestrated main body components (often 22 Fr to 26 Fr), leading to a slightly higher usage of open or endovascular iliac conduits.
- One useful modification to an iliac conduit that can be helpful in delivering and torquing large-caliber main body components or sheaths during periscope EVAR/TEVAR involves creating a patch at the distal end (**FIG 10**). This patch region is created by cutting a 10- or 12-mm Dacron graft along its long access, creating a sewing patch that enlarges the transition from graft to vessel, and not limiting the flexibility of the branch to the initial angle it is sewn into.

Contralateral Access and Cannulation of Target Visceral Branch(es)

- After the femoral access side has been chosen and prepared for main body endograft delivery, the contralateral femoral site is used to cannulate the planned visceral or renal branches from the bottom. In the periscope configuration, the parallel stent graft is often required to make a U-turn, so the more flexible covered stent, the self-expanding Viabahn (Gore Medical, Flagstaff, AZ), is preferred. This requires larger sheath access (up to 12 Fr) than the iCAST described earlier; however, for a double periscope configuration, a larger 20-Fr or 22-Fr sheath is usually necessary to perform multiple punctures into (**FIG 11**).
- The typical periscope EVAR/TEVAR involves the need for a distal landing zone (**FIG 12**). In this particular case, the celiac and one renal artery were already occluded, so the periscope technique was used to revascularize the SMA and remaining renal artery, with an 11-mm Viabahn in the SMA requiring a 12-Fr sheath *(blue arrow)* and an 8-mm Viabahn as the renal periscope requiring an 8-Fr sheath *(orange arrow)* (**FIG 13**).

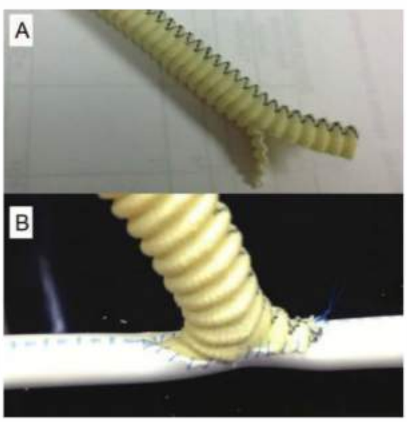

FIG 10 ● **A.** 10-mm Dacron conduit bisected longitudinally to create a sewing patch. **B.** Dacron iliac conduit sewn to native iliac artery allows easy mobility of the conduit at multiple angles of entry for large-caliber device or sheath. (From Lee JT, Lee GK, Chandra V, et al. Comparison of fenestrated endografts and the snorkel/chimney technique [published online ahead of print April 27, 2014]. *J Vasc Surg.* doi:10.1016/j.jvs.2014.03.255.)

FIG 11 ● 22-Fr sheath with multiple punctures allows three separate 6-Fr sheaths to be inserted without leakage.

Sheath Advancement and Periscope Stent Graft Positioning

- Similar to the snorkel/chimney EVAR procedure earlier, the general principles of advancing the sheath into the target visceral vessel are repeated, but in periscope EVAR/TEVAR, all is performed from the femoral approach. The SMA and renal periscopes are positioned several centimeters into the target vessel origin, with the distal end *(blue arrow)* below the bottom end of the main body stent graft *(white arrow)* (**FIG 14**).

Sequence of Deployment and Balloon Molding

- The main body endograft is deployed with the periscope sheaths still in position (**FIG 15A**). The sheaths are then slowly withdrawn to allow the periscope stent grafts (Viabahns) to deploy against the main body endograft (**FIG 15B**). Because there is often some compression of the self-expanding periscope stents, an additional balloon-expandable bare stent is placed along where there is contact with the main body endograft and a similar sequence as earlier of balloon molding is performed to minimize gutter formation (**FIG 16**).
- The remainder of the proximal aspect of the aneurysm is visualized and appropriately stent grafted with proximal extensions and ballooned (**FIG 17**), and postoperative CT-A confirms aneurysm exclusion with wide patency of the periscope stent grafts and normal target vessel perfusion (**FIG 18**).

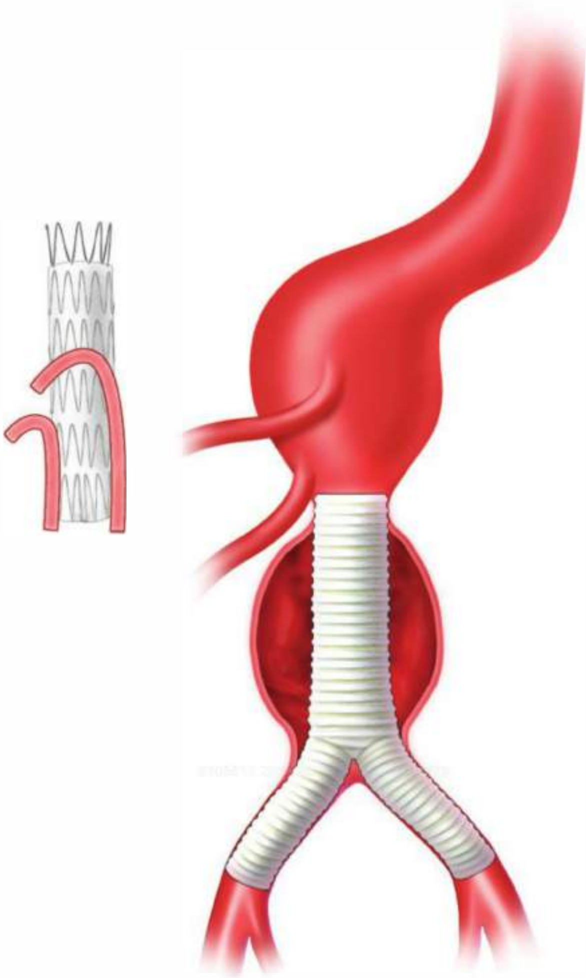

FIG 12 ● Thoracoabdominal aneurysm formed above prior open repair with occluded right renal and celiac arteries. Periscope configuration to keep SMA and right renal artery perfused.

FIG 13 ● 22-Fr sheath *(white arrow)* houses 12-Fr periscope sheath *(blue arrow)* into SMA as well as 8-Fr sheath *(orange arrow)* positioned to try to cannulate renal artery.

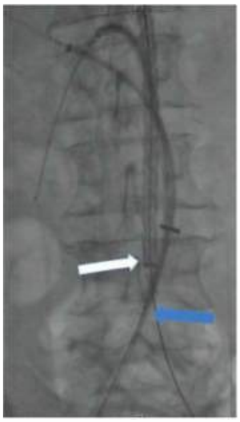

FIG 14 ● Bottom of both periscope stents (SMA and right renal) are at *blue arrow* position and therefore lower than bottom of planned distal component of main body endograft *(white arrow)*.

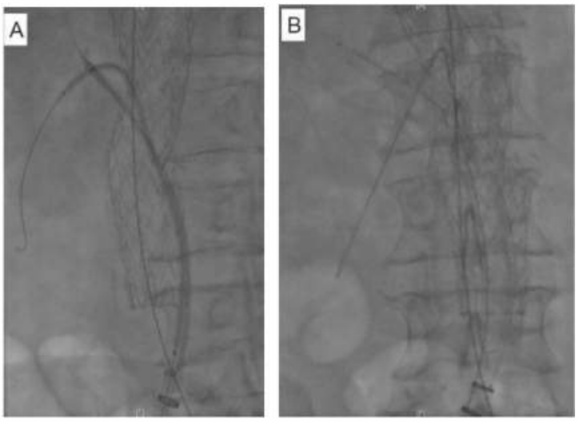

FIG 15 ● **A.** Main body endograft deployed while periscope sheaths still in place. **B.** After withdrawal of sheaths, periscope stents (Viabahns) are deployed.

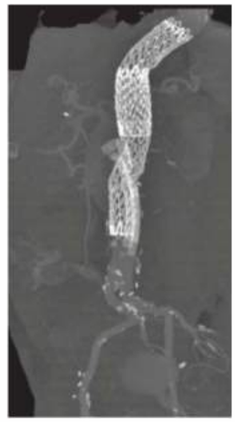

FIG 18 ● Completion CTA showing exclusion of aneurysm and periscope stents in excellent position, perfusing SMA and right renal artery.

PEARLS AND PITFALLS

Indications	■ Follow general recommendations for elective repair of abdominal aortic aneurysms (AAAs) and consider raising criteria when applying complex snorkel/chimney/periscope procedures to these often compromised patients. ■ Most of these procedures use approved devices in an off-label manner so informed consent to discuss all available options is important.
Preoperative workup	■ High-quality imaging and the ability to manipulate images on a 3-D workstation are mandatory for successful preoperative planning and device choices. ■ Adequate preoperative and perioperative hydration is important, given the amount of renal artery manipulation that occurs during these cases.
Patient setup	■ The advanced imaging afforded by a dedicated hybrid endovascular suite allows improved visualization during these very technically demanding procedures. ■ A well-trained staff and two-surgeon approach are important to ensure safe delivery of endograft components from both the femoral and brachial positions.
Arm access	■ Two 7-Fr sheaths can be placed in the high brachial position from a transverse incision, and the puncture sites need to be at least 2 to 3 cm away from each other to allow safe and independent arteriotomy closure.
Renal cannulations	■ A coaxial system with sheath and covered stent into the target renal or visceral vessel from the brachial approach optimizes safe and accurate deployment of snorkel stents. ■ Careful wire manipulation in distal renal and using less stiff wires with J-tips, if possible, minimizes likelihood of renal parenchymal injury and theoretical possibility of renal microemboli.
Balloon molding sequence	■ Careful attention to sequence of snorkel/chimney/periscope balloon sequence minimizes gutter formation, promotes good neck apposition, and prevents compression of vital visceral and renal branches.

POSTOPERATIVE CARE

- At the conclusion of the procedure, patients are usually extubated, observed for 2 to 3 days in a monitored setting (in the intensive care unit overnight if lumbar drain present), and discharged home when ambulating, tolerating a normal diet, and with stable renal function. Clopidogrel and aspirin are given if the patients are not already taking these medications for at least 6 weeks postoperatively.

OUTCOMES

- Multiple reviews of the worldwide experience with snorkel/chimney and periscope techniques continue to find it to be technically successful with target revascularization rates in the 95% to 100%, mortality in the 2% to 5% range, morbidity up to 10%, and midterm renal and branch patency rates of 92% to 96%.[12,13]
- Rupture-free survival after snorkel/chimney or periscope EVAR is excellent in the small amount of literature published

on this new approach but will be important to observe in the mid- and long-term to ensure that this technique is durable as a strategy for endovascular repair of complex aneurysms.

COMPLICATIONS

- Perioperative complications related to complex EVAR in general include cardiac ischemia, arrhythmias or exacerbation of heart failure, groin wound seroma and infection, early thrombosis of endograft components, and bleeding issues related to access site. Reported rates of these issues are not particularly different than the wealth of literature for routine EVAR.
- Particular to snorkel/chimney techniques involve the use of the arm access, which has the potential of leading to arm ischemia, nerve injury/irritation of the brachial plexus, and axillary seromas.
- Wire and catheter manipulation and poor wire hygiene can lead to inadvertent renal parenchymal injury that can lead to hematomas and excessive bleeding requiring transfusion. The rate of renal function decline is certainly more than in standard EVAR, although we do not believe it to be worse than open suprarenal surgery, fenestrated, or branched devices.
- Right arm access for multiple snorkel/chimney stents has been reported to lead to higher rates of cerebrovascular complications.[1,8] This is likely due to moderate amounts of time that sheaths are across the aortic arch and the possibility of thrombus formation that can lead to cerebral emboli.
- Gutter leaks are a unique consequence of the parallel stent graft strategy and are poorly understood. Some general guidelines involve placing as long of stents as possible in parallel configuration to force gutter leaks to thrombose, and careful long-term imaging follow-up to ensure that the aneurysm is excluded.

Chapter **18**

Branched and Fenestrated Endovascular Stent Graft Techniques

Gustavo S. Oderich   Karina S. Kanamori

- Anatomic constraints for endovascular management of abdominal aortic aneurysms include the presence of short or angulated surgical necks and aneurysmal degeneration of the origins of the visceral arteries. Fenestrated and branched endografts were introduced to enable minimally invasive repair of complex juxta- and suprarenal aortic aneurysms.[1] These devices incorporate reinforced fenestrations or directional branches, permitting incorporation of visceral artery origins into the proximal endograft seal zone without compromising end-organ perfusion or aneurysm exclusion.[2] This chapter summarizes the technical features of endovascular aneurysm repair using fenestrated and branched stent grafts for pararenal and thoracoabdominal aortic aneurysms.

DEFINITION

- The term *fenestrated repair* refers to deployment of an endograft featuring custom orifices created and reinforced at precise locations around the aortic perimeter to enable branch artery access, cannulation, and placement of a bridging stent graft in the course of aneurysm exclusion. Fenestration sites are created from patient-specific cross-sectional image data to enable exclusion of aneurysms with short or angled infrarenal necks. In most circumstances, the target arteries (e.g., renal or mesenteric) must arise from normal aorta to enable fenestrated repair. As a rule, fenestrations must be able to deploy flush with the aortic wall to ensure adequate aneurysm exclusion. "Alignment" stents (covered or uncovered, depending on individual patient circumstance) are deployed as needed to prevent target artery malperfusion as a consequence of misalignment between the fenestration and target artery orifice.
- *Branched repair* refers to endovascular aneurysm exclusion employing covered stents to directly connect the main lumen of the endograft to the target visceral artery. These devices enable repair of aneurysms involving or extending proximal to the origins of the renal or visceral vessels (e.g., type IV thoracoabdominal aortic aneurysms [TAAAs]). Of necessity, some distance must be present between the main body of the endograft at full deployment and the aortic wall at the target visceral artery orifice. Branched stent grafts are currently available in two distinct configurations:
  - *Fenestrated branches* arise from reinforced fenestrations bridged by balloon-expandable covered stents.
  - *Directional or cuffed branch* devices feature appended fabric cuffs, precisely located to enable straight, helical, down- or up-going guidewire egress, target vessel cannulation, and deployment of bridging covered stents. Self-expanding flexible nitinol stents are usually employed for this purpose.

DIFFERENTIAL DIAGNOSIS

- Most aneurysms are degenerative (previously characterized as "atherosclerotic," based on a similar, although not identical, causal risk factor profile).
- Other relevant etiologies include infection (e.g., mycotic aneurysms), inflammation (e.g., inflammatory aneurysm or aortitis), development of penetrating ulcers or asymmetric saccular enlargement, and related aortic pathologies (dissection or intramural hematoma).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients' aneurysms do not prompt symptoms prior to catastrophic rupture and are diagnosed incidentally or during screening. Indications for repair are size greater than 5.5 cm for males and greater than 5 cm for females or enlargement greater than 5 mm in 6 months.[3]
- In approximately 5% to 10% of patients, aneurysms induce periaortic inflammation and resultant retroperitoneal fibrosis involving adjacent structures, including the duodenal and ureters.[4] These patients may present with abdominal or back pain, fatigue, malaise, or low-grade fever even at relatively small diameters. Commonly, these aneurysms also enlarge at accelerated and unpredictable rates. Other uncommon presentations of abdominal aortic aneurysm disease include the presence of distal embolization with "blue toe syndrome," congestive heart failure from aortocaval fistulae, or gastrointestinal bleeding from primary aortoenteric fistulae.
- A comprehensive history should be obtained to fully appreciate the potential natural history of each patient's disease, including a comprehensive assessment of cardiovascular risk factors, current smoking habits, and a family history of aneurysmal disease or connective tissue disorders.
- Evaluation of perioperative clinical risk emphasizes cardiac, pulmonary, and renal functional status and reserve, including baseline laboratory testing, noninvasive cardiac stress testing, pulmonary function assessment, and carotid duplex ultrasonography when indicated.

DIAGNOSTIC IMAGING

- Preprocedural aortic imaging studies provide fundamental and necessary guidance for endovascular repair strategies of all types. Aneurysm morphology is best analyzed through acquisition of high-resolution computed tomography angiography (CTA) datasets.[5] CTA with submillimeter slice acquisition is recommended for optimal acquisition, allowing three-dimensional reformatting techniques, maximum intensity projections, and volume rendering.

- Stent grafts are currently custom-made to conform to patient anatomy, based on estimates of longitudinal distance, axial clock position, arc lengths, and angles derived from centerline of flow measurements.
- Anatomic limitations to be considered include difficult iliac access, excessive aortic tortuosity, visceral artery occlusive disease, and anatomic variants including multiple accessory renal arteries or early renal branch bifurcation.

STENT GRAFT DESIGN

- Device planning starts with selection of the proximal landing zone based on "healthy" aorta. The proximal landing zone should include at least a 2-cm length of "normal," noncalcified, parallel aortic wall. The outer-to-outer aortic diameter should be more than 18 mm and less than 32 mm for pararenal aneurysms and more than 18 mm and less than 38 mm for TAAAs.[6] Landing zone diameter should be no larger than the diameter of the next most proximal aortic segment.
- Fenestrated stent grafts are currently manufactured with three fenestration options: small and large circles and more proximal scallops (**FIG 1A**). *Small fenestrations* are 6 × 6 mm or 6 × 8 mm, created without crossing struts and reinforced by circumferential nitinol rings. *Large fenestrations*' diameters are 8, 10, or 12 mm and may incorporate stent struts crossing the edge or middle of the circular defect, limiting space available for alignment stents. *Scallops* are contoured indentations along the upper edge of the main body endograft fabric, 10 mm wide and ranging in height from 6 to 12 mm, depending on individual patient anatomy.[5]
- Device designs vary with aneurysm extent. For pararenal aneurysms, 70% of patients are adequately treated with two small fenestrations for the renal arteries and a scallop for the superior mesenteric artery (SMA).[5] Suprarenal and type IV TAAAs typically require four fenestrations (no scallops). Extensive TAAAs (types I to III) need directional branches, particularly if the aortic diameter is relatively large or aneurysmal at the level of the visceral arteries. The combination of directional branches for celiac and SMA management with fenestrations for the renal arteries is increasingly popular.

SURGICAL MANAGEMENT

Ancillary Tools

- These procedures require advanced endovascular skills and a comprehensive inventory of applicable catheters, balloons, and stents (Table 1). Dedicated training in fenestrated and branched techniques is highly recommended for physicians already experienced in endovascular disease management and ancillary procedures including renal and visceral artery disease management.

Perioperative Measures

- Patients with difficult aneurysm anatomy, chronic kidney disease, or advanced age are preadmitted for bowel preparation and intravenous hydration with bicarbonate infusion. Oral acetylcysteine is administered to minimize risk of periprocedural renal dysfunction following administration of iodinated contrast.
- Hybrid, fixed imaging platforms are essential for optimal results of these complex procedures. Most are performed using general endotracheal anesthesia; local or regional anesthesia may be sufficient in select cases.
- Intraoperative blood salvage systems ("cell saver") are recommended for difficult cases and all TAAAs. The creation of large, impermeable pockets within dependent portions of the surgical drapes will facilitate pooling and collection via the cell saver.

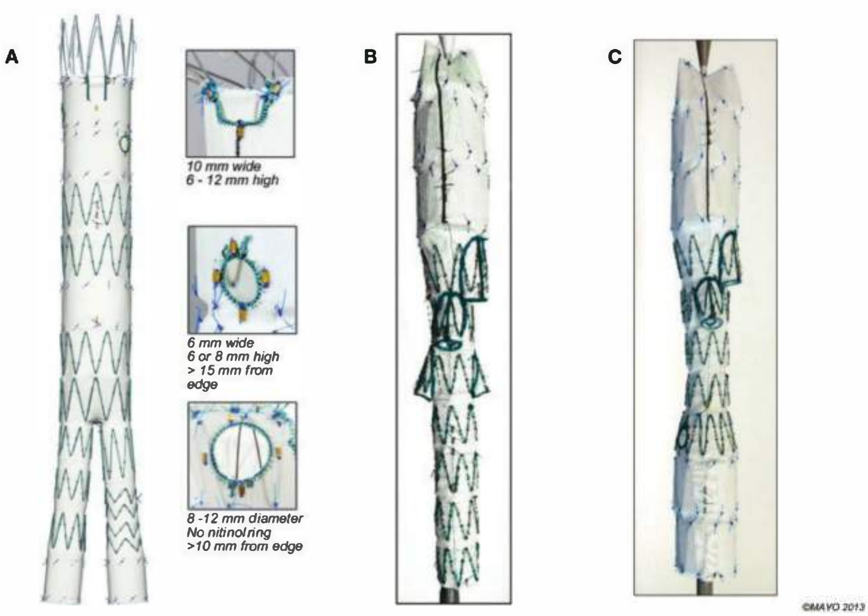

FIG 1 ● **A.** There are three types of fenestrations that can be manufactured: small, large, and scallop fenestrations. The fenestrated stent graft consists of a proximal fenestrated tubular component, a distal bifurcated universal component, and a contralateral iliac limb extension. **B.** The Cook Zenith® stent graft lineage. **C.** Newer design with two straight down-going branches and two fenestrations.

Table 1: List of Ancillary Tools Recommended for Physicians Performing Fenestrated Stent Graft Procedures

Category	Manufacturer	Application
Sheaths		
20- to 24-Fr Check-Flo sheath (30 cm)	Cook Medical, Bloomington, IN	Femoral access for multivessel catheterization
7-Fr Ansel sheath (55 cm, flexible dilator)	Cook Medical, Bloomington, IN	Femoral access for branch artery stenting
7- or 8-Fr Raabe sheath (90 cm long)	Cook Medical, Bloomington, IN	Brachial access for branch artery stenting
12-Fr Ansel sheath (55 cm, flexible dilator)	Cook Medical, Bloomington, IN	Brachial access for tortuous aortic arch to facilitate branch artery stenting
5-Fr Shuttle sheath (90 cm)	Cook Medical, Bloomington, IN	Branch artery access during difficult arch
Catheters		
Kumpe catheter 5 Fr (65 cm)	Multiple	Selective vessel catheterization
Kumpe catheter 5 Fr (100 cm)	Multiple	Selective vessel catheterization
C1 catheter 5 Fr (100 cm)	Multiple	Selective vessel catheterization
MPA catheter 5 Fr (125 cm)	Multiple	Selective vessel catheterization
MPB catheter 5 Fr (100 cm)	Multiple	Selective vessel catheterization
Van Schie 3 catheter 5 Fr (65 cm)	Cook Medical, Bloomington, IN	Selective vessel catheterization
Vertebral catheter 4 Fr (125 cm)	Multiple	Selective vessel catheterization
VS1 catheter 5 Fr (80 cm)	Multiple	Selective vessel catheterization
Simmons I catheter 5 Fr (100 cm)	Multiple	Selective vessel catheterization
Diagnostic flush catheter 5 Fr (100 cm)	Multiple	Diagnostic angiography
Diagnostic pigtail catheter 5 Fr (100 cm)	Multiple	Diagnostic angiography, selective vessel catheterization
Quick-cross catheter 0.014 in to 0.035 in (150 cm)	Spectra-Medics	Selective vessel catheterization
Renegade catheter (150 cm)	Boston Scientific, Minneapolis, MN	Selective vessel catheterization
Guide catheters		
LIMA guide 7 Fr (55 cm)	Cordis Corporation, Bridgewater, NJ	Precatheterization
Internal mammary (IM) guide 7 Fr (100 cm)	Multiple	Selective vessel catheterization
MPA guide 7 Fr (100 cm)	Multiple	Selective vessel catheterization
Balloons		
10-mm × 2-cm angioplasty balloon	Multiple	Proximal stent flare
12-mm × 2-cm angioplasty balloon	Multiple	Proximal stent flare
5-mm × 2-cm angioplasty balloon	Multiple	Advance sheath over balloon
Wires		
Bentson wire 0.035 in (150 cm)	Multiple	Initial access
Soft glidewire 0.035 in (260 cm)	Multiple	Target vessel catheterization
Stiff glidewire 0.035 in (260 cm)	Multiple	Target vessel catheterization
Rosen wire 0.035 in (260 cm)	Multiple	Branch artery stenting
1-cm tip Amplatzer wire 0.035 in (260 cm)	Multiple	Branch artery stenting
Lunderquist wire 0.035 in (260 cm)	Multiple	Aortic stent graft
Glidegold wire 0.018 in (180 cm)	Multiple	Target vessel catherization
Stents		
iCAST stent grafts 5 to 10 mm	Atrium, Hudson, NH	Branch artery stenting
Balloon-expandable stents 0.035 in	Multiple	Branch artery stenting or reinforcement
Self-expandable stents 0.035 in	Multiple	Distal branch artery stenting
Self-expandable stents 0.014 in	Multiple	Distal branch artery stenting

MPA, main pulmonary catheter; VS1, Van Schie 1; LIMA, left internal mammary artery.

- The use of iodinated contrast is minimized by avoidance of power injector digital substraction angiography (DSA) runs during device implantation and side stent placement. Whenever possible, hand injections of dilute contrast (70% saline) are used to locate the side branches. Completion aortography is obtained only after all stents are positioned and postdilated, again using diluted contrast (50%).
- To minimize contrast, precatheterization of targeted visceral arteries or use of onlay computed tomography (CT) images, when available, is recommended. In experienced hands, precatheterization adds little to the overall procedure time.

Positioning

- Patients are positioned supine with the imaging unit oriented from the head of the table. Both arms are tucked for repair of pararenal aneurysms requiring up to three fenestrations.
- Brachial artery access is used in patients treated by directional branches or those who need four fenestrations. The left arm is abducted and prepped in the surgical field up to the axilla. A working sterile side table is oriented in the same axis of the abducted arm for optimal support of necessary wires and catheters.
- Electrocardiogram (EKG) leads, urinary catheter, and other monitoring cables and lines should be taped or secured so that they are not in the path of the x-ray beam of the fluoroscopic unit and do not impede movement of the C-arm gantry.

Arterial Access

- Access is established in the femoral arteries. Patients with small, calcified, or stenotic iliac arteries may require creation of an iliac conduit for safe device delivery.
- Total percutaneous femoral access is the preferred approach in patients with noncalcified arteries or mild posterior plaque. The standard "preclose" technique enables complete hemostasis in more than 95% of patients irrespective of sheath diameter.[7] When femoral arteries are small, calcified,

or bifurcate close to the inguinal ligament, standard surgical exposure and access is obtained. Proximal and distal control is obtained using vessel loops.

- The left brachial artery is surgically exposed via small longitudinal incision in the upper arm, just proximal to the origin of the deep brachial artery.
- Intravenous heparin (80 to 100 units/kg) is administered immediately after femoral and brachial access is established. An activated clotting time longer than 250 seconds is maintained throughout the procedure with frequent rechecks every 30 minutes. Prior to deployment of the stent graft, diuresis is induced with intravenous mannitol and/or furosemide.

ENDOVASCULAR REPAIR USING FENESTRATED STENT GRAFTS

- Fenestrated–branched repair is currently performed using the Cook Zenith® stent graft lineage. Newer designs by Endologix (Ventana), Terumo (Anaconda), and Cook Medical (p-Branch) are under clinical investigation.
- The Cook Zenith® fenestrated stent graft consists of a proximal fenestrated tubular component, a distal bifurcated universal component, and a contralateral iliac limb extension (**FIG 1A**). The fenestrated tubular component is custom-made to fit the patient's anatomy. Four to 6 weeks are required for manufacturing and delivery in the United States.
- Bilateral percutaneous femoral access is established under ultrasound guidance; each femoral puncture is preclosed using two Perclose devices. Bilateral 8-Fr sheaths are introduced to the external iliac arteries over Benson guidewires (Cook Medical, Bloomington, IN). The guidewires are exchanged to 0.035-in soft glidewires and Kumpe catheters, which are advanced to the ascending aorta and exchanged for stiff 0.035-in Lunderquist guidewires (Cook Medical, Bloomington, IN).
- Choice of access site is dependent on tortuosity and vessel diameter. Provided there are no issues with both iliac arteries, the branches are performed via the right femoral approach, whereas the fenestrated and bifurcated devices are introduced via the left femoral approach. A 20-Fr (two fenestrations) or 22-Fr (three fenestrations) Check-Flo sheath (Cook Medical, Bloomington, IN) is introduced via the right femoral approach (**FIG 2A**). The valve of the

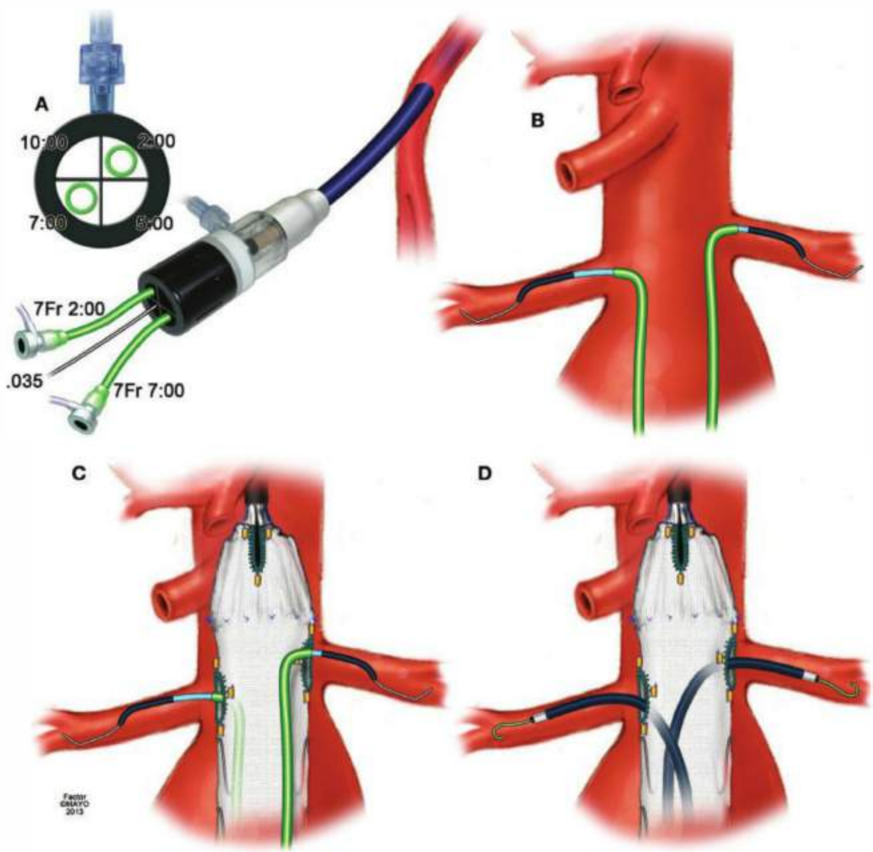

FIG 2 ● **A.** A 20-Fr (two fenestrations) or 22-Fr (three fenestrations) Check-Flo sheath (Cook Medical, Bloomington, IN) is introduced via the right femoral approach. **B.** Precatheterization of the renal arteries. **C.** Sequentially regain access into the fenestrated component, fenestration, and target vessel. **D.** An alignment stent is advanced under protection of the sheath.

Check-Flo sheath has four leaflets, which are accessed by two short 7-Fr sheaths at 2 o'clock and 7 o'clock positions.

- Precatheterization of the renal arteries is performed using 0.035-in soft glidewires and 5-Fr Kumpe or C1 catheters (Cook Medical, Bloomington, IN), which are supported by 7-Fr left internal mammary artery (LIMA) guide catheters (**FIG 2B**). Alternatively, onlay fusion CTA is recommended to minimize contrast use.
- Once the target vessels are catheterized, the fenestrated stent graft is oriented extracorporeally, introduced via the left femoral approach, and deployed with optimal apposition between the fenestrations and the target catheters.
- Proper device orientation, using the anterior and posterior markers, is essential. It is useful to deploy the first two or three stents and then rotate the imaging unit laterally, confirming alignment between the catheter and its respective fenestration. The device should be deployed slightly higher than what is anticipated, with the catheter matching the lowest of the four radiopaque markers in the fenestration. The diameter-reducing wire on the fenestrated component allows for some rotational and cranial–caudal movement to optimize alignment following initial deployment.
- After deployment of the fenestrated component, each catheter is removed from its target artery and used to sequentially regain target vessel access through the respective fenestration. (**FIG 2C**). In most cases, when alignment is carefully confirmed prior to attempted cannulation, the target vessel is accessed without difficulty.
- After the target vessel is catheterized, soft glidewire is removed and hand injection is used to confirm location. The glidewire is exchanged for a 0.035-in Rosen guidewire (Cook Medical, Bloomington, IN). The Rosen guidewire has a floppy J tip, reducing the risk of branch renal artery perforations. When additional support is required, the Amplatz guidewire (Cook Medical, Bloomington, IN) with 1-cm soft tip can be used.
- After the Rosen or stiff guidewire of choice is positioned, a 7-Fr Ansel sheath with flexible dilator is advanced. If there is difficulty to advance the sheath, an undersized balloon may be used as a dilator to facilitate advancement.
- Once the sheath is in position, an alignment stent is positioned under protection of the sheath with the tip of the stent just beyond the tip of the sheath (**FIG 2D**).
- For repairs requiring two or three vessel fenestrations, the target vessels are accessed sequentially using femoral approach. For those requiring four fenestrations, the celiac axis is accessed via brachial approach using a preloaded catheter, which is placed through the celiac fenestration and exits the stent graft via an access scallop at the top of the device.
- The diameter-reducing tie on the fenestrated segment is removed after all the target arteries are accessed and secured by 7-Fr hydrophilic sheaths.
- The top cap of the device is advanced forward to deploy the uncovered fixation stent (**FIG 3A**). The top cap is retrieved prior to deployment of the alignment stents.
- After the top cap and dilator are removed, the proximal landing zone is gently dilated using a compliable balloon such as the Coda balloon (Cook Medical, Bloomington IN, **FIG 3B**). It is critical that the balloon dilatation is performed prior to placement of alignment stents, or alternatively, each stent has to be protected by separate balloons.
- The alignment stents are sequentially deployed following removal of the diameter-reducing tie, retrieval of the top cap, and balloon dilatation of the neck. **The sequence of stent deployment is renal arteries followed by SMA and celiac axis.** Prior to each stent deployment, the position of the stent is confirmed by hand injection. The stent is deployed 3 to 5 mm into the aorta (**FIG 3C**) and flared

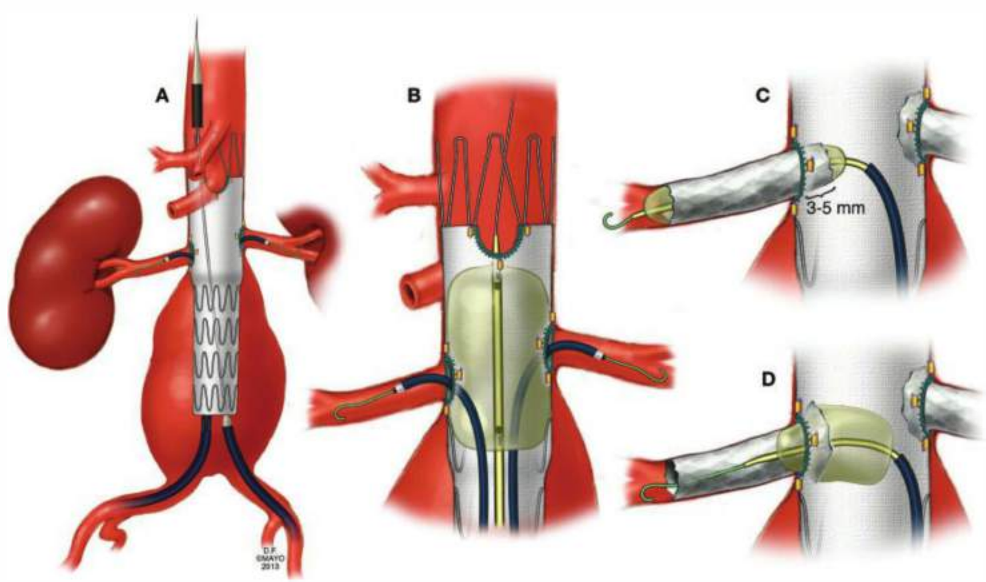

FIG 3 ● **A.** The top cap of the device is advancing forward allowing deployment of the uncovered fixation stent. **B.** The proximal landing zone is gently dilated using a compliable balloon. Stent deployed 3 to 5 mm into the aorta **(C)** and flared using a 10-mm × 2-cm balloon **(D)**.

using a 10-mm × 2-cm balloon (**FIG 3D**). A completion angiography of each branch is performed using hand injection after direct injection of 100 to 200 μg of nitroglycerin to minimize spasm.

- Following placement of the alignment stents, a distal bifurcated stent graft is oriented, advanced, and deployed with preservation of the ipsilateral internal iliac artery. The dilator of the bifurcated device may encroach the contralateral renal stent or the SMA stent. In these cases, it is useful to leave a 10-mm balloon ready to be inflated in the renal stent to prevent damage (**FIG 4A**, *inset*). The minimum overlap between the bifurcated and the fenestrated component is two full-length stents (17 mm each), but ideally, more than three full stents is recommended to minimize risk of component separation (**FIG 4B**).[8] After deployment of the bifurcated device, the dilator is removed with care to avoid damage or dislodgement of the renal stents.
- The contralateral gate is catheterized using a soft glidewire and 5-Fr catheter (**FIG 4B**). Access is confirmed by 360-degree catheter rotation. The glidewire is exchanged for a 0.035-in Lunderquist guidewire. Limited iliac angiography using contralateral oblique views with hand injection. The contralateral limb extension is deployed with preservation of the internal iliac artery (**FIG 4C**).
- A completion angiography of the aorta and iliac arteries is obtained using power injection to demonstrate patency of the visceral arteries, main body, iliac limbs, and iliac arteries.

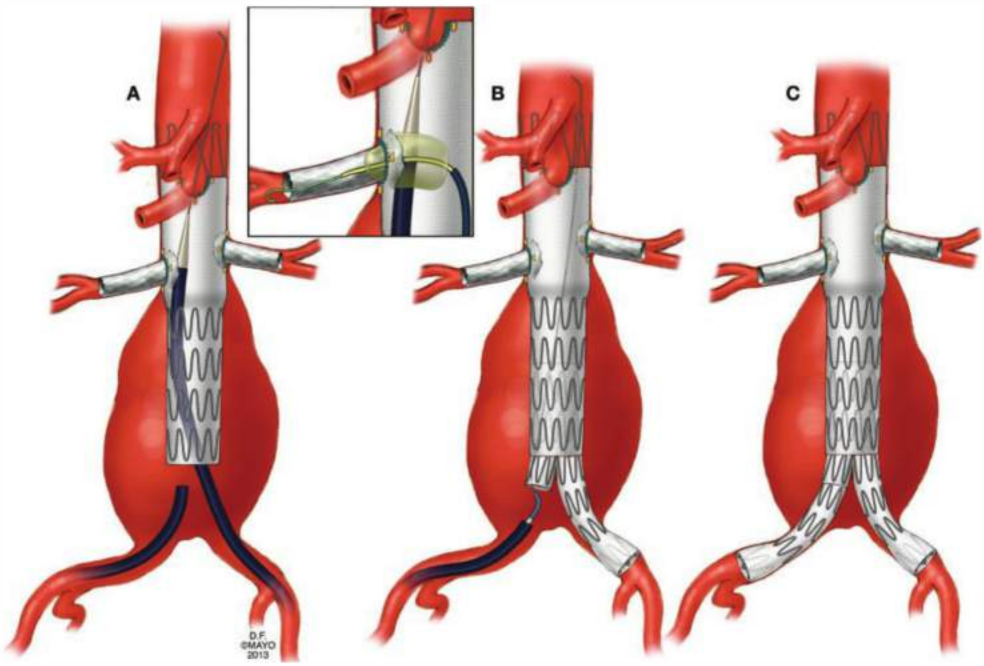

FIG 4 ● To avoid the dilator of the bifurcated device encroaching the contralateral renal stent or the SMA stent, leave a 10-mm balloon ready to be inflated in the renal stent (**A**, *inset*). **B.** The minimum overlap between the bifurcated and the fenestrated component is more than two full-length stents. **C.** The contralateral limb extension is deployed with preservation of the internal iliac artery.

ENDOVASCULAR REPAIR USING MULTIPLE DIRECTIONAL BRANCHES (MULTIBRANCH T-BRANCH STENT GRAFT)

- Directional branches created with presewn cuffs are currently available from Cook Zenith® stent graft lineage on an investigational-use basis (**FIG 1B**). A four-vessel multibranch stent graft design (T branch) is also being investigated for treatment of TAAAs.[9]
- The extent of repair varies depending on the proximal extension of aneurysm within the thoracic aorta. The procedure is performed using bilateral femoral and left brachial approach. In general, the repair starts with deployment of a proximal thoracic TX2 stent graft (Cook Medical, Bloomington, IN) followed by deployment of the T-branch stent graft (Cook Medical, Brisbane, Australia) and distal bifurcated component and contralateral limb extension. The self-expandable stents are placed into the four branches following deployment of all aortic components. The critical steps are reviewed as follows:
    - Bilateral femoral and left brachial arterial access is obtained (**FIG 5A**). A proximal thoracic stent graft is deployed if needed depending on aneurysm extent.

- Precatheterization of the renal arteries is not required, but it is critical that the distal edge of the directional branch is deployed above its intended target vessel. To guide deployment of the T-branch component, the SMA is precatheterized via the brachial approach (**FIG 5B**).
- The T-branch stent graft is oriented extracorporeally, introduced via the femoral approach, and deployed with the directional branches located proximal to its intended target vessel (**FIG 5C**).
- Deployment of the distal universal bifurcated stent graft and contralateral iliac extension are identical

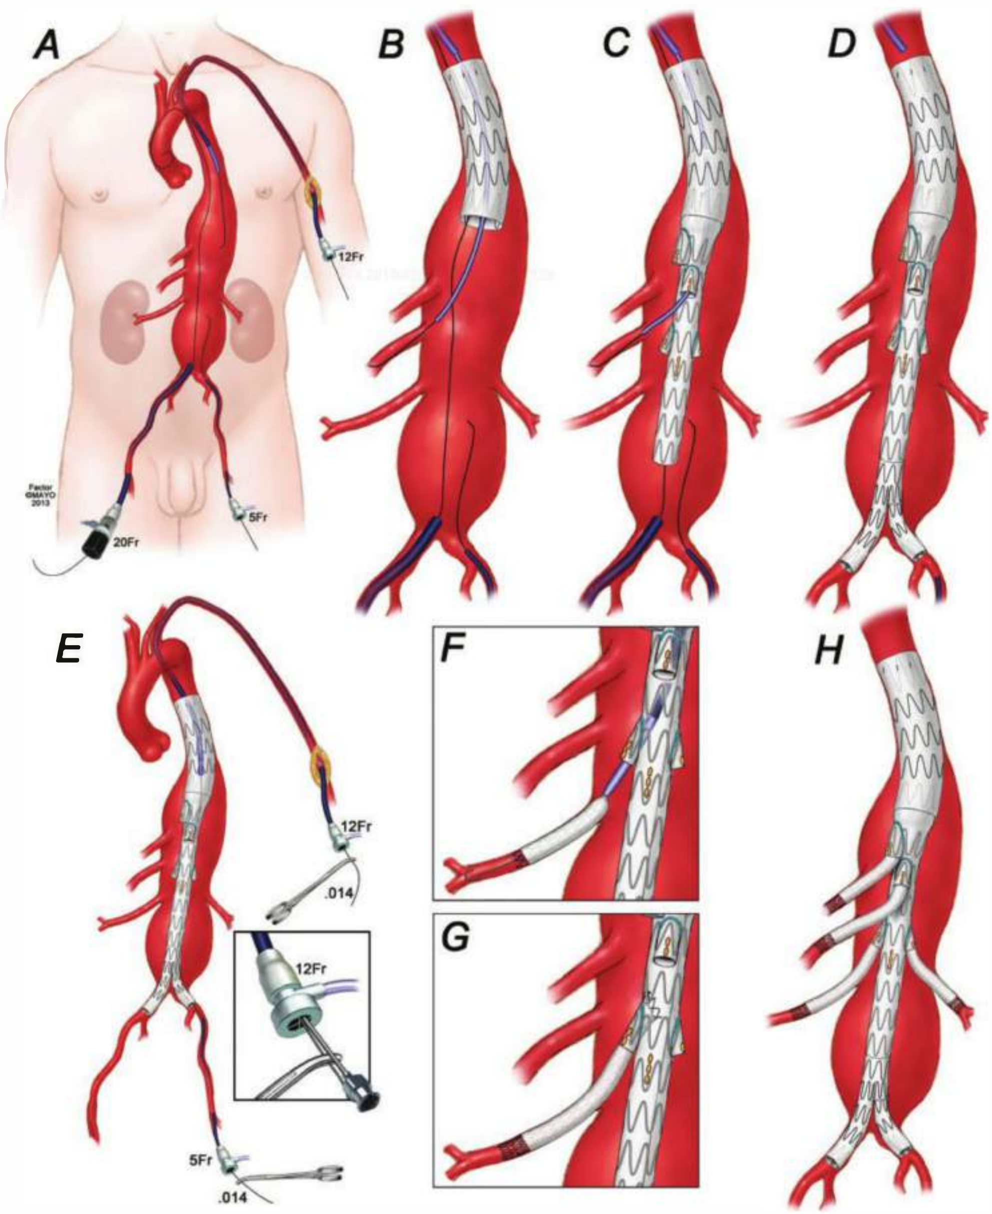

FIG 5 ● **A.** Endovascular repair using multiple directional branches is performed using bilateral femoral and left brachial approach. Deployment of proximal thoracic TX2 stent graft (Cook Medical, Bloomington, IN) **(B)**, followed by deployment of the T-branch stent graft (Cook Medical, Brisbane, Australia) **(C)**, and distal bifurcated component and contralateral limb extension **(D)**. The femoral arteries may be closed, restoring flow into the lower extremities; maintain access into one of the femoral arteries using a 5-Fr sheath (**E**, *inset*). **F,G.** 9-Fr 80-cm flexor sheath (Cook Medical, Bloomington, IN) is advanced into the target vessel, followed by placement of a self-expandable stent graft. **H.** Complete procedure.

to what was described in the fenestrated technique (FIG 5D).

- The femoral arteries are closed at this point, restoring flow into the lower extremities. It is useful to maintain access into one of the femoral arteries with a 5-Fr sheath (FIG 5E, *inset*). This maneuver allows passage of a 0.014-in guidewire from the left brachial artery to femoral artery. The guidewire is clamped in both ends, which locks the 12-Fr sheath in place and provides support for deployment of the side branches.
- The 12-Fr Ansel I sheath (Cook Medical, Bloomington, IN) is advanced via the left brachial approach and positioned inside the T-branch component in the descending thoracic aorta (FIG 5E). At this point, a 0.014-in guidewire is advanced through and through from the left brachial to femoral artery, preventing movement of the 12-Fr sheath in the aortic arch.
- Each side branch is individually catheterized in a sequential fashion, starting with the renal arteries (FIG 5F) followed by the SMA and celiac axis. A 5-Fr main pulmonary artery (MPA) or Kumpe catheter (Cook Medical, Bloomington, IN) is used to access the directional branch and target vessel. Once the vessel is catheterized, the soft glidewire is exchanged for a stiff guidewire (Rosen or short-tip Amplatzer, Cook Medical, Bloomington, IN), which is positioned in the target vessel.
- A 9-Fr 80-cm flexor sheath (Cook Medical, Bloomington, IN) is advanced coaxially within the 12-Fr sheath into the target vessel.
- Each target vessel is stented with a self-expandable stent graft (FIG 5F). The stent graft should be oversized by 1 to 2 mm and should provide at least 2 cm of distal landing zone in the target vessel, extending 3 to 5 mm into the aortic lumen of the T-branch device.
- To prevent kinks in the transition of the stent graft to the target artery, each self-expandable stent graft is reinforced by a second self-expandable uncovered stent, which is deployed 1 cm beyond the distal edge of the stent graft (FIG 5G). Selective completion angiography is obtained for each sequential branch.
- A completion angiography of the arch and thoracoabdominal aorta is obtained after all matting stent grafts are deployed (FIG 5H).

ENDOVASCULAR REPAIR USING TWO DIRECTIONAL BRANCHES AND TWO FENESTRATIONS (TWO BRANCH–TWO FENESTRATED STENT GRAFT)

- A design with directional branches for the celiac and SMA and fenestrations for the renal arteries has been widely used at the Cleveland Clinic.[10] More recently, a newer design with two straight down-going branches and two fenestrations has been used (FIG 1C). The advantage of the latter is the ability to provide short, transversely oriented branches for the renal arteries.
- The same principles already described for fenestrated stent grafts are applied with respect to device design, planning, and arterial access.
- Bilateral femoral access and left brachial artery access is needed (FIG 6A). The right femoral access is used for precatheterization of the renal arteries. The left brachial access is used for the celiac axis and SMA (FIG 6B).
- A proximal thoracic TX2 stent graft (Cook Medical, Bloomington, IN) is deployed first, depending on proximal extension of the aneurysm (FIG 6A).
- After the renal arteries and SMA are precatheterized, the fenestrated–branched stent graft is oriented extracorporeally, introduced via the femoral approach and deployed with perfect apposition between the renal fenestrations and the target renal arteries (FIG 6B).
- The celiac and SMA branch are accessed using preloaded catheters and glidewires, which are snared via the left brachial approach (FIG 6B).
- Each catheter is sequentially removed from the renal arteries and used to regain access into the fenestrated component, renal fenestration, and target renal artery (FIG 6C). Hydrophilic sheaths and alignment renal stents are advanced as previously described.
- The preloaded catheters in the SMA and celiac branch allow advancement of a 0.035-in soft glidewire, which is snared via the left brachial approach (FIG 6B). A sheath and catheter are advanced into the celiac branch. Following access into the celiac axis, a 0.035-in Amplatz guidewire is placed.
- The SMA is accessed using similar steps, and after access is established with Amplatz guidewire, a 9-Fr sheath is advanced to allow positioning of a self-expandable stent graft.
- Once all four vessels are catheterized and sheaths are positioned into the renal arteries and SMA, the diameter-reducing tie is removed, allowing complete expansion of the fenestrated–branched component (FIG 6D).
- Sequential target artery stenting is performed using balloon-expandable covered stents for the renal fenestrated branches (FIG 6E, *inset*) and self-expandable stent grafts for the SMA and celiac axis (FIG 6E, *inset*). Selective branch angiography is performed after each branch stent is placed.
- Deployment of distal bifurcated component and contralateral iliac limb extension is identical to what has been described for fenestrated stent grafts (FIG 6F).

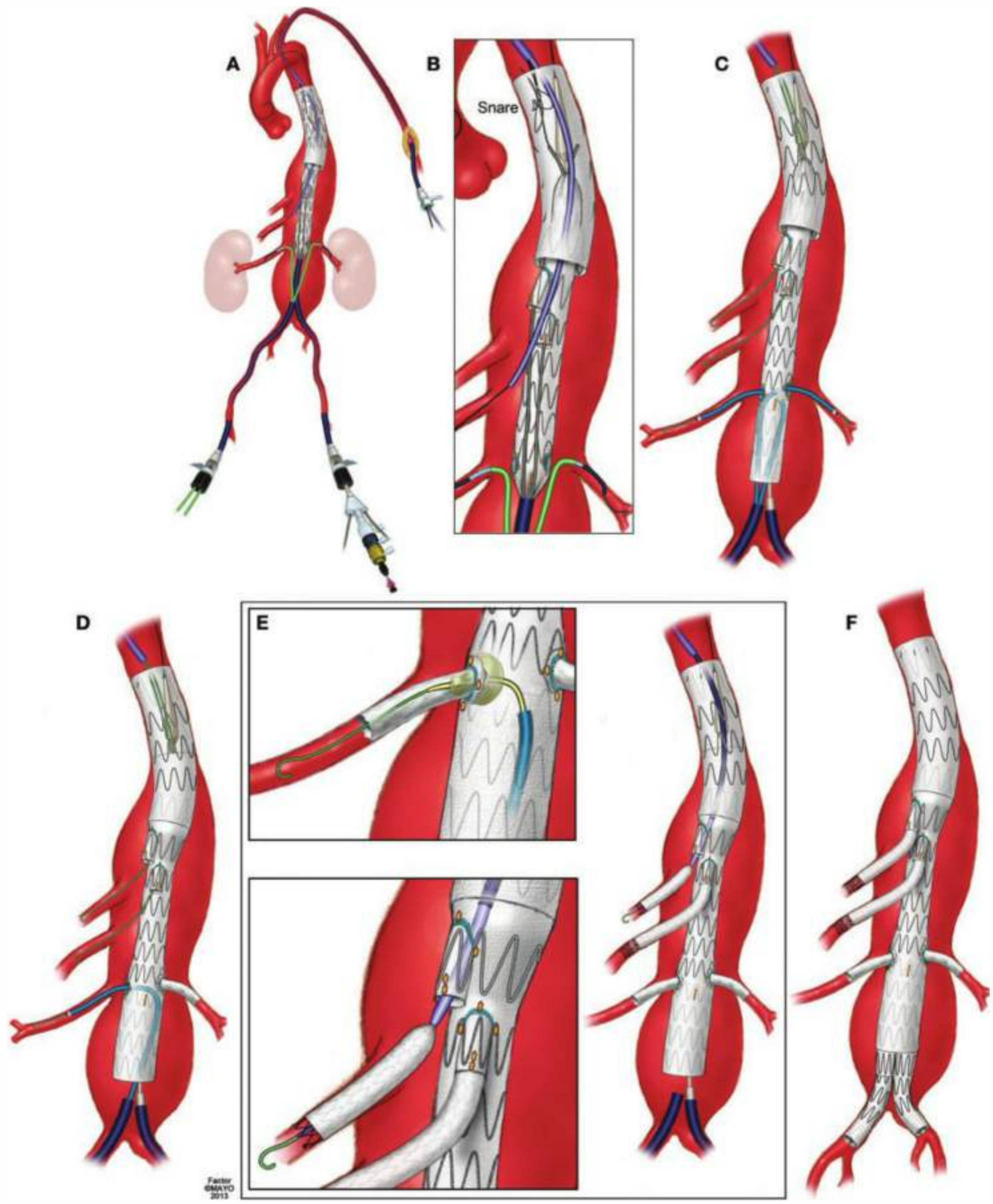

FIG 6 • **A.** Bilateral femoral access and left brachial artery access is needed. **B.** After the renal arteries and SMA are precatheterized, the fenestrated–branched stent graft is oriented extracorporeally, introduced via the femoral approach. The celiac and SMA branch are accessed using preloaded catheters and glidewires, which are snared via the left brachial approach. **C.** Regain access into the fenestrated component, renal fenestration, and target renal artery. **D.** Complete expansion of the fenestrated–branched component. Sequential target artery stenting is performed using balloon-expandable covered stents for the renal fenestrated branches and self-expandable stent grafts for the SMA and celiac axis (**E**, *inset*). **F.** Deployment of distal bifurcated component and contralateral iliac limb extension.

PEARLS AND PITFALLS

Preoperative evaluation	■ Complete history and physical examination with emphasis on cardiovascular risk factors, family history of aneurysm disease, and connective tissue disorders ■ Preoperative medical evaluation focused on cardiac, pulmonary, and renal performance ■ Aortic imaging with computed tomography angiography allows detailed analysis of aneurysm morphology for stent graft design and procedure planning.
Arterial access	■ Iliac conduits are recommended in patients with small, diseased, or excessively tortuous iliac arteries. ■ Pelvic perfusion with maintenance of internal iliac artery flow decreases risk of spinal cord injury.
Stent graft implantation	■ Precise stent graft design and implantation are critical aspects of the procedure. ■ Minimize use of iodinated contrast by avoiding contrast aortography during device implantation. ■ Precatheterization and/or onlay CT allows precise device implantation with minimal need of angiography. ■ Fenestrations are typically accessed via the femoral approach and stented using balloon-expandable covered stents. ■ Directional branches are accessed via the brachial approach and stented using self-expandable stent grafts.
Misaligned fenestrations	■ Excessive tortuosity in the iliac or visceral segment may cause misalignment of fenestrations and difficult target vessel catheterization. ■ Rotation of the device, which is constrained by a diameter-reducing tie, and use of balloon displacement or curved catheters allow successful catheterization in most cases.
Branch perforation or dissection	■ Small, diseased, and tortuous visceral arteries are prone to perforation or dissection, particularly if an Amplatz guidewire is needed to provide more support. ■ Careful attention to detail and minimizing guidewire manipulation with close attention to the tip of the guidewire help prevent this complication.
Stent kinks	■ Branch tortuosity may lead to kinks within the side stents. ■ This should be immediately recognized and treated by placement of a second self-expandable stent to prevent branch occlusion.

POSTOPERATIVE CARE

- Length of stay averages 2 to 3 days for endovascular repair of pararenal aneurysms and 4 to 5 days for TAAAs.
- Cerebrospinal fluid drainage is discontinued on postoperative day 2, after a 6-hour clamp trial and documentation of normal coagulation profile.
- Oral diet is resumed the day after the operation for uncomplicated cases requiring two to three fenestrations, but it is typically withheld for 1 or 2 days for difficult cases or those requiring four fenestrations or branches.
- A CTA and baseline duplex ultrasound of the visceral branches is obtained prior to dismissal. Follow-up includes clinical examination and imaging (CTA and ultrasound) in 6 to 8 weeks, every 6 months during the first year, and yearly 1 year, and early thereafter.
- Patients are started on aspirin indefinitely. Clopidogrel is not recommended unless there is a specific concern with one of the side branches because of small size (<4 mm), occlusive disease, or dissection. Clopidogrel should be avoided early after extensive TAAA repair because of risk of delayed spinal cord injury and paraplegia, which may necessitate replacement of the spinal drain.

OUTCOMES

- Fenestrated and branched stent grafts have been widely applied to treat pararenal and TAAAs. Early mortality rate is dependent on the extent of repair. For pararenal aneurysms, mortality ranges from 0% to 3% in single-center reports[11,12] and averages 1.8% in a systematic review.[13] TAAAs are associated with early mortality of 0% to 9% in single-center reports.[14,15]
- Technical success is high for endovascular repair using fenestrated stent grafts (91% to 100%)[16,17] and branched stent grafts (93% to 100%).[11,18]
- Endoleaks from the attachment sites (type I and type III) are uncommon with fenestrated and branched stent grafts. Type II endoleak is the most common type of endoleak and occurs in 0% to 20% of the patients.[19,20]
- Branch vessel patency is excellent with fenestrated branches, averaging 90% to 100%.[15,21] In a recent report by Mastracci and associates,[22] freedom from any branch-related complication (occlusion, kink, reintervention) was 84% at 5 years.

COMPLICATIONS

Intraprocedural Complications

- ***Fenestration misalignment***
  Neck angulation, tortuosity, and errors of design or implantation can lead to misalignment between the fenestration and the target vessel. Several maneuvers can be used to overcome misalignment between the fenestration and the vessel. Initially, the catheter and guidewire are rotated to "probe" the aortic wall in search for the vessel. To maintain access into the fenestration, a 7-Fr Ansel sheath is advanced into the fenestration and secured by a 0.018-in guidewire, whereas a 5-Fr "buddy" catheter (e.g., Van Schie [VS] 3) is used to locate the renal artery. In patients with down-going or stenosed renal arteries, it may be difficult to advance the

catheter over a soft glidewire. The catheter and glidewire may bounce up into the top cap, providing support for the catheter to be advanced deep into the renal artery.

- Diameter-reducing ties are located posteriorly, which may result in the fenestrations being pulled slightly more posterior than its intended location. A useful maneuver is to gently rotate each fenestration, usually anteriorly. Other maneuvers are rarely needed but included use of curved catheters (e.g., VS1 or SOS) for down-going vessels or vessels that are originating from the lower part of the fenestration, microcatheters, and balloon displacement of the main stent graft. The latter is rarely needed but may provide more room for catheter manipulations.
- ***Branch perforation or dissection***
  Branch vessel perforation and/or dissection can be prevented by meticulous technique, visualization of the tip of the wire, and avoiding wire manipulations. The guidewire should not be positioned in small terminal branches, which are prone to perforate or dissect. It should be visualized and stabilized during exchanges manipulations, avoiding forward or retrograde movement. If perforation occurs, it should be immediately recognized and treated using a microcatheter and coil embolization. Dissections within the main renal artery can be treated by placement of a self-expandable stent.
- ***Endoleaks***
  Type II and type IV endoleaks may occur and should be left untreated. Type I and type III endoleaks (<3%) are infrequent with proper selection of a healthy landing zone and adequate planning.[23] In the U.S. fenestrated trial, there were no type I or III endoleaks.[5] In the event of a type Ia endoleak, the proximal neck may be redilated, but all the alignment stents need to be protected by separate balloons. Type III endoleaks may result from inadequate flare, lack of apposition, use of bare metal stent, or inadequate length into the aorta.
- ***Stent kinks or narrowing***
  Kinks are highly preventable and can be anticipated from careful review of vessel anatomy by CTA. These remain a cause of reintervention or branch vessel loss if not recognized. Short stents (<2 cm) tend to avoid bends and the mid- or distal portion of the renal artery, which has greater respiratory motion. The right renal may have a posterior orientation from its course behind the inferior vena cava. If a kink is anticipated by CTA or is evident by completion angiography, a self-expandable stent should be placed. Kinks or narrowing may also result from inadequate flare, strut compression, and ostial disease. In these cases, angioplasty or stenting with a second balloon-expandable stent may be recommended.

Postoperative Complications

- Spinal cord injury
- Stroke
- Cardiac events (myocardial infarction, arrhythmias, congestive heart failure)
- Pulmonary complications (pneumonia, prolonged ventilation, tracheostomy)
- Gastrointestinal complications (ileus, pancreatitis, cholecystitis)
- Systemic inflammatory response (fever, leukocytosis, thrombocytopenia)
- Renal function deterioration
- Access-related problems (bleeding, thrombosis, pseudoaneurysm)

Chapter 19

Stenting, Endografting, and Embolization Techniques: Celiac, Mesenteric, Splenic, Hepatic, and Renal Artery Disease Management

Mohamed A. Zayed   Ronald L. Dalman

DEFINITION

- The content discussed in the following text presupposes familiarity with basic wire and catheter-based endovascular techniques. For a summary of such techniques, the reader may refer to excellent existing references.[1]
- Various occlusive and/or aneurysmal disease processes in renal and visceral arteries may necessitate endovascular interventions (Table 1).
- Progressive renal artery stenosis (RAS) or occlusion may predispose to renovascular hypertension (RVH; most common form of secondary hypertension) and ischemic nephropathy.[2] Aortic atherosclerosis at the ostia or proximal renal artery accounts for two-thirds of cases.[3] Fibromuscular dysplasia (FMD) also causes progressive serial stenoses throughout the renal arteries and may also predispose to RVH. FMD occurs most commonly in younger female patients.[4]
- Acute mesenteric ischemia (AMI) and chronic mesenteric ischemia (CMI) are life threatening but fortunately rare (1 in 1,000 and 1 in 100,000 hospital admissions, respectively) conditions.[5,6] The infrequent nature of symptomatic mesenteric ischemia may be due to the rich collateral supply derived from the celiac, superior, and inferior mesenteric arteries. CMI most commonly develops following progressive atherosclerotic occlusion of two or more mesenteric arteries, with the superior mesenteric artery (SMA) being the most critical of the three. Arterial embolization, leading to acute occlusion of the celiac artery or SMA, more commonly is associated with AMI.[6] In rare circumstances, in critically ill patients, impaired intestinal perfusion due to arterial vasospasm may occur in the absence of thromboembolic occlusion.
- Extra- and intraparenchymal renal artery branch aneurysms occur with a reported autopsy incidence between 0.01% and 0.7% and may arise from various disease etiologies.[7] Overall, the risk of acute clinical evolution (rupture or thrombosis) is low but may be increased during pregnancy, with high resultant maternal and fetal mortality. The risk of progression/rupture, as is the case in most visceral artery aneurysms, is presumed to decline significantly following menopause.
- Aneurysms of the celiac artery, SMA, and their branches are also infrequent and associated with varying etiologic entities. Splenic artery aneurysms are the most common (60%), followed by aneurysms in the hepatic (20%), superior mesenteric, and celiac arteries, in that order.[8,9] Syndromes such as polyarteritis nodosa or Kawasaki's disease may be associated with aneurysms in various segments of the mesenteric arterial circulation. Guidelines for intervention vary, depending on aneurysm location, rate of enlargement, symptom status, and demographic considerations: age, gender, and menstruation status.

Table 1: Renal/Visceral Arterial Disease

Causes of renal/visceral artery stenosis or occlusion	• Atherosclerosis • Fibromuscular dysplasia • Dissection • Coarctation syndromes • Extrinsic compression • Vasculitis • Hypercoagulable state
Causes of renal/visceral artery aneurysm	• Extension of aortic aneurysmal disease • Atherosclerotic degeneration • Blunt or penetrating trauma • Fibromuscular dysplasia • Connective tissue disorder • Iatrogenic injury

PATIENT HISTORY AND PHYSICAL FINDINGS

- RVH, with or without concurrent evidence of ischemic nephropathy, is seen in less than 50% of individuals manifesting severe RAS.[2,3] Hypertension in children, new onset hypertension in individuals younger than 30 or older than 55 years old, or accelerated hypertension should prompt suspicion for the presence of RAS. Older patients with RVH/RAS typically manifest other stigmata of systemic vascular disease, including coronary and cerebrovascular disease, in addition to peripheral vascular disease. In patients with severe bilateral RAS, renal failure may be exacerbated with recent initiation of an angiotensin-converting enzyme (ACE) inhibitor.[10] Acute exacerbations of poorly controlled RVH may manifest with "hypertensive crisis," flash pulmonary edema, or neurologic symptoms ranging from headache to seizure and stroke. Physical examination may reveal severe elevation of both systolic and diastolic blood pressures, abdominal bruits, and other manifestations of peripheral arterial occlusive disease.
- Patients with CMI are typically elderly and have a prior history of symptomatic vascular disease. Like RAS/RVH patients, CMI rarely is present without other signs and symptoms of advanced vascular disease, including aortic and mesenteric branch arterial calcification on plain x-ray films of the abdomen. Symptoms produced by CMI are frequently nonspecific and intermittent, leading to delayed diagnosis and disease progression. Classical symptoms usually include postprandial dull/crampy midepigastric abdominal pain, progressive weight loss, and "food fear" with decreased caloric intake.[11] Findings on physical examination are usually noncontributory, save those related to advanced peripheral

vascular disease (e.g., absent pedal pulses); patients frequently are malnourished and cachectic. Abdominal auscultation frequently reveals hyperactive bowel sounds, and a bruit may sometimes be auscultated.

- AMI presents more dramatically, with sudden onset of abdominal pain, often in patients suffering acute embolic occlusion of the SMA. Although pain may seem out of proportion to objective physical examination findings initially, progressive tenderness to palpation and ultimately peritoneal signs develop in parallel with diminishing bowel viability. Clinical status also rapidly deteriorates, with progressive metabolic acidosis, shock, and multisystem organ failure.[6]
- Patients with renal artery aneurysms (RAAs) may provide a history of trauma, arterial dissection, syndromic vascular conditions, connective tissue disorders, or RAS. The majority of RAAs are asymptomatic at the time of diagnosis, identified as incidental findings on cross-sectional imaging studies ordered for unrelated indications. Specific associated historical and physical findings are rare but may include acute onset hypertension, abdominal distension, flank pain, hematuria, syncope, and shock. Occasionally, an abdominal pulsatile mass is present on physical examination.[7] Although not always fatal, RAA rupture, particularly those in segmental branches, frequently predisposes to renal infarction and resultant decrease in glomerular filtration capacity.
- Patients with aneurysms of the celiac and SMAs and derived branches may manifest with a history of arterial dissection, trauma, pancreatitis, or other local inflammatory processes or infections. One-third of patients may also have aneurysmal disease in other segments of their arterial anatomy.[8] As is the case with RAAs, patients rarely present with symptoms other than rupture, which itself is also rare. Free rupture may result in hemoperitoneum, hematobilia, or life-threatening gastrointestinal hemorrhage. The risk of rupture is highest with hepatic (20% to 44% of mesenteric arterial aneurysm ruptures) and splenic artery aneurysms, the latter notoriously at risk during the third trimester of pregnancy.[12,13] Presence of a splenic artery aneurysm recognized during pregnancy should prompt consideration of immediate repair, regardless of the status of the pregnancy.[14]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Renal artery disease assessment usually begins with duplex ultrasonography, which has a reported sensitivity of 86% to 93%, specificity of 98%, and overall accuracy of 96%.[15] Duplex criteria used to diagnose more than 60% RAS include an arterial peak systolic velocity of more than 180 to 200 cm per second, a ratio of renal artery to aortic peak systolic velocity of more than 3.5, or acceleration time between onset and peak of systole of more than 100 m per second. Kidney length and resistive indexes derived from parenchymal insonation may also provide important insight into the presence, nature, and severity of end-organ disease.
- Similarly, duplex ultrasound provides a useful, noninvasive method of assessing for the presence of chronic mesenteric occlusive disease.[16] In the celiac artery, peak systolic velocities of more than 200 cm per second provides a sensitivity and accuracy for detecting a greater than 70% stenosis of 87% and 82%, respectively. In the SMA, peak systolic velocities of more than 275 cm per second provides a sensitivity and accuracy for detecting a greater than 70% stenosis of 92% and 96%, respectively.
- Computed tomography angiography (CTA) is the current gold standard for confirming the presence, severity, and extent of occlusive mesenteric vascular disease. CTA-derived images also provide insights into the potential underlying mechanism of occlusion, including FMD, associated dissection, evidence of inflammation/infection, or thromboembolic occlusion. Moreover, three-dimensional reconstructions generated from CTA datasets also provide valuable guidance for preprocedural planning. In emergent circumstances, such as those associated with suspected AMI, CTA usually represents the "go-to" diagnostic test.
- For patients with contrast allergies or other contraindications to computed tomography (CT) scanning, magnetic resonance angiography (MRA) may provide a suitable alternative, particularly for initial diagnosis and screening purposes. Overall resolution of MRA is not equal to that of CTA and in some circumstances may not provide sufficient detail for the precise surgical or interventional planning.

SURGICAL MANAGEMENT

Patient Selection

- Appropriate patient selection for endovascular intervention is paramount and dependent on therapeutic indication, anatomy, patient comorbidities, and acuity of the disease process. In the following text, we discuss considerations for patients with renal/mesenteric arterial occlusive disease, followed by considerations for patients with renal/mesenteric arterial aneurysmal disease.
- For RAS, the indication for endovascular intervention is contingent on severity of stenosis, the presence and severity of presumed resulting hypertension, and extent of residual glomerular filtration capacity. For RAS, there is no accepted indication currently for "prophylactic" intervention. Endovascular intervention is considered only in patients with severe hypertension, who have failed medical management with at least three concurrent antihypertensive medications or have demonstrated progressive loss of renal function due to ischemic nephropathy in the setting of more than 60% RAS. The future role for endovascular intervention in treating RVH has been called into question by level I data demonstrating only modest reductions in blood pressure following renal artery stenting.[17]
- Patients with critical stenosis or occlusion of at least two mesenteric arteries, in the setting of signs and symptoms consistent with CMI, are also potential candidates for endovascular management. Patients with atypical symptoms who may meet anatomic criteria for mesenteric occlusive disease often experience disappointing results following endovascular intervention.
- Given the compromises inherent in management of AMI, often in the setting of uncertain bowel viability, hybrid open and endovascular approaches may represent the safest and most expeditious option. Particularly in regard to "acute-on-chronic" occlusion of the proximal SMA, with a patent distal segment preserved by collateral flow, surgical exposure at celiotomy enables distal SMA cannulation and sheath placement. Standard angiographic techniques are

then employed to cross the occlusive proximal lesion in a retrograde fashion, with subsequent angioplasty and stenting performed to restore pulsatile antegrade flow.[18] We have employed this technique reliably under a variety of challenging clinical conditions with consistently good results.

- In patients with disease in multiple mesenteric arterial segments and symptoms concerning for mesenteric ischemia, SMA revascularization, either via endovascular or open surgical approaches, represents the most reliable and effective method for resolving critical mid- and distal gut ischemia. Decompressive laparotomy should always be considered as an essential adjunct in these circumstances, regardless of revascularization method used, to facilitate selective resection of nonviable bowel if needed and limit the noxious effects of abdominal compartment syndrome in these already compromised patients.
- In comparison, the safety and use of primary inferior mesenteric artery (IMA) endovascular intervention remains controversial in patients with disease in multiple mesenteric arteries. Recent series report relatively frequent procedure-related complications and poor outcomes following attempted IMA intervention.[19] These results may in part be due to the progressive nature of occlusive vascular disease in the most distal aortic segment at the level of the IMA and resulting difficulty in resolving significant ostial stenoses with even high-pressure angioplasty techniques.
- The criteria for elective repair of asymptomatic RAAs is controversial. Recommendations vary for intervention based on aneurysm diameter, also taking into account the size of the parent artery, extent of mural calcification, and rate of enlargement, if available. Consensus exists regarding treatment for all aneurysms larger than 3 cm in diameter.[20,21] Similarly, patients with intact but symptomatic true aneurysms, recent-onset false (pseudo-) aneurysms, and aneurysms resulting from associated FMD are also typically repaired promptly, given their presumed higher risk of rupture. RAAs in women of childbearing age with plans for future pregnancies are usually repaired, when recognized, at almost any size. Less agreement is present for RAAs larger than 2 cm but smaller than 3 cm in diameter, with treatment recommendations often customized based on individual circumstances.
- There are no set size criteria for visceral artery aneurysm repair. Although larger aneurysms are thought to have an increased potential risk of rupture, small visceral artery aneurysms are also known to rupture and manifest with life-threatening hemorrhage. Therefore, most visceral aneurysms larger than 2 cm should be repaired when identified. This recommendation does not necessarily apply to poststenotic arterial dilations (not true aneurysms) and distal SMA aneurysms. The latter are generally best managed by embolization and/or resection of the dependent loops of adjacent small intestine. In most circumstances, ruptured visceral artery aneurysms are best managed by open or hybrid approaches, allowing for assessment of bowel or end-organ ischemia in conjunction with restoration of arterial flow.

Preoperative Planning

- Prior to attempted repair or exclusion, aneurysm location and access issues should be precisely determined via cross-sectional imaging studies. Luminal plaque, thrombus burden, associated aneurysms, and preexisting dissections should also be noted. Finally, target vessel diameter should be determined at several intervals before, within, and after the lesion of interest to optimize coil, stent, and graft selection.
- The preferred method of critical renal artery ostial lesion management is by balloon-expandable stent placement. In rare circumstance, angioplasty predilation may be required to advance the appropriate stent through the renal ostia and across the stenotic lesion. Renal artery stents range from 10 to 30 mm in length and 4 to 7 mm in diameter. Transfemoral approaches to the renal artery are generally preferred due to the shorter distance to target, smaller imaging fields, and abundant availability of purpose-specific instrumentation. However, cephalad angulation of the renal artery origins relative to the aorta, the presence of extensive infrarenal aortoiliofemoral arterial occlusive disease, or significant iliac artery tortuosity may favor consideration of the left brachial artery and descending thoracic aorta as the preferred route of access.
- For the treatment of mid- to distal RAS in the setting of FMD, angioplasty alone is generally the preferred treatment modality. Either transfemoral or transbrachial approaches may be considered, depending on the considerations noted earlier. Care must be taken to minimize procedural trauma with precise determination of target artery diameter and selection of appropriately sized instruments (sheaths, balloons, and stents). Poor planning or ill-considered procedural technique may precipitate arterial dissection, thrombosis, and renal infarction.
- Depending on the degree of lesional calcification, the extent of associated juxtaostial aortic occlusive disease, lesion length and associated target vessel tortuosity, balloon- or self-expanding stent grafts may be chosen for luminal reconstitution and may provide improved long-term patency in the proximal SMA.[22] Cannulation of either the celiac or SMA may be achieved from both femoral and brachial approaches. However, in emergent or extenuating circumstances, left brachial access often proves more expeditious and effective. This is particularly true in the setting of high-grade ostial stenosis or occlusion, where brachial access and antegrade aortic sheath placement may provide improved guidewire, sheath, and crossing catheter pushability and trackability.
- Successful wire cannulation of ostial SMA and celiac lesions may require “telescoping” techniques with different sheath and wire combinations (see in the following text). This is also true of attempts to deploy devices in the mid- and distal splenic artery, where a triaxial catheter and sheath combination extending into the target lesion is frequently most effective. Given the short and often tortuous nature of the celiac artery, stable sheath placement is challenging, often representing the most difficult aspect of the procedure.
- Similar principles are used when treating aneurysms of renal and visceral arteries, including precise catheter positioning and stable sheath support. Aneurysm size, location, neck anatomy, and extent of tortuosity of feeding target vessels impact the strategy of repair. For example, for large retropancreatic splenic artery aneurysms, coil embolization of the aneurysm sac (preferably with large-end-first or nesting coils) prior to covered stent placement across the ostium of the aneurysm is necessary to ensure long-term procedural

success. For precise embolization of shallow or wide-necked aneurysms, adjuncts such as distal balloon occlusion with deployment of detachable coils may be necessary. For more accessible aneurysms with a wide-based aneurysm neck, bare metal stenting may be performed across the ostium of the aneurysm first, followed by placement of coils through the open interstices of the stent to keep the coils localized to the area of interest. Branch artery aneurysms usually occur at bifurcation points and are accompanied by small, well-defined necks and are ideally suited for embolization with microcoils (0.018-in catheter compatible) delivered through a triaxial delivery system.

- The preferred size/shape of embolization devices or covered stents may be either accurately estimated from a preprocedural CT arteriogram or determined at the time of angiographic imaging and sheath placement. Based on these measurements, coil and plug diameters may be oversized by 20% of the target vessel diameter. The length of coils selected is derived from the anticipated arterial lumen surface area that requires embolization. Similarly, the length of vascular plugs selected depends on the target artery to be embolized and the estimated luminal flow. For example, higher flow arteries, such as those proximal to arteriovenous fistulae, usually need more extensive coverage to ensure definitive occlusion. Both self-expanding and balloon-expandable stent grafts are available. The former are also typically oversized by 20%, and the latter are usually sized 1 mm greater than the target artery diameter. Attention should be given to the sheath selection to ensure adequate diameter and length. The device-specific instructions for use (IFU) should be consulted in all circumstances prior to use of occlusion devices, or more generally, any endovascular device with the potential risk for significant vascular injury.
- Depending on their specific location, some visceral artery aneurysms may be embolized without specific end-organ ischemic injury. However, embolization of distal aneurysms, such as those located within the splenic hilum, may result in splenic infarction, further bleeding, or abscess formation. Therefore, splenectomy remains a viable alternative method of splenic artery aneurysm management for many patients. Appropriate vaccinations should be administered with sufficient lead time to allow for an appropriate immunization response prior to elective splenic artery embolization procedures or planned splenectomy.

Operating Room Setup

- Procedures may be performed in an angiography suite, or in an operating room, equipped with a floating-point carbon fiber, radiolucent operating table; fluoroscopy platform; and monitor-viewing bank. However, for precise visceral artery interventions requiring steep oblique/lateral imaging and higher fluoroscopic kilovolt (kV), portable systems in the operating room setting may not provide sufficient image clarity and resolution. Under these circumstances, use of a fixed-imaging system, either in an angiography suite or hybrid operating room, will maximize the likelihood of success.
- For the majority of elective renal and visceral artery interventions, conscious sedation with a combination of short-acting analgesic and sedative agents will provide adequate patient comfort, immobility, and optimal imaging parameters. Standard patient safety measures for conscious sedation, including supplemental oxygen, standard monitoring, and availability of resuscitation equipment should be employed in compliance with local hospital policy. However, general anesthesia is clearly indicated to facilitate treatment of AMI, urgent/emergent management of aneurysm rupture, and/or hemorrhage potentially requiring bowel resection or open conversion.
- For the most part, all renal and visceral artery endovascular interventions can be performed with the patient in the supine position. The left arm may be positioned out at 90 degrees to allow for transbrachial interventions. If a transfemoral intervention is planned, the patient's arms may be extended over the head to aid with image clarity; however, most patients can only tolerate this for certain time periods prior to fatigue. Placing the patient in a 30-degree rotation to the right, on bolsters placed behind the left flank, at the time of the procedure, will facilitate "true lateral" position to localize and cannulate the origin of the SMA without requiring the image intensifier and radiation source to be in full horizontal position and limiting operator access to the patient as a result.
- In addition to a full array of complementary wires, catheters, and sheaths, premounted balloon-expandable stents and stent grafts should be available, including in low-profile platforms (0.014 in or 0.018 in). Appropriate sizes of coils and plugs should also be identified and readily available.

RENAL ARTERY ANGIOPLASTY AND STENTING

First Step

- For arterial access, a retrograde transfemoral approach is usually selected; however, antegrade transbrachial access may improve accessibility and sheath stability in the presence of significant abdominal/pelvic girth, significantly down-sloping renal arteries, or tortuosity/obstruction of the distal aorta or iliac arteries.
- Arterial access is usually obtained percutaneously using standard Seldinger technique. Bedside ultrasound may facilitate precise placement. Once an interventional sheath access is placed, intravenous unfractionated heparin is administered to maintain an activated clotting time (ACT) of more than 200 seconds.

Second Step

- Wire access to the pararenal aorta may be achieved with 0.035-in guidewire. A 4- or 5-French (Fr) flush catheter is advanced over the guidewire to approximately the level of the 1st lumbar vertebral body.
- If renal function permits, a complete aortoiliac arteriogram in anterior–posterior image intensifier orientation

should be performed to assess both the renal arteries and renal accessory arteries. A power injector should be used for the road map aortogram, using a high injection rate (e.g., 15 to 20 mL per second) and low volume (e.g., 10 to 15 mL). Breath-holding instructions should be given to the patient or the assisting anesthesiologist to allow for aortogram acquisition during end expiration. Glucagon (0.25 to 2 mg intravenous; approximately 10 minutes pre-procedure) can also be administered to diminish intestinal motility and enhance arterial visualization.

- A magnified angiogram can be repeated of areas of interest and intended treatment. For better visualization of the renal artery, the image intensifier should be oriented with a few degrees in cranial and lateral obliquity ipsilateral to the renal artery of interest.
- Intraoperative angiographic measurements are obtained to confirm device selection. A marked flush catheter or radiopaque ruler may facilitate accurate angiographic measurements.

Third Step

- A stiff 0.035-in guidewire (i.e., Amplatz, Rosen) is placed in the pararenal aorta to facilitate advancement of a 45-cm 8-Fr renal dilation guide catheter (RDC), or 6-Fr RDC sheath (i.e., Terumo Pinnacle™ destination or Cook Ansel™ Flexor™). The sheath dilator tip should not be advanced into the target vessel to avoid compromise of the residual vessel lumen.
- Wire cannulation of the renal artery is the essential first step. Depending on the angle of entry at the orifice, a number of different catheter tip shapes may facilitate successful renal cannulation (Sos 1 or 2, Cobra, Vanchi, etc.). Once cannulated, the sheath tip is advanced immediately adjacent to, but not across, the renal artery orifice (FIG 1). A 0.014-in or 0.018-in stiff guidewire with a floppy or hydrophilic tip is then employed to probe across areas of severe stenosis, through a reverse curve or angled catheter, depending on the optimal angle for access. Alternatively, a 0.035-in guidewire, with improved handling and radiopacity, may provide suitable trackability for less critical stenoses.
- Once access is achieved, the wire should be advanced to a secondary branch to optimize positional stability. Care should be taken to maintain wire tip visualization in the field of view, particularly when using hydrophilic guidewires, as they can easily perforate parenchymal arterioles when advanced too far into the segmental renal circulation. Parenchymal perforation may precipitate intra- or extracapsular hematoma formation, renal hemorrhage, and circulatory collapse unless immediately recognized and corrected.

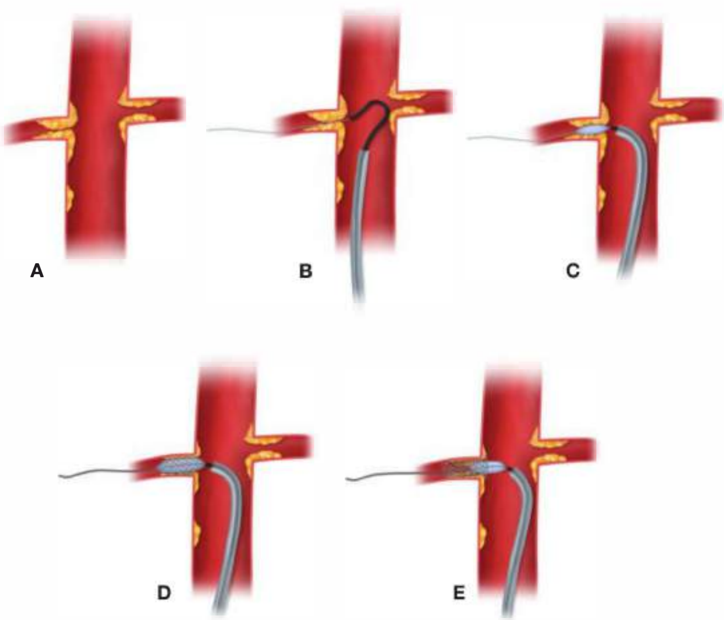

FIG 1 ● **A.** Pararenal aorta demonstrating high-grade stenosis at the right renal artery orifice. **B.** Cannulation of the right renal artery with a 0.014-in or 0.018-in glidewire guided by a curved-tip catheter. Wire and catheter cannulation system are stabilized by a 6-Fr sheath. The cannulating wire is advanced into the distal right renal artery to provide additional stability to the system. **C.** The right renal artery orifice stenosis is predilated with a low-profile, small-diameter balloon. **D.** Using sheath support for stability, an appropriately sized balloon-expandable stent is deployed across the stenosis and is protruding 1 mm into the aortic lumen. **E.** While maintaining cannulation system, protruding edge of the stent is flared into the aortic lumen with an appropriate compliant angioplasty balloon.

Fourth Step

- Prior to renal artery stenting, predilation may be necessary to provide sufficient luminal space for delivery of the crimped stent/delivery catheter (**FIG 1**). A 2- to 4-mm low-profile, semicompliant, or coronary balloon compatible with a 0.014-in or 0.018-in system can be used for this purpose. Care needs to be taken to maintain wire position during subsequent stent exchange; loss of wire position here can preclude stent delivery or precipitate luminal thrombosis if aortic and/or orificial atheroma is displaced by predilation.
- Using a low-profile 0.014-in or 0.018-in system (rapid exchange or over-the-wire [OTW]), a balloon-expandable stent (e.g., Cordis Palmaz Blue, Boston Scientific Express SD, Cook Formula) is delivered across the lesion (**FIG 1**). The low-profile nature of these devices enables facile placement, as well as contrast delivery across the lesion to confirm appropriate position. Rapid exchange or monorail systems allow for shorter wire length, aiding procedural efficiency vis-à-vis catheter/wire/device exchanges. In contrast, OTW devices provide improved pushability and trackability across constricting lesions.
- For mid- or distal RAS, the shortest balloon-expandable stent length providing complete coverage should be selected. For mid- or distal RAAs, appropriate length self-expanding or balloon-expandable stent grafts should be selected to provide adequate pre- and postaneurysm renal artery sealing zones (**FIG 2**).
- Following stent placement under fluoroscopic guidance, the balloon should be deflated fully prior to its withdrawal to avoid movement or dislodging of the stent. Areas with substantial tortuosity may precipitate arterial kinking at the transition point between stented and nonstented segments. Excessive oversizing, or overinflation of stents mounted on semicompliant balloons, may promote renal artery injury, dissection, or thrombosis. Temptation to optimize the postprocedural angiographic image, potentially at the expense of vessel integrity or anticipated long-term patency, should also be avoided.
- For ostial renal artery lesions, the balloon-expandable stent should be positioned so that the aortic end is deployed approximately 1 mm into the aortic flow stream. The aortic edge of the stent can be “flared” outward with a repeat angioplasty using the distal edge of the same balloon (**FIG 1**).

Fifth Step

- After successful deployment, the sheath should only be withdrawn after the completion imaging encompassing the entire ipsilateral kidney is performed to confirm uniform perfusion and absence of parenchymal and/or capsular injury.
- Following withdrawal of the sheath from the renal orifice, while maintaining wire access, completion paraorificial aortography is performed to confirm stent positioning and target lumen diameter. Residual stenosis, kinking, or dissection should be confirmed to be absent prior to withdrawal of the wire.

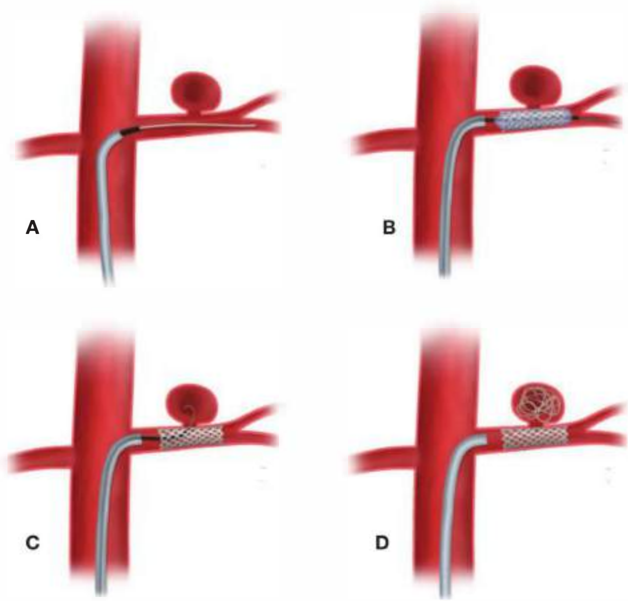

FIG 2 ● **A.** Left renal artery has an associated saccular aneurysm. Cannulation of the left renal artery is facilitated with an angled guidewire and curved-tip catheter. The cannulation system is stabilized by an appropriately sized sheath. **B.** A bare metal stent is deployed across the origin of the left RAA. **C.** A telescoping technique is used to cannulate the aneurysm sac through an interstice of the bare metal stent. Sheath tip is advanced to the renal artery orifice and catheter is advanced up to the inner luminal wall of the bare metal stent to stabilize and facilitate cannulation of the aneurysm sac. **D.** Appropriately sized coils are deployed into the aneurysm sac through the stent interstices.

VISCERAL ARTERY ANGIOPLASTY AND STENTING

First Step

- As previously noted, access considerations need to account for individual patient anatomy, operator experience and skill, available devices, potential complications, goals of treatment, and anticipated time of the procedure. Most internationalists prefer the transfemoral approach for visceral vascular access. However, proximal left brachial artery exposure and puncture often facilitates access to significantly down-sloping or tortuous mesenteric arteries.
- A 4- or 5-Fr sheath is placed in the arterial access site to facilitate advancement of a 4- or 5-Fr marked flush catheter to the paravisceral aorta.
- Intravenous unfractionated heparin is administered after sheath placement to achieve an ACT of more than 200 seconds.

Second Step

- After a standard aortogram, a magnified paravisceral aortogram can be performed with the image intensifier placed in a steep oblique or true lateral position to optimize localization and cannulation of the celiac artery and SMA origins.
- Care should also be taken here to visualize the major branches of the celiac artery and/or SMA. Attempts should be made to visualize the first significant branch of the SMA, usually the middle colic artery, to avoid inadvertent coverage and/or compromise of colonic arterial perfusion as a consequence of planned procedures.
- Visceral lesions of interest can be further characterized at this time by optimizing image intensifier obliquity. Accurate measurements are facilitated by marked flush catheter or radiopaque ruler placement.

Third Step

- After withdrawal of the flush catheter, a stiff guidewire and a long (90 cm), braided 6-Fr sheath (i.e., Terumo Pinnacle™ destination, Cook Ansel™ Flexor™) is advanced to the paravisceral aorta. Various angled sheath tips (i.e., straight, angled hockey tip, curved) can be used depending on the degree of visceral artery angulation, aortic diameter, and access approach (femoral or brachial).
- Along with selected sheath, various guide catheter types (i.e., angled, vertebral, cobra, RDC, or reverse curved SIM or Sos catheters) can be used to facilitate visceral artery cannulation.

Fourth Step

- An exchange-length, stiff 0.014-in or 0.018-in guidewire, with a floppy tip, is advanced through the preselected catheter and sheath combination. However, wire cannulation of a diseased visceral arteries orifice may be challenging. From the brachial approach, successful cannulation may be facilitated with sheath placement distal to the artery of interest, followed by gradual withdrawal of the sheath with the selected angled catheter inside the sheath protruding slightly outward. When the catheter "clicks" into place, an exploratory hydrophilic guidewire is then gently advanced to obtain luminal access. Once the lumen is cannulated, the guidewire is then advanced to a secondary visceral branch to facilitate catheter and sheath advancement, as indicated (FIG 3). Another cannulation strategy is to withdraw wire and catheter combinations from a stable sheath position

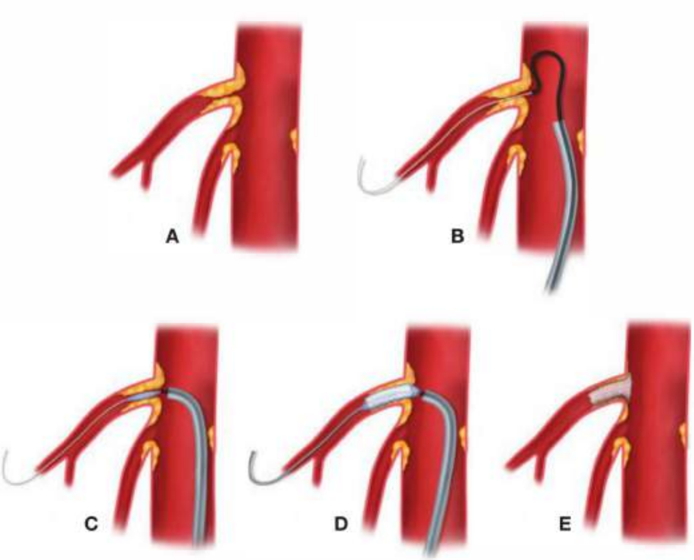

FIG 3 ● **A.** High-grade stenosis of the proximal celiac artery origin. **B.** A curved-tip guide catheter is used to facilitate celiac artery cannulated with a 0.014-in or 0.018-in guidewire. The cannulation system is stabilized with distal advancement of the guidewire into a celiac artery branch, as well as maintaining a sheath in the aortic lumen. **C.** A low-profile, compliant predilation balloon may be advanced over the guidewire to dilate the stenosis and provide a tract for future stenting. **D.** An appropriately sized balloon-expandable covered stent graft is deployed across the stenosis while slightly protruding into the aortic lumen. **E.** Full stent apposition following deployment and proximal flaring of the stent graft at the prior stenosis site.

across the anticipated vessel orifice area at various "clock" positions.

- For a "no-touch" technique, a shaped catheter or sheath tip is positioned luminally in direct proximity to the orifice of interest. A 0.014-in or 0.018-in hydrophilic guidewire is then used to localize and facilitate cannulation. To improve trackability and pushability of the system, a stabilizing "buddy" stiff guidewire may also be advanced, when necessary, to "pin" the cannulation sheath to the opposite wall.
- When single-wire cannulation proves inadequate to support catheter and sheath advancement in to the target vessel, placement of a second, or even third 0.014-in or 0.018-in wire, across the area of stenosis may facilitate successful catheter/sheath advancement.

Fifth Step

- An appropriately sized self-expanding or balloon-expandable stent graft is preferred for the treatment of visceral artery stenoses. Predilation of the tract may be necessary with a small, low-profile balloon to facilitate advancement of the balloon-expandable stent (**FIG 3**).
- The aortic end of a balloon-expandable stent used for the treatment of ostial or proximal visceral artery lesions should be positioned 1 mm into aortic flow lumen, and the stent edge should be flared out with the edge of an angioplasty balloon.
- Accuracy of deployment of self-expanding stent grafts can be improved with partial deployment of the stent while maintaining the cannulation sheath in the orifice of the visceral artery. Once the distal portion of the stent graft is accurately deployed, the remainder of the proximal stent graft can be unsheathed to allow for full deployment. An appropriately sized compliant balloon may then be subsequently used to fully mold the self-expanding stent graft to profile and/or slightly flare the aortic edge.
- For friable lesions, or lesions that may include fresh thrombus, consideration should be given to advancing and deploying balloons and stents over a filter wire (0.014-in eV3 SpiderFX embolic protection system). Although placement of a distal filter may not preclude all embolic sequelae, it may reduce the severity or significance of associated potential complications. This option may be particularly valuable in SMA interventions.

HYBRID REPAIR OF PROXIMAL MESENTERIC ARTERY STENOSIS/ OCCLUSION

First Step

- In the setting of acute or acute-on-chronic mesenteric ischemia, where exploratory laparotomy is otherwise indicated to assess bowel viability, a hybrid retrograde catheterization approach is generally preferred. At laparotomy, surgical exposure of the superior mesenteric or celiac artery is obtained. To expose the celiac artery, the left triangular ligament is incised, the left hepatic lobe is retracted to the right, and the gastroesophageal junction is retracted to the left. Further caudal dissection along the surface of the aorta may be used to expose the SMA origin.
- For purposes of both embolectomy and hybrid retrograde catheterization, exposure of the proximal section/midsection of the SMA is preferentially obtained at the superior root of the small bowel mesentery (**FIG 4**). This location generally provides access 4 or more centimeters distal to the SMA orifice, which allows stable sheath positioning to facilitate retrograde cannulation and stenting. Distal to the lower margin of the pancreas, the length of the SMA is limited by early branching of the ileocolic artery and intestinal cascade, so relatively proximal positioning should be achieved to minimize excessive dilation/trauma to the vessel by the sheath.[18]

Second Step

- When embolic occlusion is present, embolectomy is performed gently through an anterior arteriotomy. The tapering nature of the SMA in this area requires gentle catheter withdrawal with gradual balloon deflation in order to avoid iatrogenic arterial damage, dissection, or thrombosis.
- Retrograde cannulation of an exposed distal segment of the target vessel provides optimal access for definitive endovascular intervention. In emergent conditions with compromised intestine, this approach is preferential to open revascularization strategies, which may require prosthetic graft placement following prolonged, extensive dissection of the mesentery and aortic root.
- Retrograde mesenteric cannulation is facilitated by placement of a longitudinal arteriotomy in the exposed distal segment of the target vessel. To reduce the risk of injury to the exposed artery during cannulation, the arteriotomy site is closed with a prosthetic or autogenous patch. The patch itself is then cannulated to facilitate sheath placement, angiogram, stent placement as well as expedited puncture site closure at the end of the procedure (**FIG 4**).
- Relatively long sheaths (20 cm or more) should be used during retrograde cannulation to ensure that the operator's hands are clear from the fluoroscopy field and minimize operator radiation exposure during catheterization maneuvers.[18]

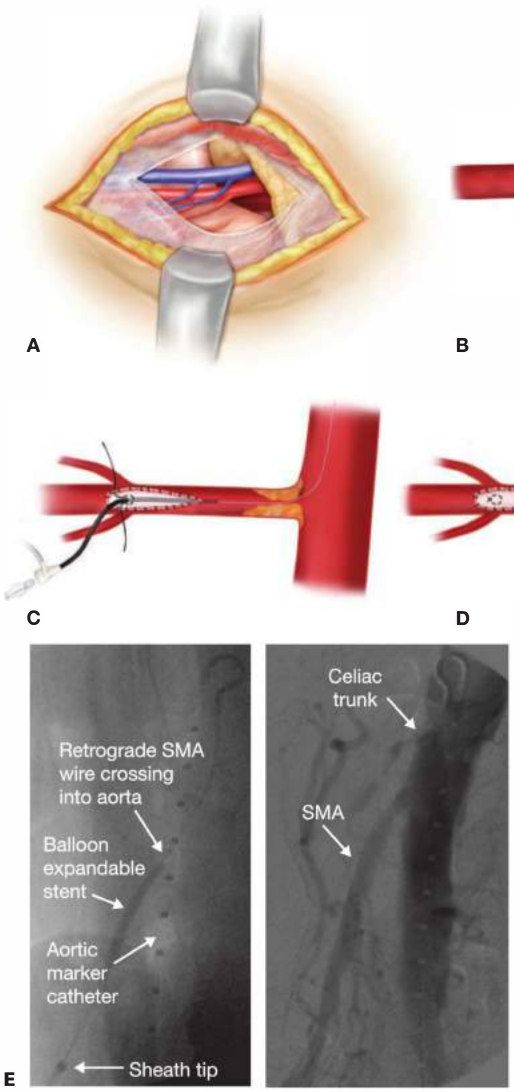

FIG 4 ● **A.** Open exposure of the proximal SMA at the caudal portion of the mesenteric root. **B.** The proximal SMA, ~3 to 4 cm from its aortic origin, is circumferentially exposed while preserving its side branches. A longitudinal arteriotomy is created and thrombectomy is performed with patch angioplasty. **C.** Sheath is placed through a puncture in the angioplasty patch and arteriogram is performed to evaluate stenosis in the proximal SMA origin. **D.** A stent is deployed using fluoroscopic guidance at the SMA origin across the identified hemodynamic stenosis. The patch puncture site is repaired to maintain hemostasis. **Ei.** Retrograde access to SMA, with inflation of balloon expandable stent extending into aorta proximally, spanning length of proximal occlusive lesion. **Eii.** Completion mesenteric arteriogram from aortic injection, showing complete restoration of mesenteric arterial lumen and normal distal arterial perfusion. Retrograde mesenteric wire has been removed, and arteriotomy closed at the patch site in distal SMA.

RENAL OR VISCERAL ARTERY EMBOLIZATION

First Step

- Arterial access can be secured via either a left brachial artery or transfemoral approach, depending on the intended target vessel and its angulation relative to the aorta.
- For standard coil embolization, a 5- or 6-Fr sheath access will be adequate. However, if an occlusion device will be used, a larger sheath size may be required depending on device specifications.
- Systemic anticoagulation with intravenous unfractionated heparin is also commonly used during these procedures.

Second Step

- Angiographic characterization may require angiograms in multiple different obliquities to fully appreciate size, extent, and angulation of the lesion of interest, particularly those affecting secondary visceral branches. In the angiographic parlance, regarding the extent, severity, and profile of a luminal obstruction, "one view is no view."
- One should note the extent of vascular collateralization associated with the vascular segment that will be embolized.

Third Step

- A telescoping cannulation technique is usually used to enhance the positioning and stability of the embolization

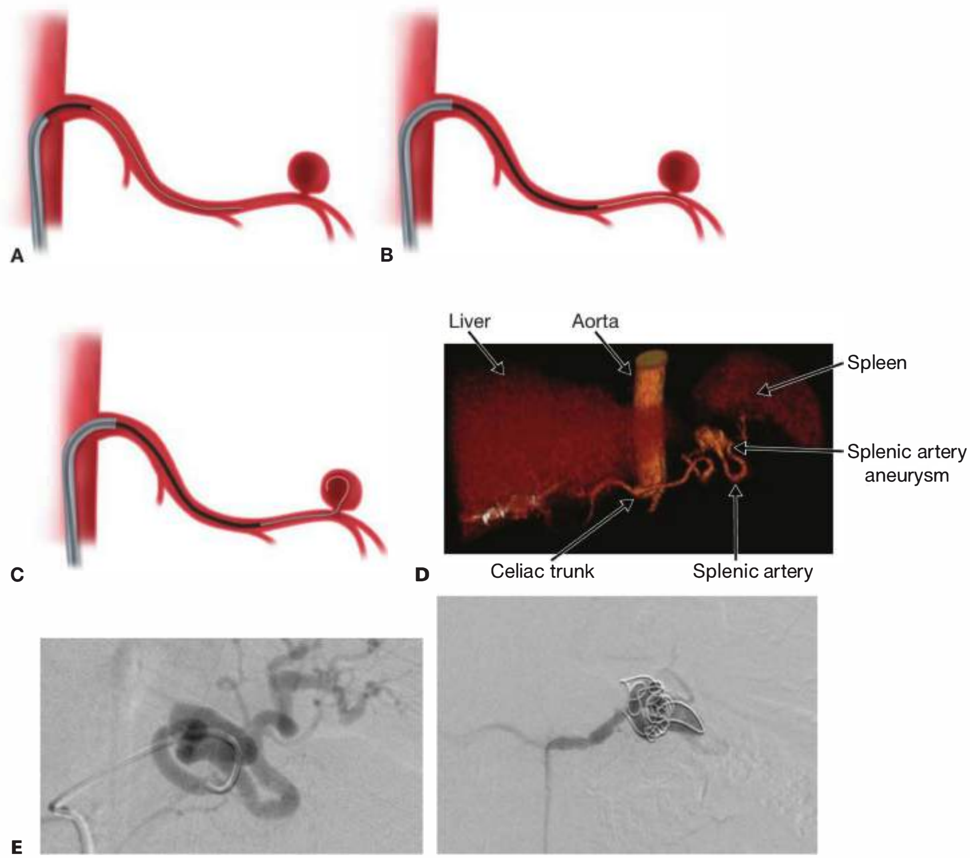

FIG 5 ● **A.** Cannulation is attempted of a saccular visceral artery aneurysm. A sheath and angled catheter facilitate cannulation of the visceral artery origin with a guidewire. **B.** A 0.035-In catheter and guidewire negotiate proximal arterial tortuosity. **C.** A microcatheter is telescoped through the 0.035-in catheter to facilitate wire cannulation of the aneurysm. **D.** Three-dimensional abdominal CTA of a female with a mid–splenic artery saccular aneurysm. **E.** Selective splenic artery aneurysm pre- and postselective coiling.

system. To perform this, a sheath is advanced as close to the target lesion as possible. A catheter is then extended from beyond the tip of the sheath and used to protrude into target lesion (FIG 5).

- Embolization of remote target lesions may require higher orders of telescoping. Placing a sheath into another larger sheath, or a 0.018-in microcatheter (i.e., Codman Prowler™, Cook CXI™, BSCI Renegade™) into a standard 0.035-in guide catheter, can help access more challenging lesions (FIG 5). Alternating wire and microcatheter advancements may facilitate cannulation of smaller and more tortuous arteries (such as the superior and inferior gastroduodenal arteries [FIG 6]) and distal/hilar splenic artery.
- If possible, the cannulation catheter/microcatheter should be advanced into the lesion slightly further than the intended embolization site, because the system can draw back during deployment of coils or plugs.

Fourth Step

- Once the cannulation catheter is positioned in the target lesion, 0.018-in or 0.035-in coils are delivered sequentially into the target area through their respective catheters. For detached coils, the metal tube housing the coil is attached to the back end of the cannulation catheter, and the stiff end of a guidewire is used to push the coil out of its housing unit and into the catheter shaft. The floppy tip of the guidewire is then replaced into the catheter to push the coil along the entire shaft of the catheter and into the lesion (FIG 5). The stiff end of the guidewire should not be used to push the coil into the lesion because it can change the cannulating catheter tip shape and lead to instability in the cannulation system and maldeployment.
- Alternatively, small aneurysm may be occluded with detachable or nondetachable microcoils or ethylene vinyl alcohol copolymer. IFU are variable and should be referred to for recommended deployment techniques.
- When coil deployment can be accurately localized, and precise coil positioning is critical to the success of the procedure, large-to-small tapered coils should be used. When arterial blood flow is needed/required to carry part of the coil into the preferred deployment location, small-to-large tapered coils are preferred in this situation. Newer "nesting" coils will reform immediately into larger, obstructing profiles. Older tubular coils need

to be advanced as they are being deployed to avoid simply lining the target artery without sufficient luminal obstruction. Attention to understanding what coils are in inventory, and how respective coil choices are optimally deployed, is essential for procedural success.

- For larger aneurysms or planned occlusion of an entire vessel lumen, a vascular plug (i.e., AGA Medical Amplatzer™ I or II vascular plug) may be preferable and a more effective means for target embolization. However, plug placement usually requires stable sheath target artery cannulation. Amplatzer™ I and II vascular plugs are produced in diameters ranging between 4 and 22 mm and lengths ranging between 6 and 18 mm. Recommended device IFU should be consulted to ensure proper device selection and deployment. When sheath access cannot be withdrawn to enable plug deployment, catheter-delivered coils should be deployed instead.
- Once a coil or plug is delivered into a lesion, its position may be modified slightly by catheter tip advancement. This maneuver, when performed properly, maximizes the obstructive surface area and resulting coil thrombogenicity.
- When multiple coils or plugs are used, deployment should also be strategized and deliberate. For example, the first coil should be placed in the deepest part of the lesion (base of an aneurysm), whereas the last coil should be placed in the entry point of the lesion (neck of an aneurysm).
- For acutely bleeding vessels (such as the gastroduodenal arteries in the setting of duodenal ulcerations), a "back-door"–"front-door" approach ensures hemostasis. This involves occluding the culprit vessel pre and post the area of bleeding (FIG 6). Coiling only one side of the bleeding artery may prevent further access attempts while not providing sufficient vessel occlusion and hemostasis. Small bleeding pelvic arteries may similarly be embolized using a Gelfoam slurry slush preparation.[23] Recommended IFU should be consulted to ensure proper preparation and administration of these slurries.

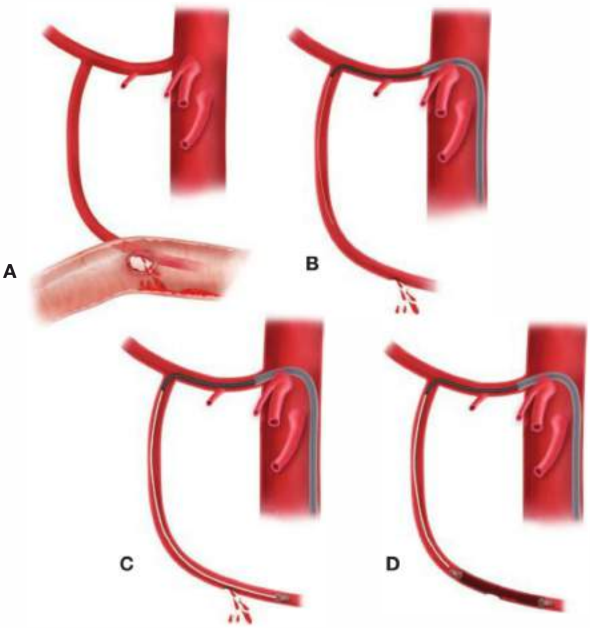

FIG 6 ● **A.** Bleeding gastroduodenal artery with an associated duodenal ulceration. **B.** Sheath cannulation of the common hepatic artery branch of the celiac artery, followed by catheter cannulation of the gastroduodenal artery. **C.** Back-door deployment of an embolization coil distal to the angiographically identified bleeding point in the gastroduodenal artery. **D.** Subsequent "front-door" embolization of the feeding segment of the gastroduodenal artery.

Fifth Step

- It is customary to perform postembolization arteriography to confirm final coil/plug positioning. Residual flow will still be evident in the recently embolized vessel segment, because the patient generally remains heparinized during this period of the procedure. If uncertainty persists as to the adequacy of embolization, arteriography may be repeated following reversal of anticoagulation, taking into account increased risks of thrombosis/embolization around the delivery sheaths and catheters proximal to the targeted lesion.

PEARLS AND PITFALLS

Indications	■ Preoperative imaging (duplex and CTA) should be reviewed in detail to ensure patient suitability and help plan out appropriate intervention. ■ Combining information gathered from duplex and CTA is beneficial, especially in situations when the stenosis is overestimated due to heavy luminal calcification.
Vessel cannulation	■ One should note the angulation of the target vessel relative to the aorta. Because this angle may vary with respiration, angiograms should be obtained while the patient is apneic (if intubated) or at end expiration. ■ Generally, renal arteries and up-sloping visceral vessels may be easier to cannulate from a transfemoral artery approach. Down-sloping renal and visceral vessels may be easier to cannulate from a proximal left brachial artery puncture. ■ Using an angulated, flexible, low-profile sheath system also aids in the cannulation process.

Angioplasty balloon selection	▪ Care should be taken in selecting appropriate size and types of balloons. ▪ Generally, only low-profile compliant balloons should be used for angioplasty interventions in the renal and visceral arteries. In rare circumstances, a noncompliant balloon may be used to help mold a stent graft to full profile. ▪ Diameter of angioplasty balloon should be estimated relative to adjacent normal vessel lumen. Oversizing is generally not necessary, and a smaller diameter balloon may be preferred when performing angioplasty across highly calcified lesions.
Stent selection	▪ Care should also be taken in selecting appropriately sized stents for desired interventions. ▪ Stent diameter should be estimated relative to normal vessel lumen diameter adjacent to target lesion to be treated and is generally oversized by approximately 1 mm. ▪ Stent length should be estimated relative to the length of the target lesion while providing enough coverage into the adjacent normal vessel lumen (area of needed coverage is variable depending on type of lesion and intervention). ▪ Oversized stents are prone to kinking and may risk damaging the target vessel. Undersized stents may lead to maldeployment, migration, and ineffective seal with adjacent vessel lumen. ▪ Sometimes, the angioplasty balloon of a balloon-expandable stent gets stuck in the stent during its removal. In this situation, pulling the balloon risks misplacing or dislodging the stent from its desired location. Instead, the operator should ensure complete deflation of the balloon and attempt slowly advancing the balloon while rotating its catheter.
Coil/plug selection	▪ Size of coils and plugs should be selected relative to lesion dimensions. Undersized coils and plugs risk migration to unintended vascular beds. ▪ Stability of the embolization delivery system should be selected relative to the size of the embolization device. Larger embolization devices may cause instability in low-profile delivery systems.
Renal/visceral artery dissection	▪ Sheath and large catheter cannulation of renal and visceral arteries should be avoided to prevent damage or dissection. ▪ If a dissection occurs, angiographic evaluation is required to determine whether it is flow limiting. All flow-limiting dissections should be stented with an appropriately sized balloon-expandable stent.
Renal/visceral arterial spasm	▪ Arterial spasms may be induced with vessel cannulation, angioplasty, or stenting. Younger patients are typically more prone for this. Arterial vasodilators, such as nitroglycerin or papaverine, may be infused into the vessel lumen by way of cannulation sheath or catheter to help relieve this. ▪ The operator should be aware that papaverine may precipitate out of solution if mixed with heparin.
Renal capsular perforation or hematoma	▪ This may be caused by inadvertent advancement of cannulating wire into the renal parenchyma. To avoid this complication, always keep the end of the wire in sight during sheath and device advancements over the wire. Also, avoiding the use of straight or angled-tip stiff glidewires in this circumstance can decrease the risk of this complication. ▪ Symptoms of renal capsular hematoma or perforation include abdominal pain and nausea, accompanied by a vasovagal response, which frequently requires aggressive resuscitation and stabilization maneuvers by the interventional team. ▪ If this complication is encountered, maintain wire access (do not remove the offending wire) to facilitate a catheter exchange to provide access to coil placement and occlusion of the perforation site. Loss of wire access can further complicate this situation; however, as long as sheath access remains in the renal artery, the relevant segmental branches can be reaccessed for coil delivery.
Removal of malpositioned/misplaced devices	▪ All attempts should be made to safely reposition malpositioned/misplaced stents, endografts, coils, or plugs. This may involve secondary cannulations, larger sheath placement, and balloon angioplasty with gentle directional force. ▪ If endovascular retrieval or repositioning is unsuccessful, angiographic flow across malpositioned/misplaced devices should be evaluated. If arterial flow is clearly obstructed to unintended vital structures or may become a significant nidus for thrombosis or hemodynamic stenosis, open surgical removal may be indicated or attempted repositioning of devices in areas of less critical hemodynamic significance (e.g., iliac arterial system).

POSTOPERATIVE CARE

- At the conclusion of the procedure, hemostasis is achieved with manual compression or, in cases requiring larger than 6-Fr sheath size, closure devices. Heparin reversal with protamine administration is also helpful unless anticoagulation is to be continued following the procedure.
- As is the case with all patients undergoing peripheral arterial intervention in our practice, patients are observed for a 6- to 24-hour period following device placement. During this period, access site hemostasis and ipsilateral pedal perfusion status is monitored periodically, along with hydration status/urine output and signs of unintended end-organ malperfusion.
- Patients treated with renal/visceral artery angioplasty or stenting receive exaggerated antiplatelet therapy in the immediate perioperative period. In our practice, we load patients with 300 mg of Plavix™ following the procedure, therapy continuing at 75 mg daily for 6 additional weeks.
- Postoperative surveillance of patients with renal/visceral artery interventions is necessary. Duplex evaluation of renal/visceral artery stents 1 to 3 months following intervention is

usually recommended, followed by repeat duplex evaluation every 6 months for at least 1 to 2 years. Afterward, stents with no evidence of in-stent restenosis or de novo disease progression may be imaged at yearly intervals. Evidence of restenosis, either by end-organ dysfunction or surveillance imaging studies, should prompt reevaluation and reintervention as necessary to maintain luminal patency and long-term success.

OUTCOMES

- Endovascular treatment of RAS has a reported technical success rate of 88% to 100%. Treatment effects on hypertension alone are quantitatively modest and inconsistent between studies.[24,25] Improvement in renal function is reported in approximately 25% of patients.
- Treatment of mesenteric occlusive disease has a reported technical success rate of 96%. Postoperative symptom improvement/resolution is reported in approximately 88% of treated patients. Primary patency is estimated at 65% to 92%, with primary assisted patency at 92% to 100%, and secondary patency at 99%.[26,27]
- Embolization and stent graft techniques for repair of renal and visceral artery aneurysms are limited to variably sized retrospective series but with acceptable technical success rates in appropriately selected patients.

COMPLICATIONS

- For renal artery interventions, complications most commonly arise from access site complications, contrast-induced nephropathy, or atheroembolization. Renal artery restenosis is reported between 5% and 66%, depending on duration of follow-up and criteria used for continued surveillance. The perioperative 30-day mortality is estimated at 0% to 5% and survival at 3 years is estimated at 74%.[28] Other less frequent complications include iatrogenic renal parenchymal perforation, capsular hematoma, arterial dissection, thrombosis, or distal plaque embolization into branch or accessory arteries.
- For mesenteric artery interventions, restenosis or occlusion of treated visceral vessels is documented in 10% to 27% of patients,[29] emphasizing the need for continued postprocedural surveillance. Less common complications include mesenteric artery perforation, dissection, or distal parenchymal embolization due to wire/catheter manipulation of areas with fresh thrombus or friable plaque. While treating branch artery aneurysms of the spleen, occasionally, portions of the splenic parenchyma may be lost due to coiling and branch occlusion, with attendant symptoms consistent with segmental splenic infarction.

Chapter **20**

Visceral Reconstruction to Facilitate Cancer Management: Celiac, Mesenteric, Splenic, Hepatic and Renal Artery Disease Management

Mohamed A. Zayed E. John Harris, Jr.

DEFINITION

- This chapter assumes basic knowledge of surgical oncology principles and the management of patients with intraabdominal tumor pathology. For further review of these topics, please refer to relevant background sources.[1,2]
- Advanced primary and recurrent abdominal malignant tumors may frequently involve adjacent arterial and venous structures. Surgical management may require curative en bloc tumor resection, with the goal of achieving negative macroscopic and microscopic margins. Adjunct vascular reconstruction may be necessary to achieve complete tumor removal.
- A wide variety of malignancies may develop in the peritoneal space and retroperitoneum. A representative range of pathologies involving intraabdominal arterial and venous structures is summarized in Table 1.
- Primary vascular tumors are exceedingly rare, frequently mimic other oncologic disease processes, and may evolve slowly—leading to delay in diagnosis and treatment. Although most commonly arising from large vessels such as the aorta and vena cava, primary vascular tumors may also originate from distal branches of the iliac, mesenteric, and renal arteries. Classification systems (Wright/Salm classification) have broadly categorized primary vascular tumors as intimal (majority, 70%) and mural.[3]

Table 1: Range of Intraabdominal Oncological Pathologies that can Potentially Involve Arterial and Venous Structures

Arterial	
Aorta	Angiosarcoma,[a] paraganglioma, pheochromocytoma, leiomyosarcoma, rhabdomyosarcoma
Superior mesenteric artery	Adenocarcinoma, neuroendocrine carcinoma, adenosquamous carcinoma, cystadenocarcinoma
Iliac artery	Adenocarcinoma, leiomyoma, endometrial stromal carcinoma, fibrosarcoma, fibroma
Venous	
Inferior vena cava	Angiosarcoma,[a] adrenocortical carcinoma, teratoma, Wilms' tumor, pheochromocytoma, neuroendocrine carcinoma, intestinal carcinoma, hepatocellular carcinoma
Renal vein	Renal cell carcinoma, adrenocortical carcinoma, pheochromocytoma
Portal vein	Adenoma, adenocarcinoma, cholangiocarcinoma, neuroendocrine carcinoma, hepatocellular carcinoma
Iliac vein	Intestinal carcinoma, leiomyoma, endometrial stromal carcinoma, fibrosarcoma, fibroma, transitional cell carcinoma, liposarcoma. leiomyosarcoma

[a]*Primary vascular tumor.*

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with complex intraabdominal oncologic pathology are best managed by a multidisciplinary care team at a tertiary care center. If tumor extension to adjacent vascular structures is suspected, surgical planning should include evaluation of potential revascularization options by a vascular surgeon.
- The initial assessment should include a thorough evaluation of the patient's presenting symptoms. This may include focal or regional abdominal pain resulting in tumor parenchyma pressing against adjacent structures. Patients may also present with gastrointestinal symptoms such as early satiety, nausea, and vomiting. Erosive gastrointestinal lesions may manifest with hematochezia, melena, or hematemesis. Constitutional flu-like symptoms, fevers, malaise, fatigue, night sweats, and muscle aches may also rarely present in patients with certain patients with rapidly expanding tumors.
- Depending on the primary site and tissue of origin, tumor-associated physical findings may not be obvious until relatively late in the disease process. Abdominal distension can result from increasing tumor volume or from serous ascites due to portal venous compression. Tumor mass effect or infiltration of the inferior vena cava (IVC) or iliac venous system may lead to unilateral or bilateral lower extremity edema, dilated abdominal wall veins, evidence of deep venous thrombosis (DVT), biliary symptoms, and renal insufficiency. Accordingly, physical examination should not only include a thorough abdominal exam with palpation of all nodal basins but also a complete vascular exam with evaluation of limb pulses, Doppler signals, and assessment of extent/grade of limb edema.
- Patient with primary vascular tumors, particularly ones with intimal expansion and growth, can present with evidence of venous or arterial embolization. Manifestations of recurrent venous pulmonary emboli include shortness of breath, respiratory distress, and hemodynamic changes including tachycardia and right heart failure. Depending on the volume of arterial emboli, symptoms can range from lower extremity pain to digital discoloration.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Tumor staging and classification systems are beyond the scope of this chapter. Please refer to other excellent references for tumor-specific staging modalities and requirements.[2,4]
- Patients deemed candidates for surgical resection by a multidisciplinary team should receive a high-resolution, thin-slice (at least 1 mm), multidetector computed tomography (MDCT) scan with intravenous contrast injection to allow for imaging during arterial and venous phases. Image acquisition should allow for multiplanar sagittal, coronal, and three-dimensional reconstructions. This type of detailed imaging provides valuable information regarding tumor margins, suspected histologic subtype, and grade and can also help determine the morphology, patency, and extent of involvement of adjacent vascular structures.
- In situations where mesenteric venous thrombosis is visualized on MDCT, specific postprocessing protocols may be further implemented to improve clarity regarding the extent of thrombus burden and associated and/or resultant venous congestion.
- Adjunct imaging studies may also include magnetic resonance imaging (MRI), ultrasonography, and rarely, angiography/venography. Particularly, in patients with concern for osseous or neurogenic tumor involvement, MRI may be particularly useful in defining tissue planes and tumor parenchyma boundaries. MRI also has a nearly 100% sensitivity for detecting intracaval tumor thrombus.
- Autogenous vascular conduit may be necessary for adequate revascularization, particularly following bowel resection and reconstruction. When anticipated, preoperative venous duplex scanning of the lower extremities will help document the presence and usage of superficial femoral vein as potential graft conduit. The presence of deep venous obstruction, either acute or chronic, may preclude venous harvest from that particular extremity. Similarly, the bilateral lower extremity greater saphenous veins should be evaluated for patency, diameter, and adequate length.
- Occasionally, preoperative or intraoperative transesophageal echocardiography may be needed to confirm the proximal extent of intracaval tumor thrombus visualized using other cross-sectional imaging modalities and determine whether the tumor thrombus is encroaching into the right atrium.[5]

SURGICAL MANAGEMENT

Patient Selection

- Whenever possible, the goal of surgical extirpation of abdominal solid organ tumors should be oncologic cure. This assumption presupposes tumor localization to a distinct anatomic region that will allow for resection with negative macroscopic and microscopic margins. Thus, the goals of the procedure should be clearly defined by sufficient preoperative high-quality anatomic cross-sectional imaging, multidisciplinary consultation, and discussions with the patient regarding the operative risks, benefits, expectant outcomes, and overall prognosis.[2,6]
- Abdominal solid organ tumors are traditionally considered unresectable when they involve the arterial or venous vasculature, are diffusely metastatic throughout the peritoneum or at remote sites, or involve the root of the mesentery or spinal cord to a significant extent. Patients with extensive tumor burden precluding resection may still be offered incomplete removal or debulking operations to potentially prolong survival and improve symptom palliation.[6]
- Equally as important as the anatomic considerations, preoperative patient functional status is a significant determinant of surgical eligibility. Performance assessments, such as outlined by the Karnofsky or Eastern Cooperative Oncology Group (ECOG) score, help predict patient-specific postoperative quality of life.[2,7] At our institution, patients who are bedridden at the time of initial assessment, severely disabled, or unable to independently perform activities of self-care are often not offered curative resection.
- Candidacy for intraabdominal vascular reconstruction is also contingent on the extent of potential or preexisting vascular compromise. As such, we have typically attempted arterial reconstruction when tumors involve critical arterial structures such as the aorta, celiac artery and its branches, proximal superior mesenteric artery (SMA), common/external iliac artery, and the internal iliac artery in the setting of an embolized, occluded, or resected contralateral internal iliac artery. Similarly, venous reconstruction is also anticipated when tumors margins appear to include the vena cava, portal, superior mesenteric, common, and external iliac veins.

Preoperative Planning

- Items to consider in preoperative multidisciplinary review include the extent of planned gross surgical resection margins, the need for preoperative arterial or venous embolization, the need for other prophylactic procedures such as placement of ureteral stents or nephrostomy tubes, and the likelihood for intestinal resection and/or reconstruction.
- Ureteral stent placement should be considered in all patients who demonstrate evidence of ureteral obstruction, renal hydronephrosis, or urinary obstructive signs or symptoms from either tumor mass effect or invasion of urologic structures. Moreover, ureteral stents should also be considered in patients with pelvic tumors where there is potential concern of ureteral injury during resection of the tumor or during vascular reconstruction.
- A thorough review of detailed preoperative imaging will greatly facilitate proper conduit selection and preparation and, ultimately, a successful outcome. Particular attention should be directed to the length of vascular segment involved by adjacent tumor, the branch points and bifurcations present along this length, and which segments, if any, are circumferentially encased by tumor parenchyma.
- Attention should be paid as to whether planned resection will include vessels which are already occluded with adequate collateral circulation already in place, or whether adjacent or contralateral vascular structures are capable of supplying adequate inflow and outflow. Vascular segments to be reconstructed should be patent and preserved to the greatest extent possible during the planned tumor resection.
- Endovascular embolization is the preferred method of preoperative vascular occlusion prior to open surgical resection. This strategy is commonly used for preoperative splenic artery/vein embolization prior to planned surgical splenectomy, internal iliac artery embolization prior to planned pelvic

tumor resection, and renal artery/vein embolization prior to planned nephrectomy with or without the need for further exposure of the retrohepatic IVC. For this purpose, the preferred size of coils/plugs is estimated based on the diameter and length measurements of the target vessel on preoperative cross-sectional imaging and is typically oversized by up to 20% of the target vessel diameter. For additional details regarding visceral embolization techniques, refer to Part 6, Chapter 19 (Stenting, Endografting, and Embolization Techniques: Celiac, Mesenteric, Splenic, Hepatic, and Renal Artery Disease Management). For additional details regarding internal iliac artery embolization techniques, refer to Part 6, Chapter 24 (Advanced Aneurysm Management Techniques: Management of Internal Iliac Aneurysm Disease).

- Aortoiliac arterial involvement often requires resection followed by reconstruction with patch angioplasty, interposition, or extraanatomic bypass. Type of reconstruction and conduit type (autogenous venous allograft, cryopreserved homograft, or synthetic conduit) is contingent on the type of tumor, extent of vascular segment involvement, and degree to which intestinal reconstruction is also anticipated. In the latter case, when contamination by succus entericus is likely, autogenous femoral vein conduits for iliac artery reconstructions and IVC or spliced femoral vein conduits for aortic reconstructions are preferred. Alternatively, when not available, rifampin-soaked, gel-sealed knitted Dacron conduit may serve as a potential substitute with acceptable results.[8]
- Reconstruction of the celiac trunk, common hepatic artery, SMA, portal vein, and superior mesenteric vein (SMV) are similarly contingent on the extent of involvement of these structures with tumor pathology. Unless the artery in question is circumferentially involved, it is our preference to resect only the portion of vessel wall directly involved with tumor while preserving the remaining vessel architecture with patch repair. Autogenous venous conduit (using superficial femoral vein or greater saphenous vein or femoral vein) is preferred for vessel segments requiring interposition grafting.
- The mainstay of treatment of primary and secondary tumors of the IVC is surgical resection and reconstruction. The extent of reconstruction is contingent on the type of tumor, extent of caval involvement, and the anatomic segments involved. Adequate retrohepatic caval exposure is challenging and may require total vascular isolation of the liver to minimize blood loss during this maneuver. In circumstances where the IVC is chronically occluded with tolerable lower extremity edema and adequate renal function, ligation and resection without reconstruction should be considered. On the other hand, patients with recent occlusion of the IVC, few venous collaterals, notable lower extremity symptoms, or renal insufficiency should be considered for either interposition grafting or patch venoplasty.

Operating Room Setup

- Preoperative endovascular embolization procedures should be performed in an angiography suite or hybrid operating room, equipped with a fixed-imaging apparatus, floating-point carbon fiber operating table, fluoroscopy platform, and monitor-viewing bank. A full complement of compatible guidewires, catheters, sheaths, coils, and plugs should also be available.
- Open tumor operative resection procedures are best performed in an operating room setting with adequate space to facilitate the maneuvering of multiple surgical subspecialty teams and their necessary operative trays/equipment.
- Most intraabdominal operative tumor resection and reconstruction procedures may be performed with the patient in the supine position. In the surgical field, the patient's lower extremities should be prepared for vein harvest if potentially necessary.
- In patients who require retrohepatic IVC exposure and reconstruction, the left lateral decubitus position should be employed to facilitate right thoracoabdominal exposure through the 8th or 9th rib interspace.
- Placement of ureteral stents will require initial positioning of the patient in lithotomy position and then subsequent repositioning of the patient to facilitate further planned surgical intervention.

AORTIC RECONSTRUCTION

- For a discussion of the technical exposure of the paravisceral, pararenal, and infrarenal aorta, please refer to Part 6, Chapters 14 (Exposure and Open Surgical Management at the Diaphragm), 15 (Retroperitoneal Aortic Exposure), and 22 (Advanced Aneurysm Management Techniques: Open Surgical Anatomy Repair).

First Step

- The surgical exposure of an intraabdominal tumor either directly adjacent or involving the aorta should aim to not only provide adequate exposure of tumor resection but also facilitate adequate proximal and distal arterial control. A traditional midline abdominal incision, extending from the xiphoid process to the pubis, can facilitate this in the majority of patients.
- In patients with wide costal margins or an anticipated need for wide parahepatic or parasplenic exposure, a bilateral subcostal incision (also known as Michigan smile) may also be useful.
- For large abdominal tumors, renal tumors, or tumors with cephalad intraabdominal extension to the level of the diaphragm, a lateral decubitus thoracoabdominal approach to facilitate both adequate tumor exposure as well as vascular proximal control and reconstruction is advised.

Second Step

- Proximal aortic control can often be obtained directly above the anticipated cephalad margin of the tumor. In this circumstance, via either retroperitoneal or transperitoneal approaches, the medial and lateral aortic margins are cleared for a distance of 2 to 3 cm proximal to the tumor margin. The exposed segment is inspected for lumbar vessel branches, which may be externally ligated as necessary to aid in exposure and control. A large, slightly curved vascular aortic clamp (e.g., DeBakey aortic occlusion clamp) is best suited to obtain proximal aortic control.

- Supraceliac or suprarenal aortic exposure may be necessary for optimal control (**FIG 1**).
- For control of the supraceliac aorta, the peritoneal cavity is entered below the level of the xiphoid process. With cephalad retraction of the left lobe of the liver, the left triangular ligament of the liver is divided and the lesser sac is entered via a longitudinal incision in the gastrohepatic ligament. Care should be taken here to avoid injury to the esophagus (identified by aid of orogastric/nasogastric tube placement) or a replaced left hepatic artery. For additional exposure, the median arcuate ligament and the right crus may be divided (**FIG 1**).
- Suprarenal aortic control is obtained following circumferential dissection and mobilization of the left renal vein off the ventral surface of the aorta. Left renal vein inferior lumbar branches should be ligated to facilitate mobilization. In rare circumstances, the left renal vein may need to be ligated during this maneuver. When this is anticipated, existing collateral veins such as the left gonadal, adrenal, or lumbar should be intentionally preserved prior to division of the left renal vein.
- Infrarenal aortic exposure can be achieved either via transperitoneal or retroperitoneal approaches. If the tumor has pelvic extensions or if exposure/control of the right iliac system is anticipated, a transperitoneal approach may be preferable.

Third Step

- Depending on the extent of aortic tumor involvement, durable repair may be achieved using either patch angioplasty or interposition grafting.
- Patch repair is commonly performed with a woven Dacron, bovine pericardium, or autogenous femoral vein. The patch is fashioned in a manner to facilitate a wide repair without narrowing the residual the aortic lumen. The anastomosis is usually performed with 4-0 Prolene sutures, in a running fashion, with one suture starting

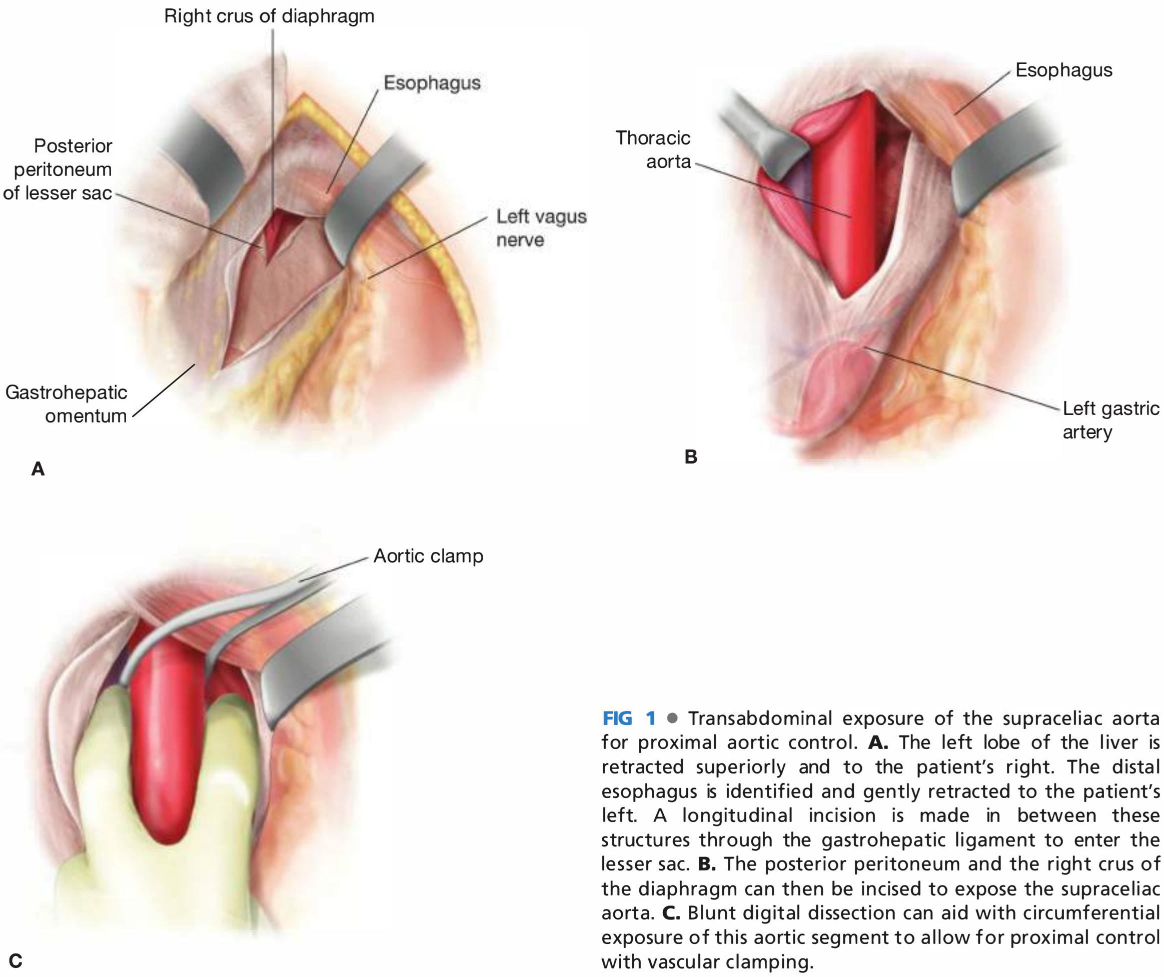

FIG 1 ● Transabdominal exposure of the supraceliac aorta for proximal aortic control. **A.** The left lobe of the liver is retracted superiorly and to the patient's right. The distal esophagus is identified and gently retracted to the patient's left. A longitudinal incision is made in between these structures through the gastrohepatic ligament to enter the lesser sac. **B.** The posterior peritoneum and the right crus of the diaphragm can then be incised to expose the supraceliac aorta. **C.** Blunt digital dissection can aid with circumferential exposure of this aortic segment to allow for proximal control with vascular clamping.

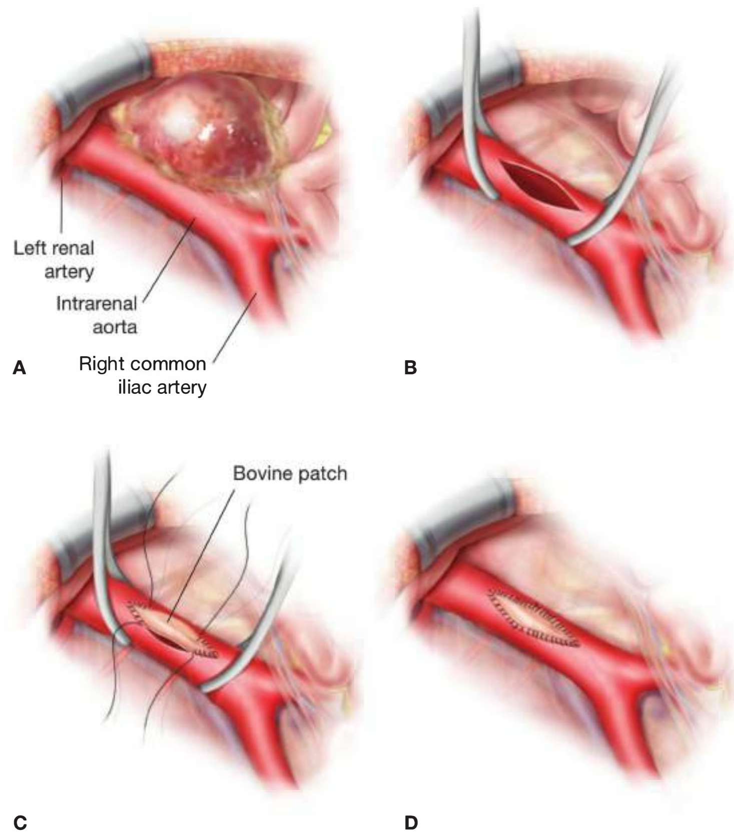

FIG 2 ● Patch angioplasty repair of infrarenal aorta. **A.** Transabdominal exposure of the infrarenal abdominal aorta and adjacent tumor mass. **B.** Following proximal and distal aortic control, mass is removed along with associated aortic wall. **C,D.** Aortotomy repaired with a abovine pericardial patch.

from each end of the patch repair. Depending on the age of the patient, presence and extent of retroperitoneal soilage by intestinal contents, and amount of retroperitoneal inflammation present, polyester pledgets may be required to minimize suture-related aortic injury and needle hole bleeding (**FIG 2**).

- Alternatively, when more extensive aortic segments are involved or the tumor cannot be safely mobilized circumferentially around the aorta, interposition grafting may be more appropriate. After resection, the residual aorta should be inspected for any intimal defects, tumor infiltration, or intraluminal thrombus. Once clean endpoints are determined, the interposition graft of choice can be brought to the field. Conduit choices include autogenous vena cava or spliced femoral veins, cryopreserved homogenous arterial conduit, or knitted or woven polyester and expanded polytetrafluoroethylene (ePTFE). Once selected, the proximal end is fashioned in such as way as to minimize diameter differences between the aorta and graft. The anastomosis is usually performed with a running 3-0 or 4-0 polypropylene suture. Once completed, the proximal clamp is temporarily released to allow the conduit to be routed in such a way to avoid redundancy, kinking, or twisting. After reclamping of the graft (to avoid repeated aortic clamping), the distal anastomosis is completed in a similar fashion after sufficient proximal and distal flushing maneuvers (**FIG 3**).
- Autogenous tissue repairs of the aorta are preferred in circumstances where intestinal continuity has been interrupted. However, if autogenous tissue is not available or not adequate for use, gel-impregnated woven polyester graft material immersed in rifampin solution is the prosthetic conduit of choice. To achieve adequate coverage, the graft is immersed in 50 mL of normal saline containing 600 mg of rifampin for at least 30 minutes.
- If the paravisceral or pararenal aorta reconstruction is required, visceral and renal vessels can be reimplanted to the interposition aortic graft. Alternatively, a premanufactured or surgeon-modified branched aortic graft can be used to facilitate end-to-end anastomoses to the visceral or renal vessels following aortic interposition graft repair, with side limbs typically 6 to 8 mm in diameter (**FIG 3**).

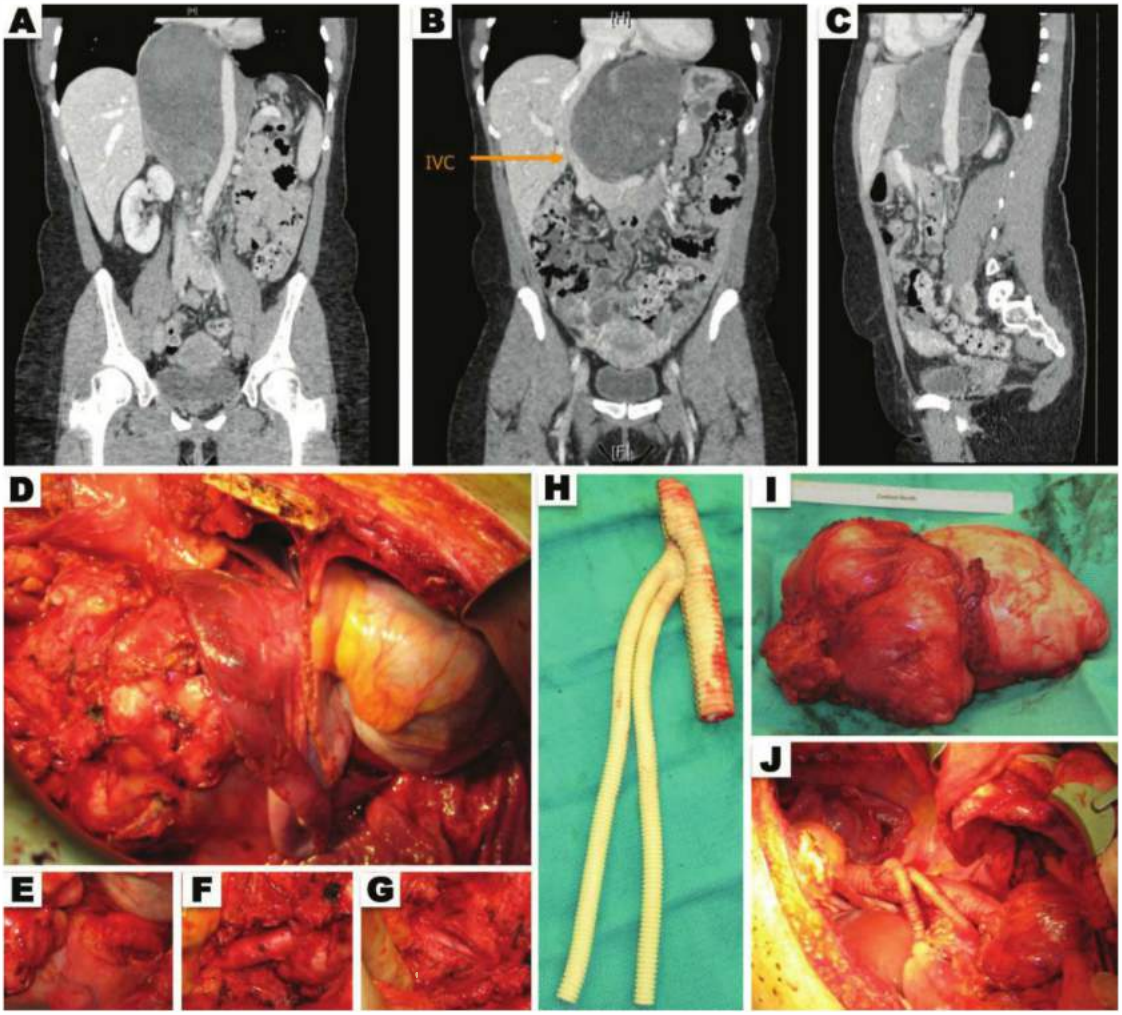

FIG 3 ● Branched aortovisceral repair following resection of a large retroperitoneal thoracoabdominal myxoid sarcoma mass. **A.** Coronal abdominal computed tomography (CT) demonstrates large thoracoabdominal and mediastinal mass directly adjacent to major organ structures and the paravisceral aorta. **B.** CT demonstrates retroperitoneal portion of tumor mass displacing IVC toward the patient's right. **C.** Sagittal CT demonstrates circumferential involvement of the paravisceral aorta with the tumor mass. **D**. Left thoracoabdominal exposure reveals a large retroperitoneal mass extending proximally directly underneath the diaphragm. The supradiaphragmatic aorta **(E)**, proximal left renal artery **(F)**, and proximal SMA **(G)** were all exposed to facilitate tumor resection and aortic branched repair. **H.** Aortic branch graft was constructed on the operative back table by attaching a 14-mm bifurcated Dacron graft to the side of a 16-mm Dacron tube graft. Following en bloc resection of the mass along with associated aortic segment **(I)**, the resected aortic segment was then repaired with the constructed graft. Branches were used for end-to-end anastomosis to the left renal artery and SMA.

SUPERIOR MESENTERIC ARTERY RECONSTRUCTION

First Step

- Exposure of the SMA, in situations where it is involved with the tumor, may be performed jointly with the surgical oncology team. Particularly in situations where the SMA is extensively involved, sufficient vascular control should obtained prior to significant debulking or resection maneuvers.
- To expose the SMA at the base of the mesentery, the transverse colon and omentum are elevated while packing the small bowel to the right. The peritoneum is then incised at the base of the transverse mesocolon, taking care to identify and preserve the middle colic and jejunal arterial branches. Judicious cephalad retraction of the inferior border of the pancreas may also improve exposure (FIG 4).

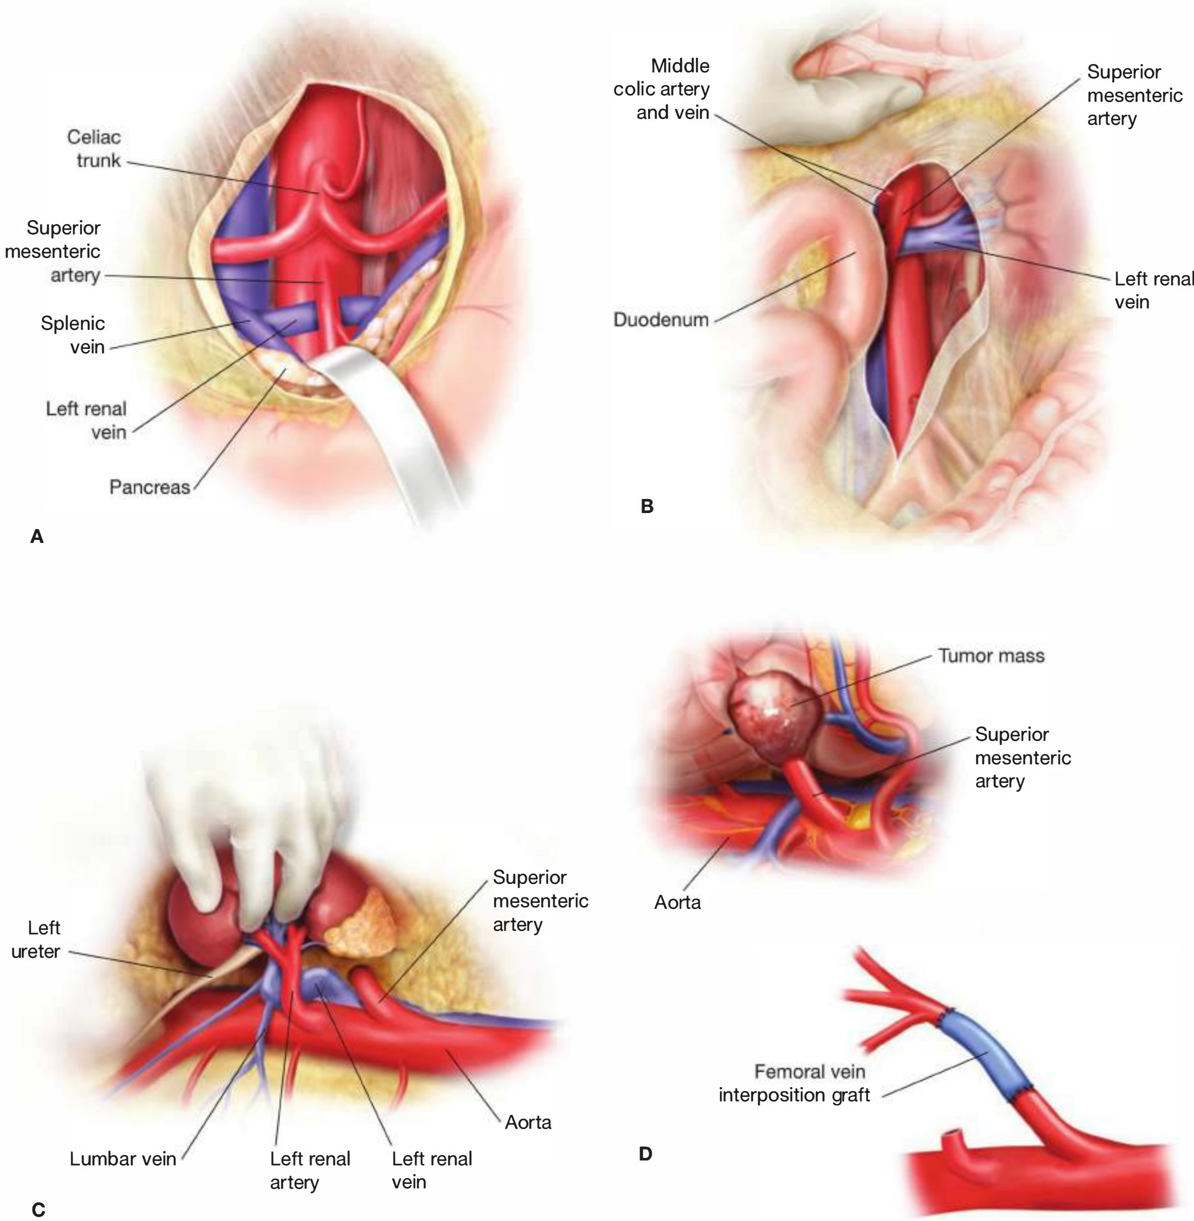

FIG 4 ● Transabdominal exposure and reconstruction of the SMA. **A.** The origin of the SMA may be exposed with mobilization and gentle retraction of the superior border of the pancreas along with extended cephalad exposure of the aorta to the level of the celiac trunk. **B.** Alternatively, the SMA can be exposed from a lateral approach with division of the ligament of Treitz and right lateral mobilization of the fourth portion of the duodenum. **C.** Exposure can be enhanced with gentle cephalad retraction of the inferior border of the pancreas and ventral mobilization of the left kidney. Care should be taken to not avulse left renal vein lumbar, gonadal, or adrenal branches during mobilization of the left kidney. **D.** Tumor mass resection with associated segment of SMA. The arterial segment is repaired with an autogenous interposition greater saphenous vein graft.

- Alternatively, proximal SMA exposure may be gained laterally, following division of the ligament of Treitz and mobilization of the fourth portion of the duodenum. Visualization of the underlying SMA can be further enhanced with gentle retraction of the inferior border of the pancreas to the level of the left renal vein (**FIG 4**).
- The splanchnic nerves must be sharply excised to effectively elevate the SMA off the anterior aortic wall.

Second Step

- Reconstruction approach is dictated by the extent of tumor ingrowth. SMA involvement may be tangential or require segmental resection to achieve appropriate tumor margins.
- Partial SMA involvement may only require resection and reconstruction of one of the SMA walls. With arterial control established, the tumor tissue and involved SMA can be sharply resected en bloc. Following inspection to ensure a disease-free patent lumen, the arteriotomy is repaired with a patch angioplasty technique. Autogenous vein is the preferred patch material when available, especially following interruption of intestinal continuity. When alimentary tract continuity is not disrupted, bovine pericardial tissue, polytetrafluoroethylene (PTFE), or polyester patch may be used for repair. 6-0 polypropylene monofilament suture is a good choice for arteriotomy closure and repair.

Third Step

- More extensive tumor involvement with the SMA may require segmental resection and interposition grafting. Variables to consider include the length of the defect, whether the SMA origin is also involved, and conduit material available for repair.
- For short segment replacement, reversed greater saphenous vein is the preferred conduit for SMA grafting. Appropriately sized saphenous vein is usually harvested from the thigh, distended, and prepared for interposition. The tumor tissue is resected en bloc with the involved segment of SMA. Following confirmation of adequate margins, sequential end-to-end proximal anastomosis is performed. The graft is then brought to length while avoiding any twisting or kinking of the graft. The distal end-to-end anastomosis is then similarly performed. Spatulation of both the arterial endpoints and saphenous conduit may or may not be helpful, depending on size discrepancy.
- For long segment resections or resections involving the origin of the SMA, a long retrograde "question mark" graft, so named for its appearance on contrast arteriography following the procedure, is used to route arterial blood from the right iliac artery around the base of the mesentery to the distal SMA. Alternatively, an antegrade bypass from the supraceliac aorta may be tunneled posterior to the pancreas and brought out coaxially along the course of the distal SMA. Finally, when the SMA origin is involved but sufficient distal SMA is present to allow mobilization, the SMA may be reimplanted on the distal aorta if a disease-free segment can be identified by palpation or from assessment of preoperative imaging studies. For bypass options under these circumstances, cryopreserved arterial homograft or 6-mm polyester or externally supported PTFE are typically preferred conduits. Care is once again taken to avoid conduit twisting or kinking during placement or tunneling.
- Although a potential option, direct bypass from the region of the origin of the SMA to the distal mesenteric artery is problematic in that fashioning the bypass requires elevation of the mesentery, with the distal anastomosis positioned on the posterior aspect of the distal mesenteric artery. Although the graft may function well with the mesentery elevated, reduction of the intestines into the abdomen invariably causes graft conduit, autogenous or prosthetic, to kink and potentially thrombose. In this circumstance, it is almost impossible to fashion an interposition graft of appropriate length, so approaches such as retrograde grafting or reimplantation should be considered as preferred alternatives.

SUPERIOR MESENTERIC VEIN OR PORTAL VEIN RECONSTRUCTION

First Step

- Exposure of the portal vein is facilitated via entry of the peritoneal cavity and interruption of the umbilical vein and falciform ligament. The porta hepatis can be better visualized with cephalad retraction of the right lobe of the liver, downward retraction of the colonic hepatic flexure, and medial mobilization of the first and second portions of the duodenum. The portal vein is then easily identified in the right posterior border of the hepatoduodenal ligament. This exposure can be extended from the hilum of the liver to the head of the pancreas inferiorly. Inferiorly, care should be taken to identify and preserve the coronary vein and splenic vein (**FIG 5**).
- In most instances, the neck of the pancreas is divided as part of the tumor exposure and resection, which improves caudal exposure of the portal vein, splenic vein, and SMV.
- Exposure of the SMV can be achieved via exposure distal to the splenic vein confluence or via similar techniques used to expose the SMA. At the base of the transverse mesocolon, the SMV can be found lying to the right of the SMA near the midline. Multiple dense lymphatics overlying the vein often require careful dissection and meticulous control. Care should also be taken to identify and preserve the middle colic vein proximally and ventral venous tributaries distally (**FIG 5**).

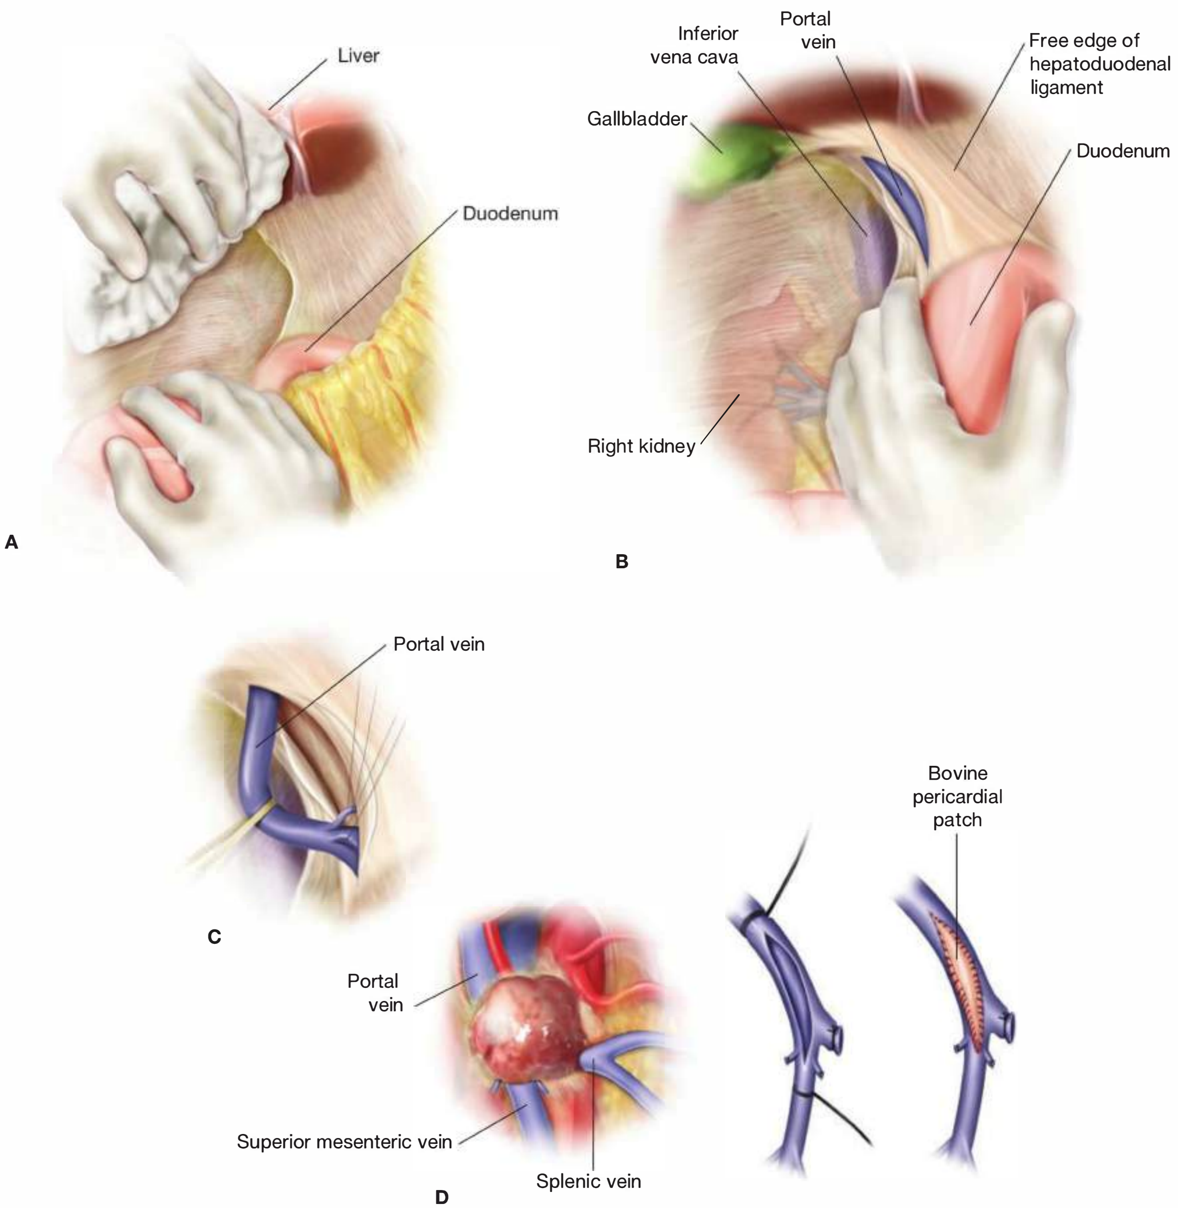

FIG 5 ● Transabdominal exposure and reconstruction of the portal vein and SMV confluence. **A.** With cephalad retraction of the right lobe of the liver, the posterior peritoneal attachments of the first and second portions of the duodenum may be visualized. **B.** The portal vein and proximal SMV may be exposed through a longitudinal incision along the lateral free aspect of the hepatoduodenal ligament. **C.** Venous tributaries draining into the portal vein and SMV confluence may be ligated to facilitate exposure and reconstruction of this venous segment. **D.** Tumor mass resection with associated ventral segment of the portal vein and SMV confluence and repair with a patch venoplasty using a bovine pericardial patch.

Second Step

- The extent of tumor involvement with the SMV and portal vein is variable. Reconstruction is often required to preserve mesenteric outflow.
- Following establishment of vascular control, en bloc resection of the tumor and associated venous structures can be performed. Partial involvement is best managed via patch venoplasty. Preservation of an intact back wall of the splenic SMV confluence is often beneficial in maintaining the structural integrity of the bifurcation. SMV and portal vein patch venoplasty repairs can be performed using autogenous saphenous vein or bovine pericardium. A 6-0 polypropylene suture repair is used to close the vein, running or interrupted (**FIG 5**).
- Tumor involvement requiring complete resection of the portal vein or SMV will require interposition graft reconstruction. Interposition grafting with autogenous superficial femoral vein or cryopreserved venous homograft is preferred when intestinal resection and reconstruction is anticipated. Alternatively, 6- or 8-mm ringed PTFE when venous conduit is unavailable or inadequate. The distal end-to-end anastomosis is completed first, followed by the proximal end, with either interrupted or triangulated running sutures to prevent purse-stringing and anastomotic narrowing (**FIG 5**).

INFERIOR VENA CAVA RECONSTRUCTION

First Step

- Infrahepatic IVC exposure can be facilitated either through right retroperitoneal or transperitoneal exposure. Exposure is typically dictated by the extent of other planned intraabdominal procedures and anticipated tumor resection margins.
- For right retroperitoneal exposure, the flank is elevated to 15 to 20 degrees with the patient positioned in the supine position. A transverse incision can then be made extending from the rectus abdominis to the tip of the 11th or 12th rib. The external oblique, internal oblique, transversus abdominis muscles, and transversalis fascia are divided to create the retroperitoneal plane via blunt dissection. With judiciously placed self-retaining retractors, a 6-cm segment of the right lateral aspect of the pararenal and infrarenal vena cava may be easily exposed (**FIG 6**).
- For a transperitoneal exposure, either a midline laparotomy or bilateral subcostal incision will facilitate adequate exposure. Once the peritoneal space is entered, the small bowel is retracted to the left and the lateral peritoneal attachments of the right colon are divided. This facilitates medial mobilization of the right colon and mesentery and provides access to the retroperitoneal attachments of the second and third portions of the duodenum. Once these attachments are divided, the underlying vena cava can then be adequately exposed from the suprarenal level to the common iliac veins. Ligation and division of the ventral pararenal lymphatics, right lateral lumbar veins, and anterior crossing left gonadal vein will aid in caval mobilization during proximal and distal circumferential dissection. Vascular tapes may be placed around the proximal and distal exposed segments of the vena cava to facilitate vascular control. Care should be taken to not avulse medial lumbar veins with over aggressive mobilization of the vena cava during these maneuvers (**FIG 6**).
- For extended retrohepatic IVC exposure, a right thoracoabdominal incision may be performed with the patient positioned in a left lateral decubitus position. Once the peritoneal cavity is entered, the right triangular ligament and lateral and posterior peritoneal attachments to the right hepatic lobe can be divided. Medial retraction of the right hepatic lobe can then be performed to facilitate visualization of the lateral surface of the retrohepatic IVC (**FIG 6**). Hepatic compression here, especially following placement of self-retaining retractors, can increase hepatic congestion and ischemia and should be minimized to the greatest extent possible. In situations where caval visualization is not adequate despite optimal hepatic retraction, proximal extension or even division of the sternum may be necessary to facilitate safe exposure. Once adequate exposure is achieved, circumferential control can be achieved following ligation and division of small hepatic venous branches that course between the caudate lobe of the liver and the IVC in this region.
- The suprahepatic IVC can be exposed following ligation and division of the round ligament and wide division of the falciform and coronary ligaments. Caudal retraction of the bare dome of the liver facilitates visualization of the suprahepatic vena cava and at least two of the three main hepatic veins. Careful dissection of the areolar tissue surrounding these veins allows for circumferential exposure of each of these veins as well as this segment of the vena cava.

Second Step

- Once the vena cava is controlled both proximally and distally, the tumor mass can be dissected off other pertinent structures to facilitate en bloc resection. Systemic anticoagulation is accomplished with unfractionated heparin sulfate (100 units/kg intravenous infusion) and reversed with protamine sulfate, 1 mg/100 units of heparin, when vascular reconstruction or retraction is complete.
- Prior to removal of the tumor mass, the patient is placed in Trendelenburg position and vascular clamps positioned proximal and distal to the anticipated margins of resection. If the involved segment of the IVC is limited to only a few centimeters or one side wall, a long Satinsky side-biting vascular clamp may be used for partial caval occlusion (**FIG 6**).
- Acute occlusion of the suprarenal or retrohepatic IVC may induce profound hypotension due to significant preload

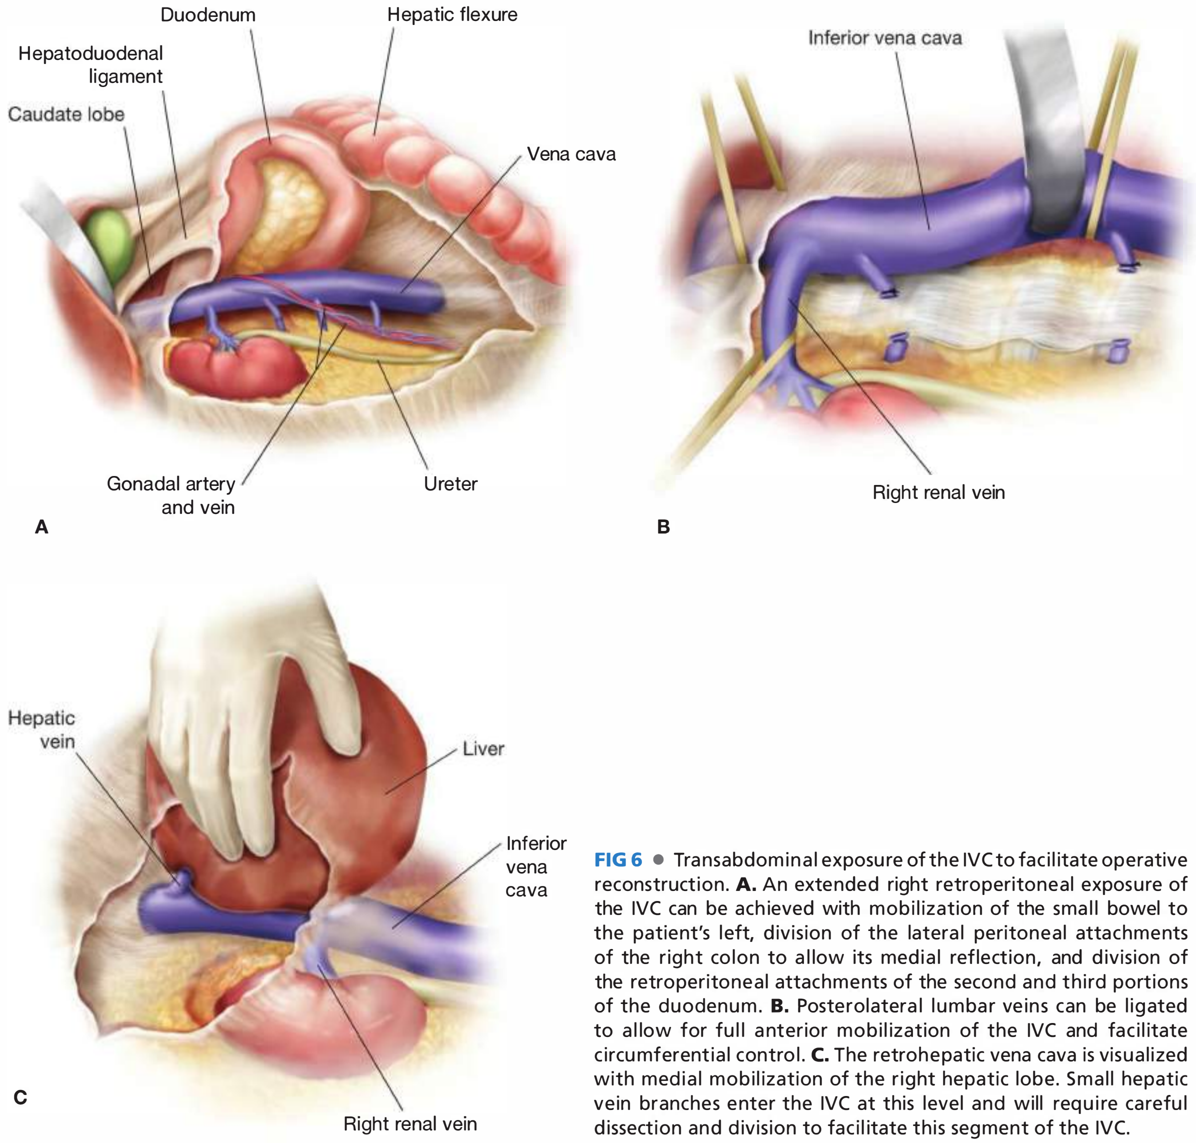

FIG 6 ● Transabdominal exposure of the IVC to facilitate operative reconstruction. **A.** An extended right retroperitoneal exposure of the IVC can be achieved with mobilization of the small bowel to the patient's left, division of the lateral peritoneal attachments of the right colon to allow its medial reflection, and division of the retroperitoneal attachments of the second and third portions of the duodenum. **B.** Posterolateral lumbar veins can be ligated to allow for full anterior mobilization of the IVC and facilitate circumferential control. **C.** The retrohepatic vena cava is visualized with medial mobilization of the right hepatic lobe. Small hepatic vein branches enter the IVC at this level and will require careful dissection and division to facilitate this segment of the IVC.

reduction. In these circumstances, preemptive aggressive fluid resuscitation, gradual clamping of the vena cava, or partial occlusion may be better tolerated. Alternatively, venovenous bypass or atriocaval shunt placement may be necessary. Please refer to prior references for further details regarding preparation and placement of atriocaval shunts.[9,10]

- Specific isolation of the retrohepatic vena cava requires control of both the hepatic inflow and outflow. Inflow control is achieved with cross-clamping of the infrahepatic vena cava as well as with a Pringle maneuver (clamping of the hepatic artery and portal vein). Outflow control is achieved with suprahepatic or infradiaphragmatic clamping of the IVC.

Third Step

- The strategy for reconstruction is dictated by the extent of the IVC defect and the concomitant need for other vascular reconstructions. Typically, the vena cava is repaired, when necessary, following arterial reconstructions to decrease end-organ ischemia. The duration of caval occlusion should be limited to less than 30 minutes to minimize venous congestion and resultant ischemia.
- For small caval defects, primary repair may suffice when the lumen diameter is reduced by less than 50%. Otherwise, autogenous internal jugular vein or bovine pericardial patch repair may be incorporated into the repair. Lower extremity vein harvest is not preferred for caval reconstruction due to increased risk for distal thrombotic complications.

- For replacement of the IVC, when necessary, interposition graft using externally supported ePTFE is the preferred conduit. Following resection of the involved segment, the transected ends of the vena cava are inspected for any residual disease within the lumen. Controlled sequential flushing of the transected ends also ensures patency. The graft diameter is chosen to be deliberately smaller than the caval segment being replaced to promote higher velocities within the graft segment following reconstruction. The proximal anastomosis is completed first using either a running 4-0 or 5-0 Prolene suture. The distal anastomosis is then similarly performed with the patient in Trendelenburg position. Prior to completion of the distal anastomosis, proximal and distal clamps are sequentially removed, a Valsalva maneuver is induced by the anesthesiologist, and the graft is filled with heparinized saline while flushing is performed to minimize retained air and the risk for air embolization.
- External support rings are maintained to the greatest extent possible to avoid compression of the graft, including at midgraft segments where end-to-side anastomoses are necessary for renal vein or common iliac vein reimplantation. For repair of the confluence of the common iliac veins, we have successfully modified this procedure by incorporating a short segment of nonsupported bifurcated ePTFE graft into the repair. Externally supported ePTFE grafts are then sutured to the nonringed segment with ePTFE suture. The suture lines are then covered with BioGlue or sterile Dermabond to prevent suture line bleeding and the graft is then placed in situ (**FIG 7**).

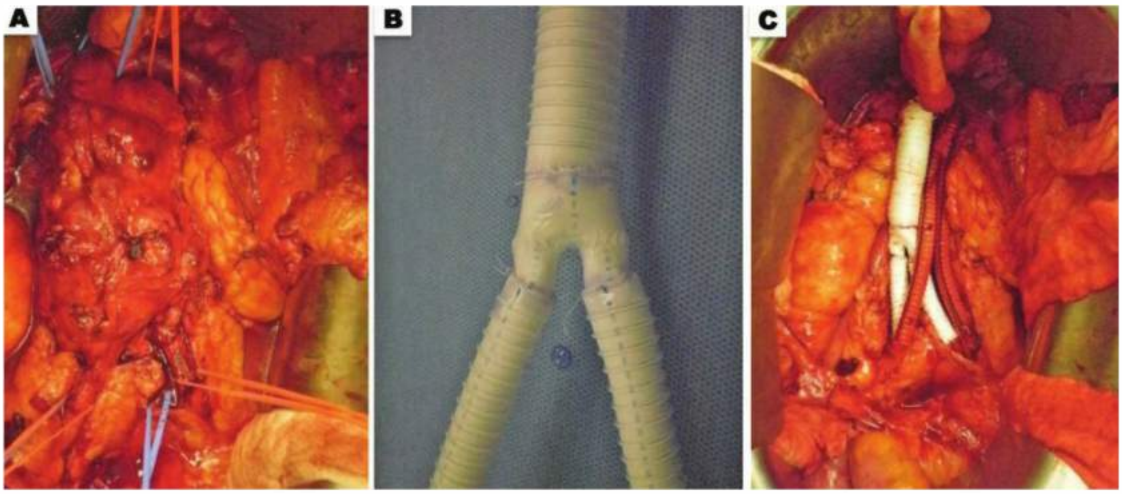

FIG 7 ● IVC and aortic reconstruction in the setting of intraabdominal resection of a large retroperitoneal high-grade leiomyosarcoma. **A.** Operative exploration demonstrated a large retroperitoneal mass with circumferential involvement with the infrarenal aorta and IVC. Proximal infrarenal aorta and distal bilateral common iliac arteries were circumferentially exposed and controlled. The proximal infrarenal IVC and distal left common iliac vein were also controlled. **B.** Back-table construction of a custom PTFE bifurcated graft for reconstruction of the IVC. This was performed by suturing a 16-mm ringed PTFE graft to two 10-mm ringed PTFE grafts using a 6-0 Gore-Tex suture. The anastomosis was reinforced with Dermabond. **C.** Following tumor mass resection along with associated IVC, infrarenal aorta, and proximal bilateral common iliac arteries, the vena cava is reconstructed using the custom-constructed bifurcated PTFE graft. The resected aortoiliac segment was reconstructed using traditional techniques using a bifurcated Dacron graft.

PEARLS AND PITFALLS

Preoperative workup	■ It is imperative that a comprehensive plan for resection and vascular reconstruction be developed and agreed upon by all participating surgical specialties well in advance of the procedure. ■ Adequate preoperative evaluation will facilitate discussion of planned vascular reconstructions as well as the risks and anticipated outcomes of the procedure.
Intraoperative anticoagulation	■ The presence of adequate systemic anticoagulation prior to vascular occlusion is essential to the optimal outcome of the procedure. Anticoagulation may be delayed to minimize tumor bed bleeding during resection but should be established well in advance of planned vascular reconstruction. ■ An activated clotting time (ACT) of greater than 250 seconds is recommended during vascular repairs to avoid thrombotic complications. Reversal of anticoagulation following completion of arterial repairs is also standard practice.

Arterial repairs	■ If the aorta is known to be involved with tumor, it is imperative that proximal control be established well proximal to the anticipated margin of resection. ■ To optimize outcome, the presence and extent of underlying vascular arterial disease should be fully appreciated. For example, complete aortoiliac or aortofemoral reconstruction may be necessary when significant atherosclerotic disease is present in the distal aorta (as an alternative to segmental patching or replacement). Similarly, endarterectomy of residual SMA or celiac artery diseased lumens may be necessary to optimize patency of patch or interposition graft repairs. ■ Attempts should be made to preserve as many SMA and celiac artery branches as possible during vascular reconstruction to maintain adequate bowel perfusion. This is particularly important if concomitant bowel resection is anticipated.
Venous repairs	■ In the setting of complete compression or occlusion of the IVC, the indications for reconstruction following resection may be less compelling. Reconstruction of chronically occluded iliac veins is generally not indicated under any circumstances during oncologic resections—particularly when patients are free preoperatively of significant lower extremity edema. ■ Air embolus is a significant potential complication of extensive venous reconstruction. The risk of air embolization may be minimized when repairs are performed with the patient in Trendelenburg position and with timely Valsalva induction by the anesthesiologist during retrograde flushing maneuvers prior to completion. If a large air embolus is suspected, blood can be aspirated directly from the vena cava or right atrium while the patient is maintained in Trendelenburg and left lateral decubitus position.
Renal vascular repairs	■ Right renal vein reconstruction and/or reimplantation to the vena cava is necessary because there is no adequate collateral venous outflow from the right kidney. During right renal vein reimplantation, the right renal artery should also be controlled and clamped to avoid venous congestion injury to the kidney. ■ Left renal vein can be sacrificed and ligated if the left adrenal and gonadal veins are intact. However, if left kidney venous outflow collaterals were ligated during exposure and reconstruction, the left renal vein should be preserved or reconstructed whenever possible.
Postoperative bleeding	■ In the immediate postoperative period, sudden or acute anemia, abdominal pain, abdominal distension, or hemodynamic instability should be approached with heightened awareness for possible intraabdominal bleeding. ■ Particularly in patients with recent pancreatic reconstructions, bowel-associated leaks may compromise arterial/venous repairs and can lead to acute catastrophic bleeding requiring urgent intervention.
Methods to avoid lower extremity edema	■ Patients are prone to increased lower extremity edema following lower extremity venous harvest or intraabdominal vena cava reconstructions. For these patients, lower extremity elevation in the immediate postoperative period is recommended. ■ Early compression therapy of the lower extremity can also significantly minimize the extent of lower extremity edema in the perioperative period. Arterial insufficiency should be ruled out prior to initiation of compression therapy to avoid compromise of already limited arterial inflow.

POSTOPERATIVE CARE

- Patients are typically managed in a monitored setting where periodic vascular examination is available and vasoactive agents are administered as necessary to maintain homeostatic arterial perfusion pressure.
- Intravenous fluid resuscitation is maintained in the short-term perioperative period until the patient resolves an anticipated course of intestinal ileus.
- All patients should be initiated and maintained on an antiplatelet agent, typically 325 mg aspirin daily.
- In patients who preoperatively received therapeutic anticoagulation, this should slowly be restarted 1 to 2 days following the patient's operation to minimize perioperative bleeding complications.
- Patients with large PTFE interposition caval grafts are typically anticoagulated for at least 6 months postoperatively and potentially lifelong depending on risk factors, history of prior DVT, and extent of reconstruction required to restore caval continuity.
- Early mobilization and DVT mechanical and/or chemical prophylaxis should be initiated as soon as safely possible in the postoperative period.

OUTCOMES

- Abdominal tumor resection with vascular reconstruction is feasible for many malignancies previously deemed unresectable.
- In a series of 47 patients who underwent IVC reconstruction with en bloc tumor resection, there was an 80% 5-year patency rate of the vascular reconstruction and a 45% 5-year survival.[11]
- In a series of 17 patients with SMA and portal vein reconstructions with pancreatic mass resection, there was an 88% primary patency rate. Two patients returned to the operating room for vascular-related complications. Eighty-two percent of patients were reported alive over follow-up period (4 to 48 months).[12]
- In a series of 14 patients receiving retroperitoneal sarcoma resection and major arterial and venous reconstruction, primary

arterial patency was 58% and primary-assisted patency was 83%. Venous patency was 78%. Local recurrence occurred in 21% of patients and 5-year disease-free survival was 52%.[13]

- In a series of 141 patients who underwent resection of retroperitoneal soft tissue sarcomas with either major arterial or venous structure involvement, arterial continuity was retained in all patients and venous continuity was retained in 80%. Perioperative morbidity was 36% and mortality was 4%. Midterm arterial patency was 88.9% and venous patency was 93.8%. The overall 5-year patient survival was 66.7%.[14]

COMPLICATIONS

- Intraoperative bleeding
- Perioperative infection
- Thrombosis or occlusion of repair or graft site
- Venous air embolism
- Wound complications due to poor nutrition or possible radiation to operative field
- DVT from hypercoagulable state

Chapter 21

Hepatic- and Splenic-Based Renal Revascularization

Fred Weaver   Sung Wan Ham   Grace Huang

DEFINITION

- The hepatic and splenic arteries represent suitable alternative inflow sources for renal artery revascularization. The most common indications for basing bypass procedures from these arteries include abdominal aortic occlusion or insufficiency or, alternatively, a scarred or hostile periaortic retroperitoneum. Hepatic- or splenic-based renal revascularization also minimizes increases in cardiac afterload induced by aortic cross-clamping, which may be of benefit in patients with congestive heart failure. Alternative terms for hepatic- or splenic-based renal revascularization include hepatorenal bypass, splenorenal bypass, splanchnorenal bypass, or extraanatomic renal revascularization.

DIFFERENTIAL DIAGNOSIS

- Renal revascularization is most commonly performed to alleviate "resistant" renovascular hypertension. Resistant hypertension is defined by a systolic blood pressure greater than 140 mmHg in patients taking at least three antihypertensive medications, representing 5% to 10% of all hypertensives. A subsegment of these patients has secondary hypertension due to renal artery pathology or endocrine tumors. Alternative causes of resistant hypertension include
  - Renal artery
    - Atherosclerosis
    - Aneurysm
    - Arteriovenous fistula
    - Fibromuscular dysplasia
    - Takayasu arteritis
    - Other vasculitides involving the renal artery (i.e., Behçet's syndrome, polyarteritis nodosa)
    - Trauma
  - Endocrine tumors associated with hypertension
    - Pheochromocytoma
    - Primary aldosteronism
    - Cushing's syndrome
    - Primary adrenal hyperplasia
    - Hyperthyroidism
    - Acromegaly

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient age: In younger patients, renovascular hypertension generally arises from nonatherosclerotic pathologies, such as Takayasu's arteritis or fibromuscular dysplasia. In patients older than 50 years of age, atherosclerosis is most common etiology.
- Associated risk factors are those typical for all occlusive arterial disease: tobacco use, diabetes, hyperlipidemia, and hypertension.
- Length of the hypertensive diathesis: Was the hypertension easily controlled for a period of time, with a recent increase in the difficulty of control? Is the hypertensive diathesis severe and recent in onset? If either is true, the patient is more likely to have a secondary hypertension.
- Recognition of the systemic burden of vascular disease present provides important perspective on indications and treatment options. Many vascular maladies involve multiple vascular beds. Is there evidence of disease involving the carotid artery, lower extremity arterial tree, and/or thoracic and abdominal aorta?
- A history of postprandial pain, significant unintentional weight loss, and food avoidance is suggestive of mesenteric occlusive disease.
- Prior pancreatitis may complicate attempts at splenic-based renal revascularization.
- Prior Hodgkin's disease or other neoplasms requiring mantle or midline abdominal radiation
- For general operative risk considerations, recognition and documentation of the presence of coronary artery disease, previous coronary stents, or surgical coronary revascularization as well as valvular disease and congestive failure is fundamental to surgical planning.
- Documentation of renal function as evidenced by increased serum creatinine, pedal edema, or recent requirement for renal replacement therapy
- Recognition of prior aortic procedures, or intraabdominal nonvascular procedures such as a retroperitoneal lymphadenectomy for testicular cancer, which may complicate retroperitoneal dissection and aortic exposure
- Family history of syndromic aortic diseases such as Marfan's, Ehlers-Danlos, and Loeys-Dietz
- The specific antihypertensive regimen in place prior to surgery needs to be verified and documented.
- To obtain the most accurate baseline measurement, the highest pressure obtained from either arm should be recorded and retained.
- A complete vascular examination must be performed, with particular attention paid to pulse deficits and bruits. In particular, diminished femoral pulses or an abdominal bruit may indicate significant aortic or branch vessel occlusive disease, potentially complicating revascularization plans. The presence of concomitant carotid bruits may suggest carotid occlusive disease that should be assessed prior to renal revascularization. The presence of an aortic aneurysm should be excluded by abdominal palpation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Laboratory assessment of renal function should include, at a minimum, serum creatinine, blood urea nitrogen (BUN), and electrolytes. Baseline glomerular filtration rate can be estimated from the serum creatinine level and body mass index using the Cockcroft-Gault equation.
- The co-occurrence of endocrine syndromes, such as pheochromocytoma or functional adrenal tumors that potentially contribute to resistant hypertension should be evaluated with appropriate serologic studies.

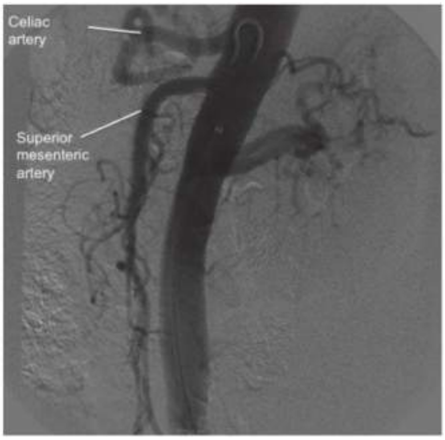

FIG 1 ● Abdominal angiogram with lateral view shows a normal celiac artery.

- Renal artery duplex ultrasonography is performed to document existing renal artery disease, renal mass, and intraparenchymal renal flow indices. Hemodynamically significant renal artery stenosis (>60%) are determined by duplex-derived assessment of peak systolic velocity measurements across lesions. Baseline characteristics (i.e., kidney size, velocity, spectral waveforms, resistive indices) serve as reference points for future surveillance imaging following revascularization.
- Selective visceral and renal arteriograms are obtained to define normal and variant vascular anatomy, including lateral imaging of both the celiac and superior mesenteric arteries (**FIGS 1** and **2**).
- Computed tomography (CT) arteriography of the abdomen and pelvis, with arterial and venous pelvis, may provide additional useful information regarding the extent of aortic disease and other associated abdominal pathology (**FIGS 3** and **4**). Catheter-based arteriography alone may not identify significant arterial wall disease or the presence of aneurysmal lesions. However, the expense, contrast load, and radiation associated with complementary arteriographic imaging modalities may not be justified or appropriate in every patient, so anatomic information obtained from these examinations should be integrated into the operative plan on an iterative basis. Preoperative, imaging-based planning is combined with direct intraoperative assessment to create the most effective and durable revascularization possible for each patient.
- Documentation of celiac, hepatic, splenic, and superior mesenteric artery patency is a mandatory prerequisite for these procedures. Significant stenosis of the celiac origin or hepatic or splenic artery occlusive disease will prevent successful renal revascularization from these arteries. Associated superior mesenteric artery disease also needs to be considered, particularly when the gastroduodenal artery provides significant collateral flow from the celiac plexus to the mesenteric bed. Renal artery anatomy, including branch vessel involvement and the presence of multiple renal arteries also needs to be documented.
- Bilateral lower extremity vein mapping is also necessary to identify potential graft conduit. Standard vein mapping techniques, including imaging in a warm room with the patient in reverse Trendelenburg position, should be employed to ensure accuracy and reproducibility.
- For selected patients, a more extensive preoperative evaluation for coronary artery or valvular disease should be considered. This may include both a transthoracic echocardiogram and cardiac stress evaluation. Selective pulmonary evaluation may be required in patients with chronic obstructive pulmonary disease (COPD)–associated respiratory

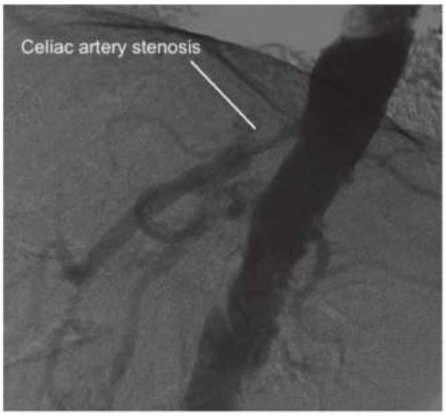

FIG 2 ● Abdominal angiogram with lateral view shows a stenotic celiac artery.

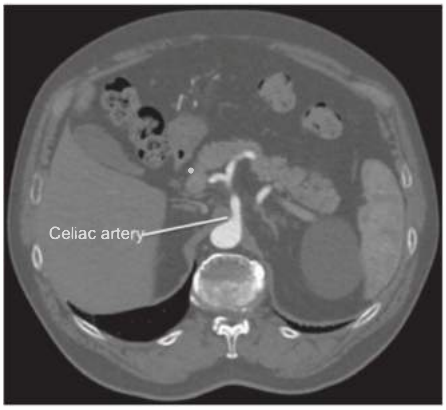

FIG 3 ● Axial CT scan image shows a normal celiac artery origin.

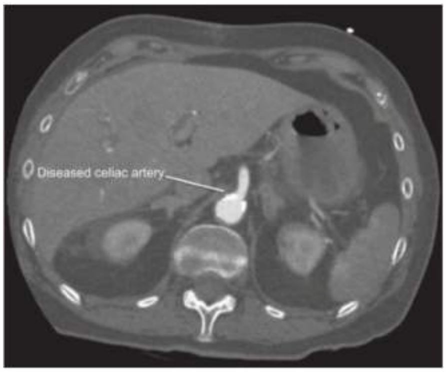

FIG 4 ● Axial CT scan image shows a diseased celiac artery origin.

compromise. Additional vascular assessments should be performed as indicated, including carotid duplex ultrasonography to assess the significance of carotid bruits identified on physical examination.

SURGICAL MANAGEMENT

Preoperative Planning

- The indications for hepatic and splenic artery–based renal revascularization are similar to those for aorta-renal revascularization and are discussed elsewhere.[1,4]
- Although aorta-renal bypass is most direct and generally most expeditious, extraanatomic renal revascularization may be preferable in selected circumstances as previously noted.
- Review of preoperative imaging is performed to determine variant vascular anatomy, if present. Anatomy of the existing renal artery disease is assessed.
- The hepatic–right renal bypass requires a conduit, preferably autogenous vein.
- The spleno–left renal bypass may be performed with or without graft conduit. The native splenic artery is sufficient length, usually to extend directly to the left renal artery, when fully mobilized. When necessary due to variant anatomy, or prior inflammation or scarring around the pancreas, venous conduit can also be employed.
- Planning for availability of duplex ultrasonography in the operating room (OR) will facilitate intraoperative confirmation of adequate target revascularization and renal perfusion.

Positioning

- Patient is placed in supine position with both arms tucked.
- A small bump is placed under the respective flank.
- The operative field is prepped from the nipples to the knees.

HEPATORENAL BYPASS

Placement of Incision

- Optimal access is gained through a right subcostal incision extending from the midline to the tip of the 12th rib. In large or obese patients, the medial extent of the incision can be extended across the midline as a chevron (FIG 5).
- When necessary, an upper midline incision may also provide sufficient exposure.

Hepatic Artery Exposure

- The hepatoduodenal ligament is exposed by retracting the right lobe of the liver cephalad.

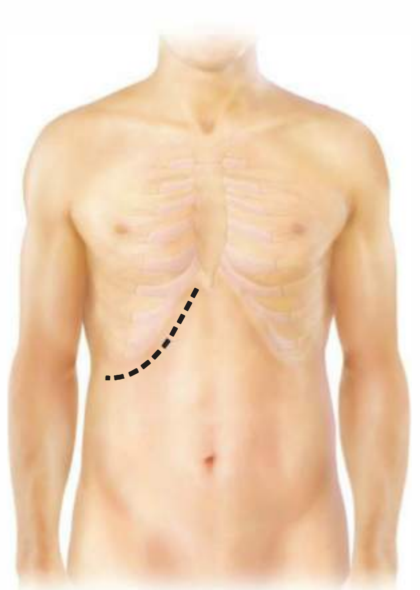

FIG 5 ● Right subcostal incision extended to the tip of 12th rib.

- The right colon and duodenum are reflected anteriorly and to the left (Kocher maneuver). The small intestine is packed toward the pelvis with moist laparotomy pads.
- The hepatoduodenal ligament is incised longitudinally. The hepatic artery is located in the porta hepatis medial to the common bile duct (FIG 6).
- The gastroduodenal artery is identified as the first large branch coursing caudad and encircled with a silastic loop. The gastroduodenal artery should be preserved in the presence of superior mesenteric artery occlusive disease as it provides important collateral circulation to the small intestines.
- The hepatic artery is controlled proximally and distally with silastic loops (FIG 7).

Right Renal Artery Exposure

- The right colon and duodenum are reflected as detailed earlier to expose the inferior vena cava and right renal vein.
- The right renal artery is located posterior and superior to the main renal vein. Depending on its position, the renal vein is retracted either cephalad or caudad. To ensure the main renal artery is exposed, the dissection should be carried to its aortic origin. This requires medial retraction of the inferior vena cava and division of lumbar veins when necessary.
- The right renal artery is controlled using a silastic loop.
- The main renal artery is exposed circumferentially and then distally to the three segmental renal artery branches. Each branch is identified and controlled with a silastic loop. This is a critical operative maneuver that excludes the presence of branch disease and ensures a successful renal artery revascularization (FIG 7).

Distal Anastomosis

- The distal anastomosis is performed first to take advantage of the additional degrees of freedom provided by the mobile graft.
- An appropriate length of greater saphenous vein is harvested from the thigh. The patient is heparinized 100 units/kg. The vein itself is reversed before placement.

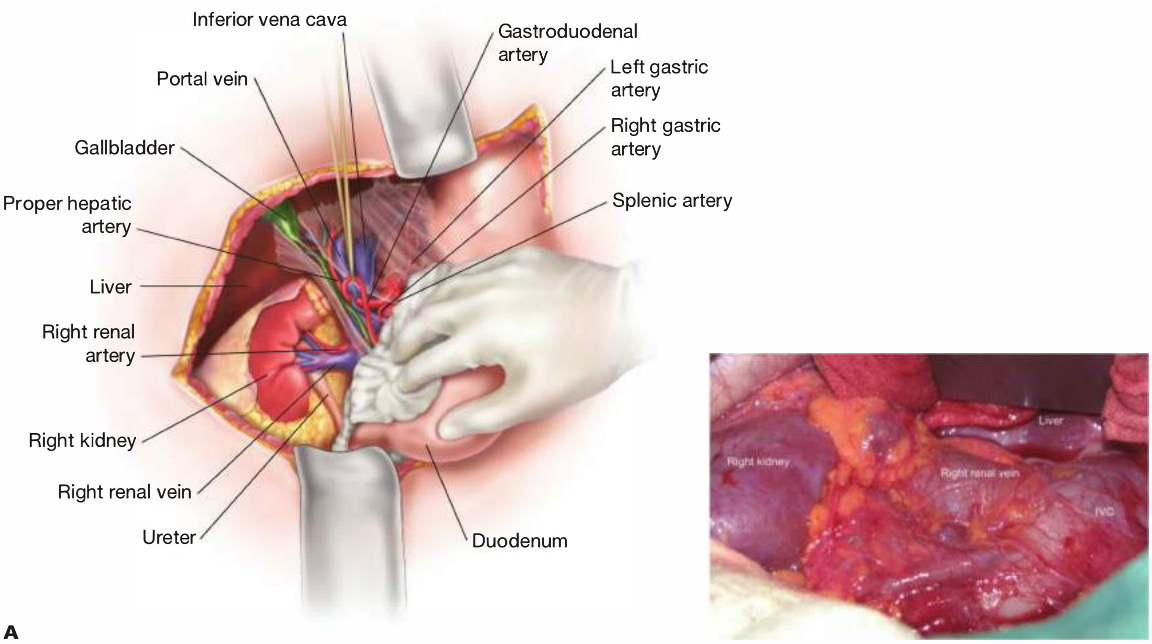

FIG 6 ● **A,B.** Kocher maneuver with porta hepatis dissected. IVC, inferior vena cava.

- The proximal renal artery is mobilized following its division from the aorta, at its origin. The proximal stump is oversewn with 5-0 polypropylene suture.
- Redundant renal artery is trimmed distally from its origin until the disease-free segment is reached. The mobile renal artery is then transposed anterior to the inferior vena cava.
- The vein graft and renal artery are spatulated and the end-to-end anastomosis created with continuous 6-0 polypropylene suture, knotted at opposite ends of

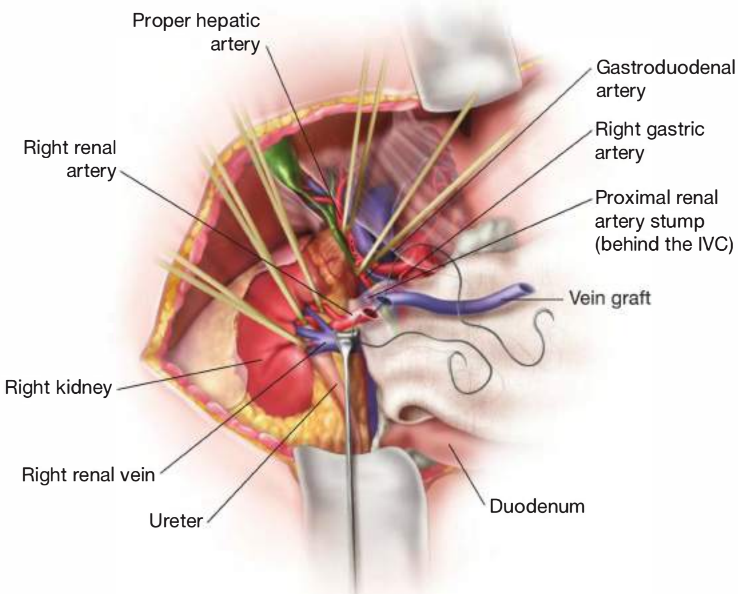

FIG 7 ● **A,B.** Right renal artery and distal branches encircled with silastic loops. Distal anastomosis is performed first. IVC, inferior vena cava. *(continued)*

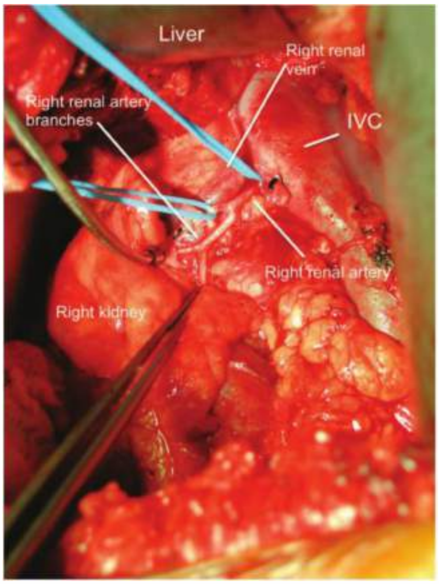

B

FIG 7 ● *(continued)*

the anastomosis to prevent purse-stringing. Alternatively, depending on renal artery diameter, eight interrupted sutures may be distributed circumferentially around the lumen. The smaller the renal artery diameter, the more advantageous the interrupted technique. Loupe magnification is necessary to ensure optimal results regardless of which suture technique is chosen (**FIG 7**).

- Once the distal anastomosis is completed, the vein graft is oriented longitudinally to prevent twisting or kinking prior to completion of the proximal anastomosis.

Proximal Anastomosis

Hepatic artery

- Small vascular clamps or removable clips are used to control the proximal and distal hepatic artery.
- An arteriotomy is made on the hepatic artery and extended using Potts scissors.
- The vein is spatulated and an end-to-side anastomosis is again performed with running polypropylene suture (**FIG 8A**).

Gastroduodenal artery

- The gastroduodenal artery may be used as an alternative inflow vessel if sufficiently large (4 to 6 mm in diameter). This anastomosis may be performed either end-to-end or end-to-side, but prior to division of the gastroduodenal artery, consideration should be given toward its contribution to the mesenteric circulation (**FIG 8B**).

Intraoperative Duplex Ultrasonography

- We recommend insonation of the graft and both anastomoses using appropriately sized 7-MHz scan heads to ensure technical proficiency following completion of the bypass. In recent years, our practice has come to rely on

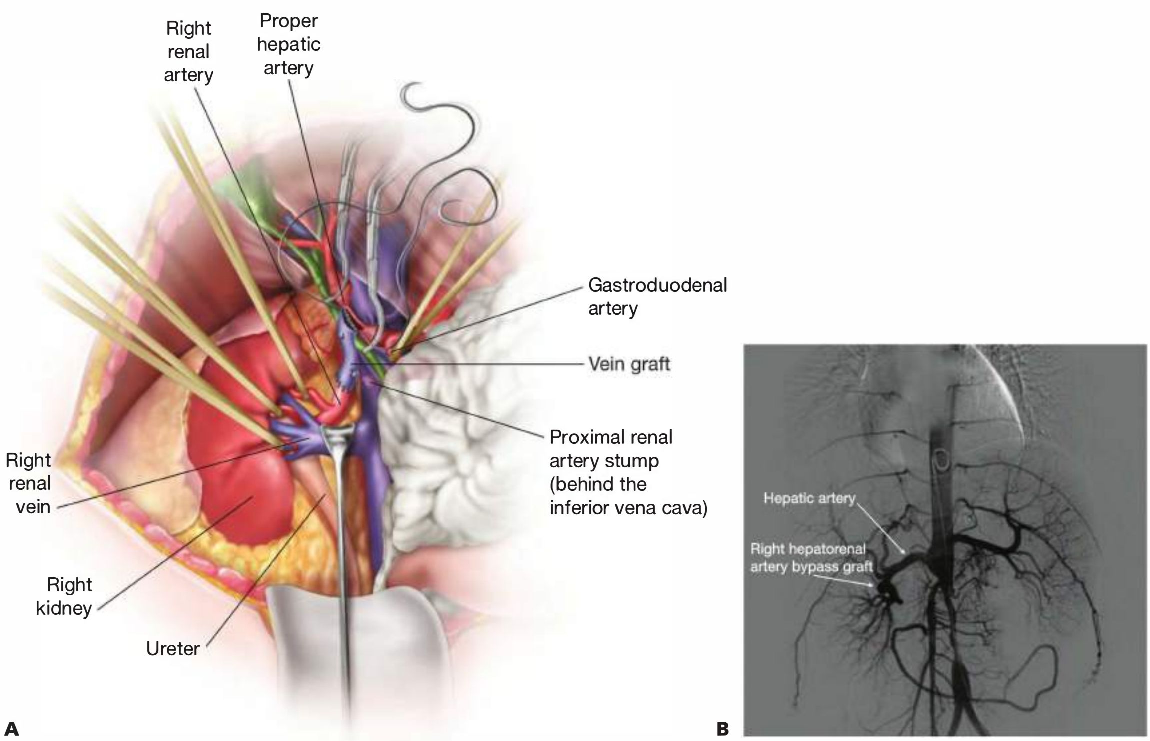

FIG 8 ● **A.** The proximal anastomosis between the hepatic artery and vein graft. **B.** Anterior-posterior angiographic image demonstrates a hepato-renal artery bypass.

duplex ultrasonography for intraoperative assessment of all small and medium size autogenous reconstructions, especially in light of the reduced frequency of such procedures in the era of endovascular and hybrid reconstructions. Renal artery reconstruction is unforgiving in that failure in the perioperative period cannot be expeditiously addressed after the abdomen is closed, almost always precipitating kidney infarction and permanent reductions in creatinine clearance.

- Spectral waveforms, velocities, and B-mode are all employed to detect technical errors requiring immediate repair.

SPLENIC–RENAL BYPASS

Placement of Incision

- Exposure is obtained through a left subcostal incision extending from the midline to the tip of the 12th rib. In large or obese patients, the medial extent of the incision can be extended across the midline as a chevron (FIG 9).
- As was the case on the right side, the upper midline incision may also provide sufficient access depending on body habitus, prior surgeries, and operator experience.

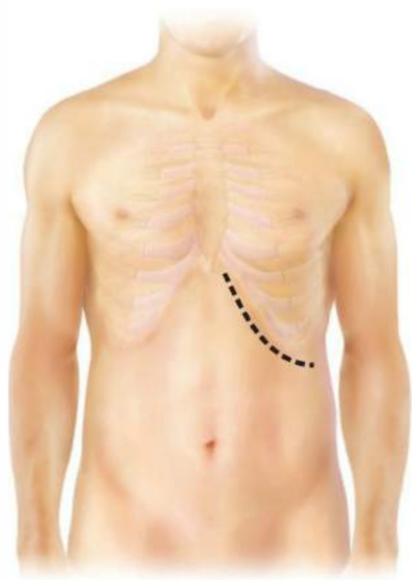

FIG 9 ● Left subcostal incision extended to the tip of 12th rib.

Splenic Artery Exposure

- The greater omentum is elevated exposing the transverse mesocolon. The ligament of Treitz is taken down and the inferior mesenteric vein is ligated and divided. The plane between the pancreas and kidney is entered and the pancreas elevated. The splenic vein is embedded in the body of the pancreas—avoid injury during mobilization of the distal pancreas. The splenic artery should be palpable along the cephalad border of the pancreas. It is mobilized free of surrounding parenchyma moving medially and laterally until sufficient length is obtained to fashion either a primary bypass or support an autogenous vein conduit (FIG 10).

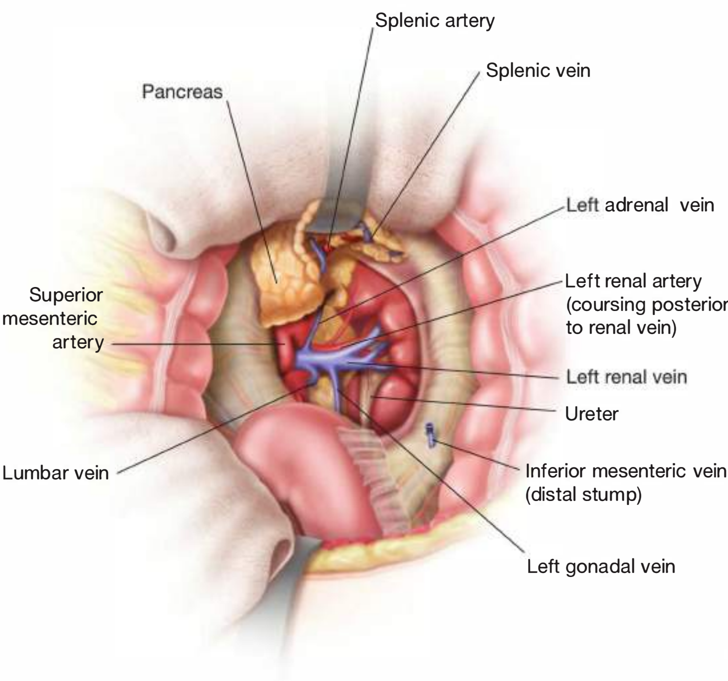

FIG 10 ● Left renal artery and vein exposure. Division of the inferior mesenteric vein allows cephalad retraction of the retropancreatic plane, which allows visualization of the splenic artery.

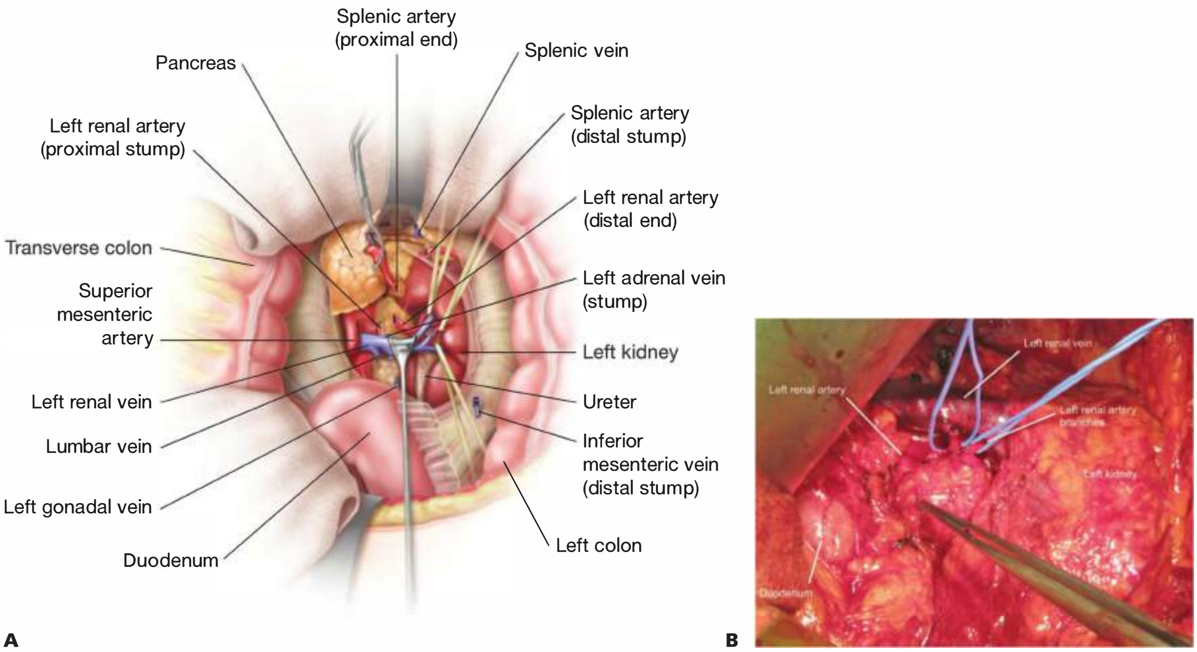

FIG 11 ● **A,B.** The splenic artery and left renal artery are divided. The gonadal, adrenal, and lumbar veins are ligated and divided, allowing complete mobilization of the left renal vein.

Left Renal Artery Exposure

- After mobilizing the distal pancreas, the left renal vein is located just inferior and slightly caudad.
- The left renal vein is circumferentially mobilized. This requires division of its nonrenal tributaries: the gonadal, adrenal, and lumbar veins. Dividing these veins greatly enhances renal vein mobility, facilitating renal artery exposure from its position just cephalad and posterior to the vein.
- As previously described on the right, the left renal artery is dissected to its aortic origin and controlled with a silastic loop. The distal artery and its three segmental branches are identified and encircled with silastic loops. The importance of mobilization is again emphasized (**FIG 11**).

Splenic–Renal Anastomosis

- The patient is heparinized with 100 units/kg of unfractionated heparin. The left renal artery is clamped at the origin and divided. The renal stump is oversewn with a 5-0 polypropylene suture. The distal main renal artery is spatulated distal to the existing renal artery disease.
- The mobilized splenic artery is divided with sufficient length to extend behind the pancreas to the left renal artery without undue tension. The distal splenic artery is oversewn.
- The mobilized splenic artery is spatulated and anastomosed end-to-end to the left renal artery, again with either running or interrupted polypropylene suture depending on the respective arterial diameters (**FIG 12**).
- Alternatively, when splenic artery length is insufficient, reversed saphenous vein may be employed as a bridge graft. Again, to optimize the degrees of freedom, the distal anastomosis is performed first, followed by end-to-end or end-to-side anastomosis to the splenic artery. The vein graft is positioned posterior and inferior to the body of the pancreas.

Intraoperative Duplex Ultrasonography

- As described earlier

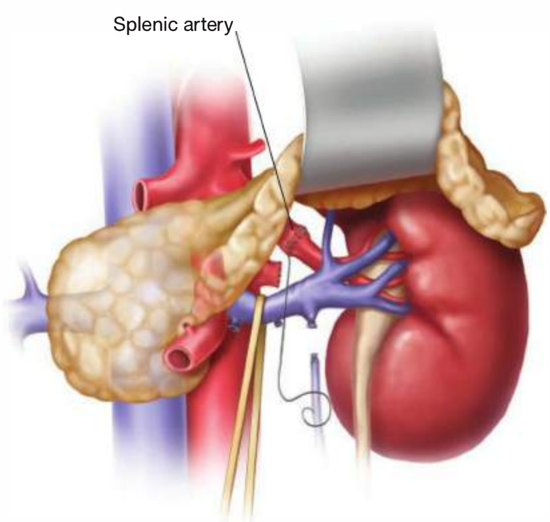

FIG 12 ● Completed anastomosis between the splenic artery and left renal artery.

FINAL INSPECTION

- With completion of the revascularization procedures, all anastomoses and oversewn renal artery origins are inspected for hemostasis. Heparin anticoagulation is reversed with protamine, in a quantity sufficient to normalize the activated clotting time (ACT). Palpation of the SMA at the base of the mesentery is performed to confirm a pulse. Operative traction and/or preexisting disease may compromise SMA flow or precipitate an occult dissection. If the SMA pulse is absent, or the intestinal viability uncertain, mesenteric artery revascularization may be necessary.

PEARLS AND PITFALLS

Preoperative imaging	■ Surgical planning may require CT and catheter-based arteriography as complementary references for surgical planning. ■ Celiac artery stenosis is an absolute contraindication for hepatic- and splenic-based renal revascularization.
Preoperative vein mapping	■ Autogenous vein is the preferred conduit for renal revascularization. ■ Lower extremity vein mapping allows assessment for suitable conduit.
Exposure of the renal artery	■ Circumferential exposure of the entire main renal artery and the three segmental branches is imperative for placement of the renal anastomosis distal to existing disease
Graft orientation	■ Longitudinal orientation needs to be confirmed repeatedly during graft tunneling and orientation. Excessive reliance on graft marking or "striping" as the sole method of orientation may lead to inadvertent kinking or twisting.
Intraoperative duplex	■ Completion duplex scanning is easy, quick, and invaluable in identifying technical errors, which may compromise graft patency and renal viability. ■ Unlike lower extremity bypass procedures, perioperative graft occlusion cannot typically be identified expeditiously to prevent end-organ compromise.

POSTOPERATIVE CARE

- Postoperative care typically involves central venous and arterial pressure monitoring in an intensive care unit (ICU) environment, at least for the first 24 to 48 hours.
- Serial monitoring of serum creatinine, urine output, and acid–base status is essential in the early postoperative period. Unexplained changes in acid–base or elevation of serum creatinine could indicate occlusion of the revascularization itself or progressive mesenteric ischemic.
- Blood pressure is maintained in a physiologic range with vasoactive medications as necessary. Oral antihypertensives are resumed on postoperative day 1 and adjusted depending on the response to renal revascularization.
- Diet is resumed as bowel function returns; nasogastric suction is usually not required.
- Blood pressure and antihypertensive medication requirements may decrease after renal revascularization and should be adjusted prior to discharge.
- Follow-up surveillance duplex ultrasonography is performed at 6 and 12 months then annually thereafter. Detected abnormalities suggesting stenosis of the renal reconstruction may be addressed with remedial endovascular intervention or surgical revision when indicated.

OUTCOMES

- Large case series documenting the outcomes following isolated hepatorenal and splenorenal artery bypass are sparse. Published results are derived from two relatively large series, generally demonstrating acceptable perioperative morbidity and mortality with improved renal function and blood pressure and durable patency.
- Moncure et al. reported 77 patients who underwent 79 procedures (29 hepatorenal, 50 splenorenal bypass) for the treatment of renovascular hypertension and renal preservation. The perioperative mortality was 6%. Deterioration in renal function occurred on three occasions but only in patients with bilateral simultaneous repair. Cure or improvement in hypertension was observed in 52 of 63 patients. Renal function was preserved or improved in 67 of 77 patients.[2]
- Another series by Geroulakos et al. document similar outcomes with extraanatomic renal artery revascularization for atherosclerotic renal artery disease. Forty-five hepatorenal and/or splenorenal bypasses were performed in 38 patients for the treatment of renovascular hypertension, renal preservation, or both. There was one postoperative death from myocardial infarction and two cases of early graft

thrombosis. There was a significant decrease in postoperative mean serum creatinine as well as the average number of antihypertensives. Over a median follow-up of 33 months, there were 10 deaths all from cardiac issues.[3]

COMPLICATIONS

- Bypass graft thrombosis
- Intestinal ischemia due to preexisting disease or traction injury to SMA during operative procedure
- Bleeding from renal, hepatic, splenic anastomosis, ligated renal artery stump, portal vein if injured
- Acute renal failure requiring temporary or permanent dialysis
- Pancreatitis, splenic infarction, common duct injury
- Incisional hernia

Chapter 22

Advanced Aneurysm Management Techniques: Open Surgical Anatomy and Repair

Elizabeth Blazick Mark F. Conrad

DEFINITION

- An aneurysm is defined as a permanent, focal dilation of an artery to a size that is greater than 50% of the normal or expected transverse diameter of the vessel. Although dimensions differ slightly for men and women, practically speaking the normal diameter for the abdominal aorta is 2 cm; therefore, the abdominal aorta is considered aneurysmal when it reaches 3 cm in transverse dimensions.
- *Fusiform* aneurysms are the most common configuration and are a symmetric enlargement of the entire vessel, whereas a *saccular* aneurysm is a focal outpouching that results in an asymmetric bulge of the vessel wall.
- Aneurysms may occur in virtually any vessel in the body but are most commonly seen in the infrarenal abdominal aortic aneurysm (AAA). The *neck* is the length of normal aorta between the osteum of the lowest renal artery and the beginning of the aneurysmal aorta. The term *juxtarenal* is used to describe AAAs that do not involve the renal arteries but because of proximity (<1 cm neck) require clamping above the renal arteries to complete the proximal aortic anastomosis. In a *suprarenal* aneurysm, at least one of the renal arteries arises from aneurysmal aorta, implying the need not only for a proximal clamp but also renal artery reconstruction at the time of the repair (**FIG 1**). This chapter will focus on the indications and techniques for repair of infrarenal and juxtarenal AAA.
- AAA size and/or expansion rate is an important predictor of rupture, and as such guides indication for repair in asymptomatic patients.[1]
- Other predictors for increased risk rupture include female gender, positive family history of aneurysms, smoking status (higher for current smokers versus never smokers and previous smokers), hypertension, and chronic obstructive pulmonary disease (COPD).[2–5]

PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history and physical exam is imperative in the evaluation of a patient being considered for aneurysm repair.
- History of present illness: Determine how the aneurysm was discovered. Often, AAAs are an incidental discovery on an imaging test done for another purpose. Be sure to ask about abdominal or back pain, which may indicate this is a symptomatic aneurysm that would require more urgent repair.
- Past medical history: Patients with concomitant renal, cardiac, or lung disease tend to have more complications perioperatively and should be medically optimized prior to proceeding with elective repair. Although there is no benefit to preoperative cardiac revascularization in asymptomatic patients, those with known cardiac disease or risk factors should be evaluated by a cardiologist.[6]
- Family history: Close to 15% of patients with AAA will have a first-degree relative with aneurysmal disease. Patients with AAA should be counseled to alert their siblings and children to this condition, so they may be screened appropriately.[3]
- Social history: Smoking has been linked to increased risk of aneurysm formation and rate of expansion. Patients should be counseled on smoking cessation.
- Review of systems: In addition to the generalized systems review appropriate for all patients undergoing major surgery, particular attention should be directed to other vascular comorbidities. In particular, query about previous cerebrovascular accident (CVA) or transient ischemic attack (TIA) symptoms, amaurosis fugax, mesenteric ischemia, lower extremity ischemic symptoms (claudication, rest pain, ulcers), and work up positive symptoms as appropriate.
- On physical exam, perform a thorough abdominal exam, although be aware that the positive predictive value for localizing a small- to moderate-sized AAA on exam is poor.

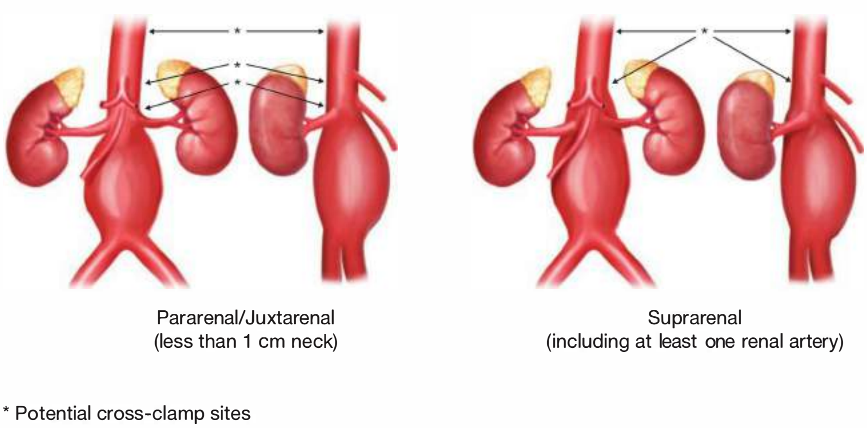

FIG 1 • Anatomic differences between a juxtarenal AAA, where the neck of normal aortic diameter is less than 1 cm, and a suprarenal AAA, where the takeoff of at least one renal artery arises from the aneurysm.

A small proportion (1% to 10%) of patients with AAA will have a concomitant aneurysm elsewhere, so be cognizant that those patients with known AAA and a prominent femoral or popliteal pulse may need further imaging to exclude an aneurysm in these locations.[7]

- Conversely, patients who initially present with peripheral aneurysms such as femoral (85%) or popliteal aneurysms (60%) have a much higher rate of concomitant AAA and aortic screening should be performed in these patients.[7,8]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Of all imaging techniques used for AAA surveillance, B-mode ultrasonography is the least expensive and does not expose the patient to radiation. Currently, the U.S. Preventative Services Task Force (USPSTF) recommends an ultrasound as a screening test for males between the ages of 65 and 75 years who have ever smoked 100 or more cigarettes over a lifetime. There are no official recommendations for women. It is generally accepted that a negative screening ultrasound exonerates the patient from further screening or surveillance imaging, as the likelihood of new aneurysm development of clinical significance after the age of screening is extremely low. If a screening ultrasound detects a small aneurysm, yearly ultrasounds are indicated until the sac approaches a size where repair may be indicated, at which time further imaging with computed tomography (CT) is recommended.[7,9]
- Computed tomography angiography (CTA) provides a more accurate assessment of aneurysm size, extent, branch vessel proximity and involvement (which may determine if the aneurysm is amenable to endovascular or open repair, and if open repair is to be done, where the proximal clamp should be applied) and is the test that should be used for planning open AAA repair. A thorough exam should include thin (1.5 cm or smaller) cuts of the chest, abdomen, and pelvis with contrast administered in the arterial phase (**FIG 2**).
- It is important to note the location of the aneurysm and its relationship to the renal arteries. Renal anatomy should be noted as well, including any accessory renal arteries and the presence of a pelvic or horseshoe kidney. The renal vein usually travels anterior to the aorta but can be posterior and this should be noted as it may influence operative approach. Other venous anatomy such as a duplicated or left-sided inferior vena cava (IVC) should be noted as well.

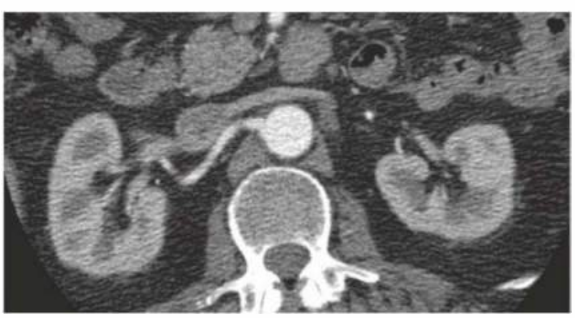

FIG 2 ● Axial cut of a CTA showing the takeoff or the right renal artery and the more commonly seen renal vein lying anterior to the aorta.

SURGICAL MANAGEMENT

- The decision to operate on an asymptomatic patient is based on three primary factors: the risk of the aneurysm's rupturing, the risk associated with aneurysm repair, and the patient's life expectancy. The operative risk and overall life expectancy should be assessed. Assuming that a patient is fit enough to proceed with repair, size is currently our best predictor of rupture. The UK Small Aneurysm Trial and ADAM VA Trial recommend treatment for all patients with an infrarenal AAA larger than 5.5 cm in size, with consideration for repair in women with AAA of 5.0 cm given their higher risk of rupture and likely smaller baseline aortic size. These studies also support repair for those patients who have an increase in diameter of greater than 0.5 cm over a 6-month period (Table 1).[10,11]
- Although there are no large trials looking specifically at iliac aneurysms, repair is generally recommended when they reach 4 cm or greater in size. Iliac aneurysms are more often seen in patients with a concomitant aortic aneurysm and only a quarter of patients with iliac aneurysms will have isolated disease.
- All open repairs should be performed under general anesthesia. It is preferable for the anesthesia team to evaluate the patient prior to the day of surgery so that appropriate time for developing an anesthetic plan, lines, and other means of hemodynamic monitoring is allowed. The use of an epidural for pain control in the postoperative period is useful. In addition, arrangements should be made for autotransfusion given the unavoidable amount of intraoperative blood loss.
- Preoperative understanding of anatomy is of the utmost importance. The surgeon must understand the proximity of the aneurysmal aorta to the renal and visceral vessels and if these branch vessels are affected, as this will impact where the proximal cross-clamp will be applied. If at all possible, clamping should only be done on nonaneurysmal aorta with minimal thrombus or calcification to minimize risk of distal embolization of debris or clamp injury, and all aneurysmal aorta should be resected even if this means involvement of the visceral or iliac segment. If the aorta contains a significant amount of debris or there is little space between branch vessels, a more proximal clamp site in the supraceliac aorta should be considered. It is important to discuss the proposed clamp site with anesthesia preoperatively, as this will affect their management of the patient. The choice of clamp site should be made during the preoperative stage, as the intraoperative need to move the clamp higher is associated with adverse outcomes.

Table 1: Indications for Repair of Abdominal Aortic Aneurysm

- Leak or frank rupture
- Size (5.5 cm in males, 5 cm in females for aortic aneurysm, 4 cm for iliac aneurysms)
- Increase in size of >0.5 cm over a 6-month period
- Symptomatic (pain, compression on adjacent structures)
- Dissection within aneurysm

- Planning for the distal anastomosis requires review not only of the aortic bifurcation but the iliacs as well. If there is aneurysmal or occlusive disease within the iliac arteries, concurrent repair with a bifurcated graft may be appropriate; otherwise, the majority of AAAs are repaired with a tube graft to the iliac bifurcation. Anastomosis may predicate method of distal control, which can be obtained with a single clamp across the bifurcation or both iliac origins, or occlusion balloons (Foley catheters or Pruitt occlusion balloons) for heavily diseased vessels.
- Key pre-operative planning concerns are summarized in Table 2.

Table 2: Operative Planning

- Is a retroperitoneal or transperitoneal approach better?
- Where is the best location for proximal control? Are there any alternatives should intraoperative findings preclude using this site?
- Will clamping involve renal or visceral ischemia?
- Will the renal or visceral arteries need to be reconstructed as part of the repair? If so, what size grafts should be used for the bypass?
- Where is the renal vein? Does it pass anteriorly or posterior to the aorta? Will the kidney be taken up or left down?
- How will distal control be obtained? Will reconstruction involve the iliac arteries or can the distal anastomosis be to the bifurcation?
- What size/type graft should be used?

- There are two approaches for the open repair of the infrarenal or juxtarenal aortic aneurysm: transperitoneal or retroperitoneal (**FIG 3**). Which approach is used for an infrarenal AAA is based on several factors: body habitus (obese patients are often best approached via retroperitoneal), prior surgery (concern for intraperitoneal adhesions), and location of clamp (above the renal arteries may favor a retroperitoneal approach), whereas planned intervention on the right renal or iliac artery would be better approached from the front (transperitoneal).

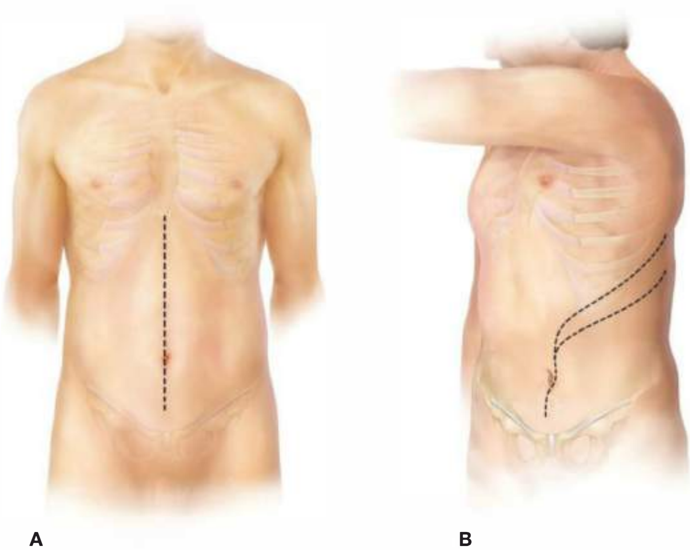

FIG 3 ● Incision for the two approaches to aneurysm repair. **A.** Transperitoneal and **(B)** retroperitoneal. The retroperitoneal approach can be modified for higher exposure on the visceral aorta.

TRANSPERITONEAL APPROACH

- Positioning: The patient is positioned supine on a standard operating room (OR) table with both arms extended. The area from the nipple line to midthighs should be included in the prep field to allow exposure for a high incision as well as the groins should access to the femoral vessels be needed. The hair is clipped and a towel is placed over the perineum. Any previous incisions within the prep field are marked. A Steri-Drape or Ioban is used to secure the drapes in position. Once in position, check pulse volume recording (PVRs) and/or distal pulses.
- Incision: A generous midline incision from the xiphoid to the pubis is made and dissected until the peritoneal cavity is entered (**FIG 3**). It may be necessary to extend the incision cephalad lateral alongside the xiphoid if higher exposure is needed or in emergent situations such as a rupture where immediate supraceliac control is needed. A self-retaining retractor system should then be positioned. We prefer the Omni retractor as the open configuration of the system does not limit the width of exposure.
- Dissection: Reflect the greater omentum and transverse colon cephalad and pack these structures away in a moistened towel or lap pad on top of the patient's chest. The small bowel should be retracted to the right and packed within a separate moistened towel.

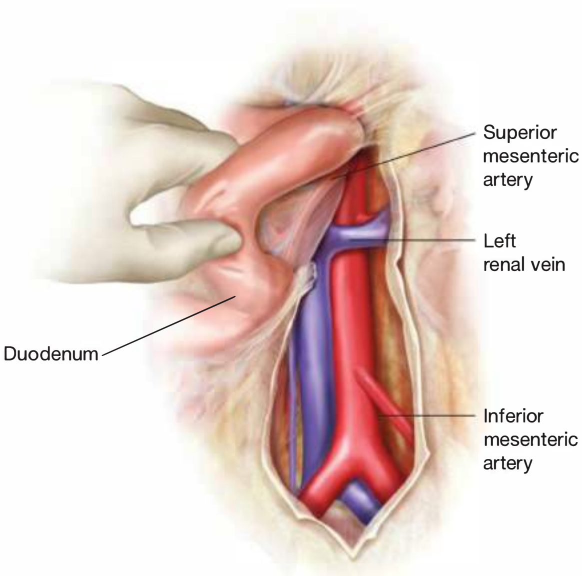

FIG 4 ● Division of the ligament of Treitz (LOT). After reflecting the colon cephalad and the small bowel to the patient's right, the LOT can be divided to expose the infrarenal aorta.

The small bowel is gently placed behind a self-retaining retractor, taking care not to compromise the superior mesenteric artery (SMA). This exposes the ligament of Treitz, which can be divided along the jejunum to the level of the aorta (**FIG 4**). Reposition the retractor to allow as much small bowel to be out of the field as possible, and take down the ligament of Treitz with electrocautery, taking care not to injure the bowel. The inferior mesenteric vein is usually ligated during this dissection. This allows access to the infrarenal aorta where the overlying retroperitoneal tissue can be dissected free. Depending on how much aorta is needed for an adequate cuff of the proximal anastomosis, an anterior renal vein may need to be mobilized cephalad, with ligation of the gonadal and/or adrenal vein for better exposure (**FIG 5**).

- Exposure of the supraceliac aorta (**FIG 6**): The maneuver is only needed in cases where high abdominal aortic exposure is needed, such as in a rupture. The left lobe of the liver must be retracted laterally by taking down the triangular ligament. Next, identify and dissect free the gastroesophageal junction after dividing the gastrohepatic ligament, which is most expeditiously done by palpating for the nasogastric tube and applying caudal traction. Division of the gastrohepatic ligament must be done with the thought that a replaced left hepatic artery would be coursing beneath this structure. The esophagus can be retracted to the patient's left, and this maneuver will expose the aorta. An aortic compressor can be used in extreme circumstances; however, dissection of the aorta circumferentially and surrounding the aorta with a shoestring if the patient's condition allows is preferable. This exposure, although useful when urgent supraceliac control is needed, will not allow access to the visceral segment of the aorta. In order to gain this exposure, a right or left medial visceral rotation should be incorporated into the dissection. The use of a right medial visceral rotation will allow access to the right renal artery, as well as placing the SMA on 90-degree tension and is useful for clearing a clamp site in those patients with a juxtarenal aneurysm who have very little room between the renals and SMA (**FIG 7**). The use of a left medial visceral rotation also allows for exposure to the entire visceral segment of the aorta as well as the left renal artery. Care in this approach must be made to avoid injury to the spleen and tail of the pancreas.

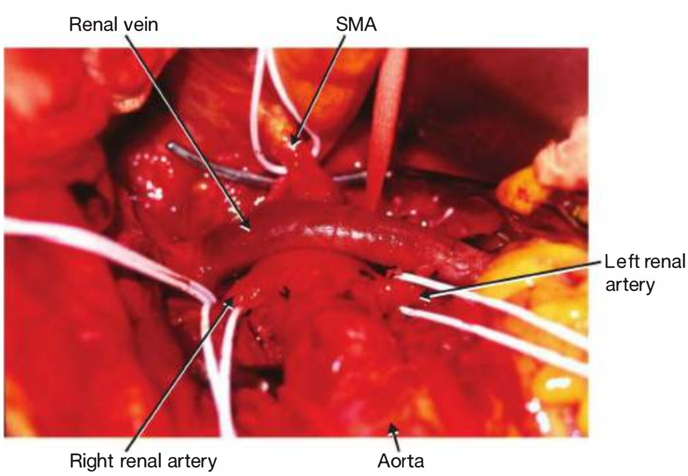

FIG 5 ● (illustration and photo): Mobilization of the left renal vein. Cephalad or caudal mobilization of the left renal vein to expose the origin of the renal arteries. Ligation of several venous sidebranches may be needed for safe mobilization. (*continued*)

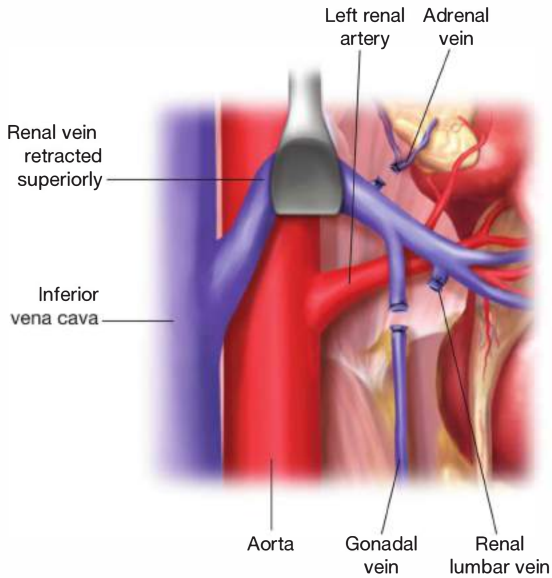

FIG 5 ● (*continued*)

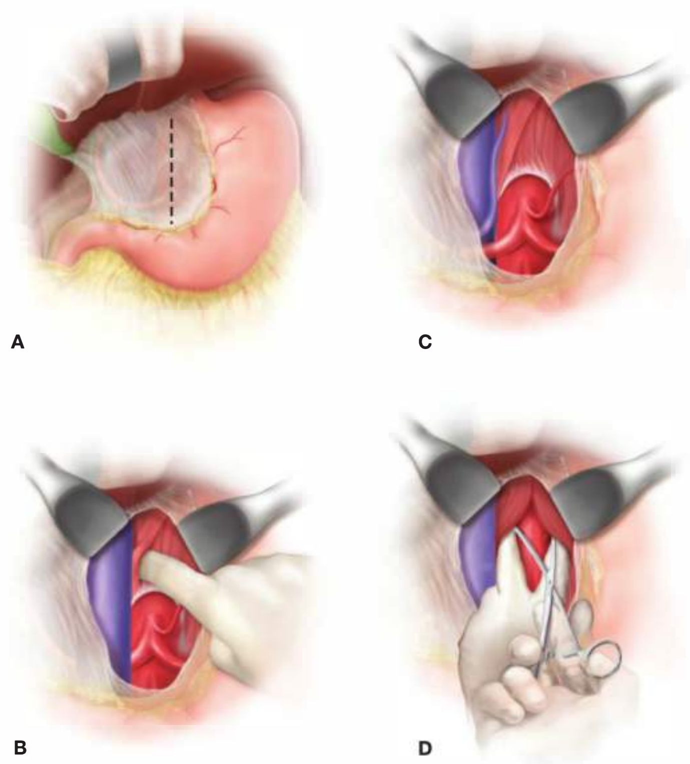

FIG 6 ● Gaining control of the supraceliac aorta. **A.** *Dotted line* shows the location for division of the gastrohepatic ligament. **B.** Once the ligament is divided, the crus is encountered. **C.** Bluntly divide the fibers of the crus. **D.** Using fingers for retraction, control of the aorta can be gained with a clamp, although circumferential control is optimal.

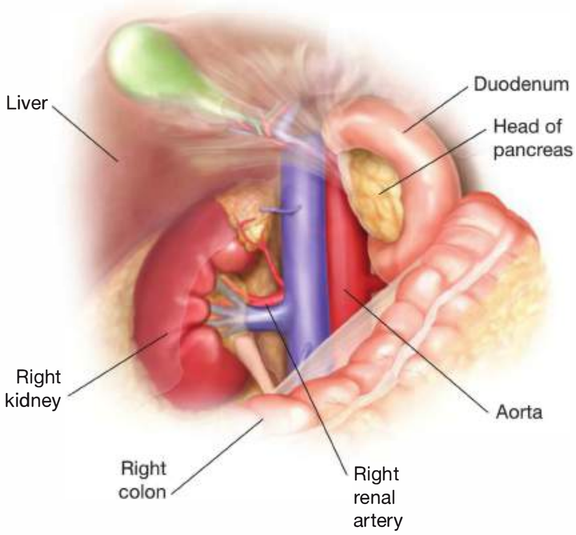

FIG 7 ● Exposure of the aorta and right renal artery via right medial visceral rotation.

RETROPERITONEAL APPROACH

- Positioning: Once asleep, position the patient in the lateral position with the left side up at an approximately 60-degree angle (**FIG 8**). Extend the right arm on an armboard, being sure to leave room for an Omni or other self-retaining retractor post. The upper left arm should be placed on another armboard and padded to prevent neural injury. The bed should be flexed at the patient's flank to open up the area between the ribs and the anterior superior iliac spine. Position the legs so that the lower leg is straight and the upper leg is bent. Use two pillows as padding between legs. A beanbag can be inflated to keep the patient in place, and use thick cloth tape over the hip to secure the patient on his or her side. Ideally, the patient should be placed on a beanbag; however, blanket rolls can be used anteriorly and posteriorly to further secure the patient. Be sure to allow access to prep from the spine posteriorly to the umbilicus anteriorly and from the nipple line to the groins. All bony prominences and pressure points should be well padded to avoid injury. Use clippers to remove hair within the prep area. Prep from the axilla and nipple line to the upper thigh. Mark all previous incisions and use a Steri-Drape or Ioban over the entire prepped area to secure the drapes. Once in position, check PVRs and/or distal pulses.
- Incision: Unless clamping is planned at or above the level of the SMA, a standard retroperitoneal incision over the 11th rib will provide adequate exposure (**FIG 3**). Carry the incision from the posterior axillary line to the anterior border of the rectus. Avoid entry into the pleural cavity if possible, being cognizant that the further posterior the incision is carried, the higher likelihood this will occur.
- Divide the transversalis fascia and enter the retroperitoneal space down to but not violating Gerota's fascia. This space can be more easily identified by resecting a distal segment of the 11th rib, as the tranversalis fascia and transversus abdominal musculature inserts along the inferior border of this rib. It is possible to stay entirely within a retroperitoneal plane; however, if the peritoneum is violated, the abdominal contents can be packed away with retractors or the peritoneum can be repaired with a running 3-0 chromic

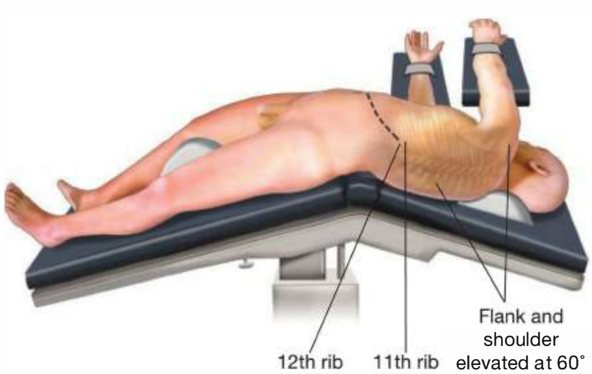

FIG 8 ● Positioning for retroperitoneal incision.

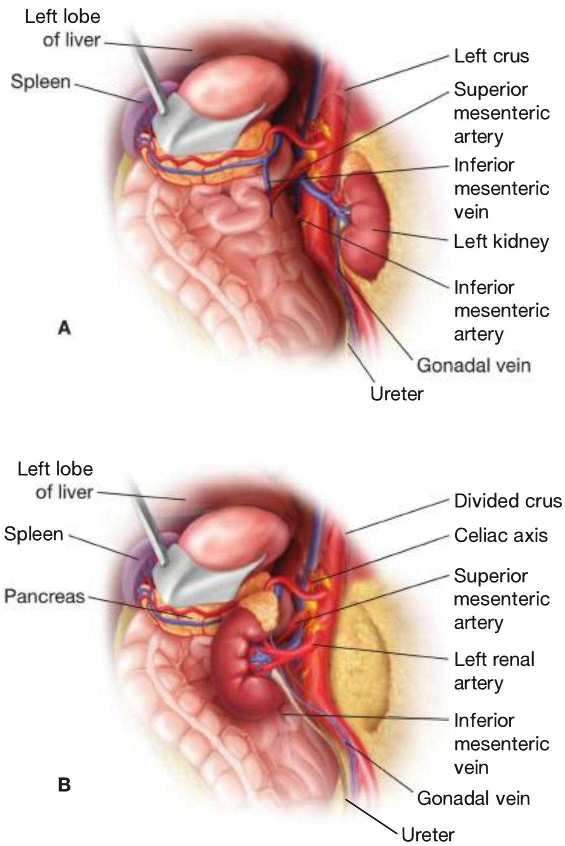

FIG 9 ● The aorta can be approached in an anterorenal plane **(A)** or a retrorenal plane **(B)**.

suture. The aorta may be approached via an anterorenal (colloquially referred to as "leaving the kidney down") or retrorenal plane ("taking the kidney up") (**FIG 9**). Generally, the aorta is approached via a retrorenal approach unless there is a renal vein running posterior to the aorta. As the retroperitoneal dissection continues, the left ureter should be identified and swept toward the midline and placed behind a retractor to avoid injury during dissection of the aorta. The renal artery is identified and dissected back to its origin to identify the aorta

- Dissection: The renal artery should be cephalad to the vein, and once this is identified, it can be used as a landmark and dissected back to the aorta.The renal lumbar vein should be identified and ligated to avoid injury and excessive bleeding. Once the origin of the renal artery is identified, a right angle can be placed along the surface of the aorta and the overlying retroperitoneal tissue divided with electrocautery. It is imperative here to get on the aorta and stay on the aorta to avoid excessive bleeding from the retroperitoneal tissue. The aorta is exposed to the bifurcation and can be dissected circumferentially here if a clamp site is planned; however, the left iliac vein can course posterior to the bifurcation and should be avoided. It is often easier to expose an area of the left common iliac artery for clamping and control the right common iliac artery with an occlusion balloon from within. It is unwise to gain circumferential control of the iliacs in this situation as the iliac veins are often adherent to the posterior aspect of the artery and are easily injured, leading to rapid exsanguinating blood loss. Identify and isolate the inferior mesenteric artery (IMA) with a vessel loop. Pay particular attention to identifying and not injuring the ureters, which will eventually cross anterior to the iliac vessels. If necessary and if the incision is placed along a higher rib space, the dissection can be carried caudal to expose the entire visceral segment if need be (**FIG 10**).

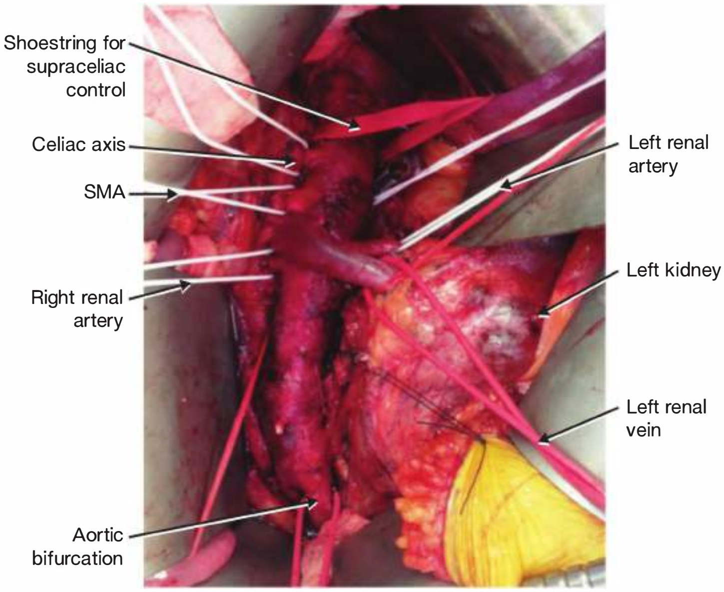

FIG 10 ● Exposure of the entire abdominal aorta from a retroperitoneal approach. Here, the kidney is "left down" in an anterorenal plane. All vessels are surrounded with vessels loops.

AORTIC CLAMPING AND REPAIR

- Regardless of approach, it is important during circumferential dissection of the aorta to avoid injury to the posterior lumbar arteries, which are usually paired. If they are encountered and require ligation, carefully circumferentially dissect out the artery, tying the proximal side of the vessel, and using another tie, double clip on the distal side prior to dividing. When dissecting on the aorta, care must be taken to minimize aggressive manipulation and subsequent atheroembolization, particularly if preoperative imaging shows extensive mural debris.
- Choice of graft: There are several choices for conduit during repair. Generally, a polytetrafluoroethylene (PTFE) or Dacron tube graft is sewn from the proximal aorta to the bifurcation. In those patients with extensive bifurcation or iliac disease, a bifurcated graft may be used. If this is the case, the proximal single lumen portion of the graft should be as short as possible to prevent kinking, ideally less than 4 cm. Tunneling the limb to the femoral level should be done only if necessary, and if so, care must be taken to run the graft posterior to the ureter. The aorta can be measured for the appropriate graft with aortic sizers, but often, an estimation of size can be made from the preoperative CTA. Regardless, the majority of patients can be repaired with an 18- to 22-mm graft (**FIG 11**).

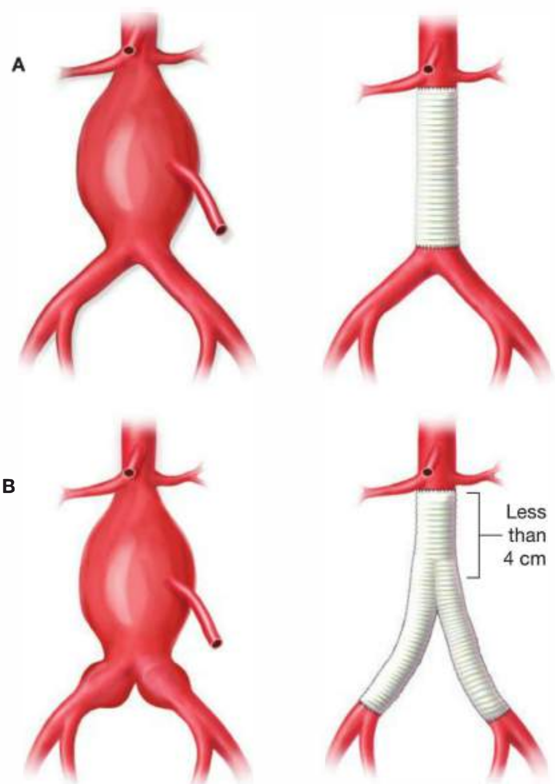

FIG 11 ● **A.** Tube graft from infrarenal aorta to bifurcation and **(B)** bifurcated graft from infrarenal aorta to iliac or femoral vessels.

- Choosing the site of the proximal anastomosis: This will depend on the quality of the proximal neck of the aneurysm and the vicinity of the visceral vessels. In the most straightforward scenario, an adequate cuff of normal aorta is present below the renals to allow for infrarenal clamping and an end-to-end anastomosis. A suprarenal clamp can be used to provide space to sew to a short infrarenal cuff. If aneurysmal tissue extends to the visceral branches, or if there is significant antherosclerotic disease of the branches, a beveled anastomosis may be required, possibly including an endarterectomy of the origin of a branch vessel or a bypass to the left renal artery (**FIG 12**). This should be apparent based on careful review of preoperative imaging and planned for well before clamping of the aorta. From the retroperitoneal approach, every effort should be made to incorporate the right renal artery into the anastomosis.
- In preparation for clamping, the patient should be systemically heparinized at a dose of 70 units of heparin per kilogram and allowed to circulate for 3 to 5 minutes. It is important to communicate with anesthesia prior to clamping and unclamping so they may anticipate and address subsequent hemodynamic shifts. Generally, the systemic pressure should be dropped in preparation for the proximal clamping. If the visceral segment is involved, bulldog clamps should be applied to the visceral vessels prior to aortic clamping to avoid embolization. The proximal clamp is carefully applied and secured with a shoestring around the clamp. The aortic sac is then opened with electrocautery and heavy scissors proximally and distally. Mural debris should be carefully removed to identify all patent lumbar arteries. Distal control can then be obtained with balloon occlusion into each iliac with Foley catheters if external control was not previously done due to calcific disease. All lumbar vessels with back-bleeding into the aorta should be suture ligated with 2-0 silk in a figure-of-eight fashion. In heavily calcified aortas, focal endarterectomies may be necessary for effective ligation of each vessel.
- Sewing of the proximal anastomoses: There are several ways to complete the anastomosis, and choice is based on a combination of surgeon preference and tissue quality. Regardless of technique, the posterior row of sutures should be done first. Ensure that there is adequate exposure of the proximal aorta; this may require the use of a self-retaining retractor within the opened sac or stay sutures on the edges of the sac. Place the graft on the patient's chest upside down, so the posterior aspect of the graft lies anteriorly. If the posterior row is to be done in an interrupted fashion, the first mattress suture is placed in the middle of the graft from outside to in, placing a snap on the needled ends of the sutures. Place four more mattresses, two on each side, working your way to the 3 o'clock and 9 o'clock positions on the graft. Care must be taken to ensure there are no gaps between sutures; all travel must be within a mattressed stitch and not between stitches. Once all sutures are placed in the graft, begin placing the aortic sutures from inside to outside on the aorta. The proximal aorta is usually not completely transected and the posterior wall can be used to create

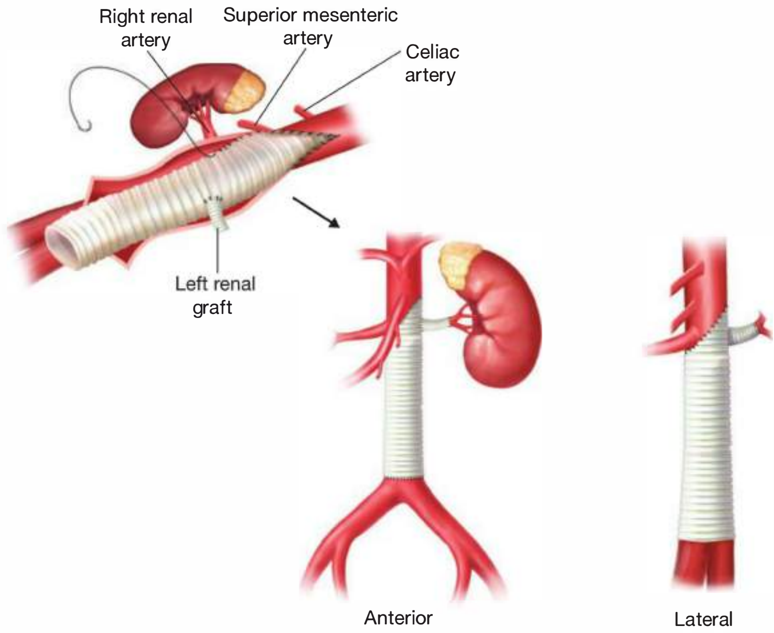

FIG 12 ● Beveled anastomosis with bypass to the left renal artery. The suture line runs just inferior to the right renal artery.

a Creech bite that uses the aortic wall as a pledget. Once all sutures are placed, each individual stitch is pledgeted and tied down snugly. The anterior row is then completed, starting from each side and working your way to the center, such that the anterior-most stitch is the final stitch placed. These are also pledgeted and tied into place. Once the proximal anastomosis is completed, an atraumatic clamp should be applied to the body of the graft, and the proximal aortic clamp slowly released to test for integrity of the repair. Any leaks in the suture line should be addressed at this time, particularly along the posterior row, as this will be inaccessible once the distal anastomosis is in place. It is unwise to attempt to place stitches on a fully perfused aorta, and the proximal clamp should be reapplied if repair stitches are necessary. In addition, pledgets should be used with these stitches. A running anastomosis can also be performed with a 3-0 Prolene and an atraumatic needle. The back row is again began in the middle of the graft with deep Creech bites on the aorta. The graft can be parachuted in to make the suture line taut. The back row should be inspected to ensure that it is snug and additional sutures are used at the 3 o'clock and 9 o'clock positions to secure the back row and run to the top of the aorta (**FIGS 13** and **14**).

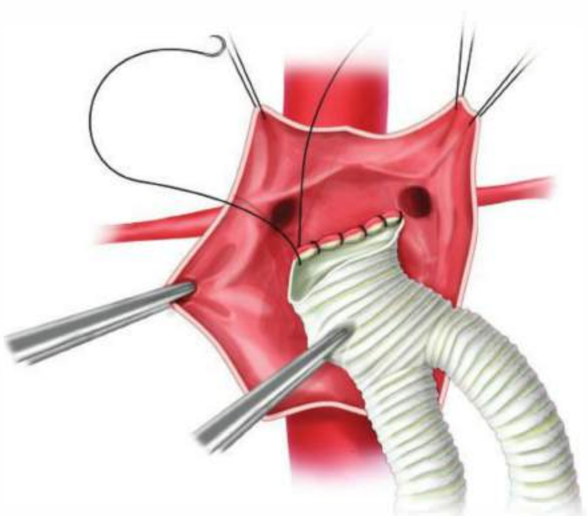

FIG 13 ● Construction of the posterior row of the proximal anastomosis. Note that the anterior and lateral aspects of the aorta is divided but the posterior wall is left intact in this figure, using "Creech" suturing technique.

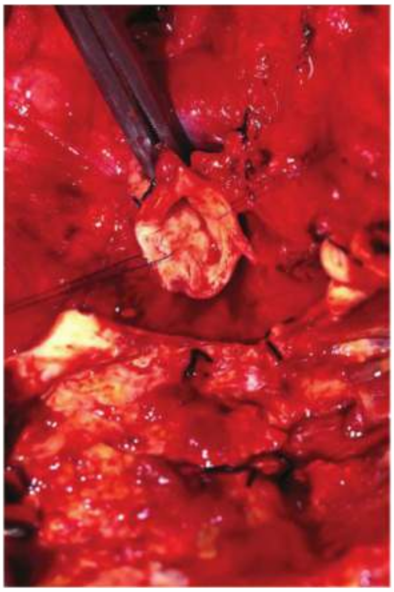

FIG 14 ● Aortic cuff. The aorta can be totally transected and stay sutures applied in preparation for the anastomosis.

- IMA implantation: Although the IMA can generally be ligated without clinical consequence, there are certain situations where it may be beneficial to reimplant the vessel to avoid bowel ischemic complications. Patients with altered pelvic blood flow, such as those with prior gastrointestinal surgery or occluded hypogastric arteries, should especially be considered for IMA reimplantation. Furthermore, visual inspection of the sigmoid colon prior to closure should be done, and IMA reimplantation done if there appears to be questionable viability of the bowel. Additionally, prior to IMA ligation, an assessment of back-bleeding (and thus the collateral circulation to the IMA territory) should be performed and reimplantation considered in cases where the back-bleeding is poor.
- Creating the distal anastomosis: After the proximal anastomosis is completed and hemostasis is ensured, the graft should be pulled taut to the location of the distal anastomosis (or anastomoses if a bifurcated graft is to be used). The graft should be measured to ensure no redundancy or kinking occurs but not so tight as to put undue strain on the proximal anstomosis. The distal can be done in a running or interrupted fashion, as described previously. When sewing, the assistant should use a forceps to pull the graft distally and remove tension on the anastomosis, decreasing the chance the sutures will be too loose.
- Flushing and unclamping: Just prior to the completion of the distal anastomosis, the graft will need to be flushed proximally and distally to remove clot, air, and debris. After flushing, irrigate the graft with heparinized saline and complete the anastomosis. Once both anastomoses are completed, communicate with the anesthesiologist that the clamps are ready to be removed. There is often a substantial drop in systemic blood pressure as the lower extremities are reperfused, and they will need to prepare to react accordingly. It is more appropriate to tolerate a slightly longer clamp time and allow the anesthesiologist to regulate the blood pressure accordingly then unclamp a hypotensive patient. As the surgeon slowly unclamps, the assistant can hold manual pressure at the level of the femoral arteries to allow any debris to flush into the pelvis, which may tolerate embolization better due to the extensive collateral network. Pressure is then released on the femoral vessels and systemic pressure is monitored. If there is a substantial hypotensive response, partial or complete reclamping may need to be performed to allow the anesthesia team time to treat the hemodynamics. Once unclamped, inspect the anastomosis and sac for bleeding. There may be new lumbar bleeding as a result of pelvic reperfusion that was not apparent during the graft placement. Diffuse oozing can be treated with Surgicel and Gelfoam. Once unclamped, check pulses and Doppler signals in iliacs and any clamped branch vessels, as well as distal pulses and/or PVRs. If lower extremity PVRs are significantly worse than preoperatively, this should raise concern for embolization and may warrant a groin exploration and thrombectomy.
- Sac closure: This is especially important during the transperitoneal approach, as an uncommon but disastrous late complication from open aortic surgery is the aortoenteric fistula, which occurs when graft and/or anastomosis erodes into the bowel. To help prevent this, the walls of the now decompressed aortic sac should be closed over the graft, and sewed in a running fashion with a long 3-0 silk or chromic suture. If there is insufficient sac to close, a flap of omentum can be mobilized and placed over the graft prior to returning the visceral to its anatomic location. The sac of the aorta can be a not insignificant source of bleeding, so electrocautery should be used along the cut edge of the sac to ensure hemostasis prior to sac closure, and persistent bleeding should be suture ligated.
- Drainage and closure: If the pleural cavity was entered, drainage will be required either by use of a red rubber suction catheter placement during diaphragmatic repair or postoperative chest tube placement. Additional placement of a closed suction Jackson-Pratt (JP) or Blake drain in the peritoneal or retroperitoneal (RP) cavity can be done on a selective basis; we generally place a drain if there is some concern over excessive mobilization near the tail of the pancreas and thought a pancreatic leak may occur, or in coagulopathic patients where ongoing bleeding may be of concern. Special attention should be paid to inspecting the spleen, and we have a low threshold for splenectomy if there is any injury to the organ. The abdominal wall should then be closed in layers.

PEARLS AND PITFALLS

- Ideally, proximal clamp time should be less than 30 minutes. It is therefore imperative to have all tools and grafts ready and all team members briefed on the operative plan prior to clamping. However, for an infrarenal clamp, the operator will have several hours if necessary to complete the anastomosis. If the clamp is suprarenal, complications begin with more than 40 minutes of ischemia.
- Injury to the common iliac vein or distal IVC during dissection is a potentially lethal complication. It is important to completely mobilize the vein and perform a primary repair under direct vision. Blind suturing in a bleeding field will only lead to disaster. If exposure cannot be obtained, it is acceptable to transect the overlying artery (aorta or iliac) to allow access to the vein. This is a complication that is much better to avoid than treat.
- The ureters can be injured during the transperitoneal or retroperitoneal approach, and every time the retractors are repositioned or as you begin to dissect a new plane, the ureters should be identified.

POSTOPERATIVE CARE

- Patients should be monitored in an intensive care unit (ICU) postoperatively, with blood pressure goals generally of a systolic blood pressure from 100 to 140 mmHg for a straightforward infrarenal or juxtarenal repair. Blood pressure goals should be higher for thoracoabdominal repairs to promote spinal cord perfusion.
- Patient may be weaned to extubated as soon as possible after the operation, even in the OR if appropriate.
- An NGT is kept in place given the bowel manipulation, and this is left in place for the first postoperative day. Although it is not imperative to keep in place until there is full return of bowel function, we will keep in place an additional day if outputs are unusually high. We generally start standing rectal suppositories on the first postoperative day.
- If there is a chest tube in place, we leave this to suction until removal, which is done when output is less than 150 mL per 24 hours and the chest x-ray (CXR) shows no large effusion.
- Mobilization should be done as soon postoperatively as possible. These patients will require physical therapy and many will ultimately require inpatient rehab.

OUTCOMES

- Mortality for an elective, open infrarenal AAA repair is less than 5%, and although the risk increases for those with a juxtarenal or suprarenal repair, our recent experience shows that 30-day mortality in patients with juxtarenal repair is 2.5%. Mortality increases in the instance of an urgent or rupture to as high as 70%.[1,5]
- Patient-specific predictors of postoperative complications include older age, COPD, chronic renal disease (creatinine >1.8) or history of myocardial infarction (MI)/congestive heart failure (CHF).[1]
- Operative-specific predictors of postoperative complications include long OR or clamp times, hypothermia, high blood turnover, and a high perioperative fluid requirement.

COMPLICATIONS

- Bleeding
- Infection
- Splenic injury (consider adding splenectomy to operative consent)
- Renal failure
- MI
- CVA
- Spinal cord ischemia (increased risk with suprarenal and thoracoabdominal repairs)
- Anastomotic breakdown
- Aortoenteric fistula
- Pancreatitis

Chapter 23

Advanced Aortic Aneurysm Management: Endovascular Aneurysm Repair—Standard and Emergency Management

Vinit N. Varu Ronald L. Dalman

DEFINITION

- An abdominal aortic aneurysm (AAA) is defined as a localized enlargement of more than 1.5 times the diameter of the most adjacent, proximal uninvolved aorta; by consensus, this represents more than 3.0 cm in most persons. Definitions vary somewhat between men and women, most likely normalized by body surface area or body mass index (BMI).
- The most common etiology of AAAs is progressive, transmural degeneration of the aortic wall. The full scope of pathogenetic considerations and relevant mechanisms is beyond the scope of this chapter but, in summary, although aneurysm disease shares many important risk factors for aortic and peripheral vascular occlusive disease, important differences exist, and current thinking regarding pathogenesis recognizes that aneurysmal and occlusive disease of the aorta are distinct pathologic processes. Hence, the colloquial term "atherosclerotic aneurysm," although in common use, is an inaccurate and potentially misleading characterization of the most common clinical presentation for AAA.
- Risk factors for development, expansion, and rupture are multifactorial[1] (Table 1). Smoking is the only modifiable risk factor that has been associated with all three.
- The risk of AAA rupture increases with progressive diameter enlargement.[2] Rupture and subsequent aneurysm-related mortality may be prevented by elective surgical repair, either by open interposition grafting or endovascular aneurysm repair (EVAR).
- EVAR provides similar long-term survival versus traditional open repair, as well as enhanced perioperative survival. The perioperative survival benefit is sustained for several years following surgery.[3] EVAR is now the de facto standard of care for both elective and ruptured AAA repair in patients who are anatomically suited to receive currently available devices.

Table 1: Risk Factors for Aneurysm Development, Expansion, and Rupture

Symptom	Risk Factors
AAA development	• Tobacco use • Hypercholesterolemia • Hypertension • Male gender • Family history (male predominance)
AAA expansion	• Advanced age • Severe cardiac disease • Previous stroke • Tobacco use • Cardiac or renal transplant
AAA rupture	• Female gender • ↓FEV_1 • Larger initial AAA diameter • Higher mean blood pressure • Current tobacco use (length of time smoking >> amount) • Cardiac or renal transplant • Critical wall stress—wall strength relationship

AAA, abdominal aortic aneurysm; FEV1, forced expiratory volume in 1 second.
From Chaikof EL, Brewster DC, Dalman RL, et al. The care of patients with an abdominal aortic aneurysm: The Society for Vascular Surgery practice guidelines: executive summary. J Vasc Surg. 2009;50(4):880–896.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients may be entirely asymptomatic despite suffering from large, advanced AAAs. Most commonly, AAAs are found incidentally on imaging studies obtained for other reasons. Occasionally, they may be identified by the presence of prominent aortic pulse, proximal to the umbilicus, on physical exam. Less frequently, AAAs may cause distal limb ischemia secondary to embolization, or fulminate congestive heart failure if they rupture into the adjacent inferior vena cava, creating an acute aortocaval fistula. Only 30% to 40% are noted on physical examination, with detection of pulsatile abdominal mass dependent on aneurysm size. As noted by Sir William Osler, prior to the era of ubiquitous availability and use of cross-sectional abdominal imaging in the evaluation of abdominal pain: "There is no disease more conducive to clinical humility than aneurysm of the abdominal aorta."
- Patients with a ruptured AAA may present with moderate or extreme back and abdominal pain, syncope, hypotension, and mottling of the lower extremities, in conjunction with progressive abdominal distension. When sufficiently stable to remain conscious and conversant, pain is reproducibly elicited by direct palpation of the abdominal aorta. Many patients with ruptured AAA present in extremis, others with progressively hemodynamic deterioration and pain of several hours duration. Patients may actually linger for several days with "contained" retroperitoneal hemorrhage following AAA rupture.
- A thorough vascular history should be noted and modifiable risk factors, including smoking, hyperlipidemia, and hypertension, addressed in patients with AAAs. Smoking cessation is recommended to reduce the risk of aneurysm growth and rupture, and statins may also be beneficial in this regard.
- AAAs occur almost exclusively in the elderly (mean age of repair 72 years of age) and male patients outnumber female by 4 to 6 is to 1.[1] When AAA is recognized in younger patients, it is usually in association with hereditary risk, syndromic aortic conditions such as Marfan syndrome, or in the setting of focal aortitis or mycotic aneurysms. The latter tend to occur most frequently in the suprarenal abdominal aorta, at or directly proximal to the origin of the celiac artery, underneath the crus of the diaphragm. Aneurysmal degeneration of the abdominal aorta may also occur late following thoracic and abdominal aortic dissection.

- Factors associated with increased risk of rupture include female gender, large initial diameter, low forced expiratory volume in 1 second (FEV_1), current smoking history, and elevated mean blood pressure.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Screening decreases aneurysm-related mortality in AAA disease.[4] Current guidelines recommend a screening ultrasound for 65- to 75-year-old at-risk individuals, defined as men who have smoked more than 100 cigarettes in their lifetime or men or women with a family history of AAAs.[5]
- Thin-slice computed tomography (CT) imaging, with intravenous contrast injection timed to opacify the abdominal aorta and runoff vessels, remains the standard modality for operative planning. The extent, morphology, and accessibility of the aneurysm via retrograde iliofemoral access determine the suitability for an endovascular repair. Other relevant anatomic considerations include the location and volume of laminar intraluminal thrombus in the region of the "surgical" neck (defined as the length between the lowest renal artery and the start of the aneurysm); angulation of the surgical neck, size and tortuosity of access vessels; presence and significance of anomalous and accessory renal arteries; diameter at the aortic bifurcation; and diameter of the more proximal abdominal aorta (provides useful guidance as to the likely long-term diameter of the surgical neck).
- For cases of suspected AAA rupture, bedside transcutaneous ultrasonography may be used to detect the presence of intra- or retroperitoneal fluid (or blood) or assess for confounding conditions eliciting abdominal pain. When sufficiently hemodynamically stable, however, CT aortography should be obtained to assess for suitability for endovascular repair.[6]

SURGICAL MANAGEMENT

Indications

- Patients with "symptomatic" AAAs (e.g., pain likely originating from the aneurysm despite absence of retroperitoneal hemorrhage on CT aortography) are at increased risk of rupture and urgent intervention is recommended. Of those AAAs that rupture, more than half will die prior to hospitalization. Of those that undergo attempted operative repair, approximately 50% mortality is to be expected. The latter estimate is highly dependent on hemodynamic conditions, duration of symptoms, and comorbid conditions present at the time of surgery and is not useful in predicting survival of individual patients.[1]
- For asymptomatic AAAs, management is determined by the maximal orthogonal transverse diameter at the time of evaluation or rate of aneurysm enlargement over time. AAAs less than 4.0 cm are at low risk of rupture and should be monitored with serial imaging; those larger than 5.4 cm are at high risk of rupture and should be repaired. Surveillance is recommended for most patients in the range of 4.0 to 5.4 cm, although young healthy patients and especially women may benefit from repair in AAAs between 5.0 and 5.4 cm.[1]

Preoperative Planning

- Anatomic measurement obtained from high-quality CT aortography, preferably reconstructed with millimeter or submillimeter slices, is paramount to successful endovascular repair. Ideally, precise diameter and path length measurements are derived from three-dimensional (3-D) reconstruction of the two-dimensional (2-D) source images (via TeraRecon™, OsiriX™, or similar software).
- Precision is most essential in determining diameter throughout the surgical neck and common iliac landing zones proximal to the bilateral iliac bifurcations. Graft oversizing of 10% to 20% is typically used in the region of the surgical neck. Length measurements are obtained from the lowest renal artery to the iliac bifurcation, using path lengths, when available, from image reconstruction software noted earlier.
- Multiple aortic endografts are approved for use in the United States at the current time, and device selection should be tailored to individualized anatomic requirements. Contraindications to endovascular repair may include inadequate neck length, diameter, and angulation; thrombus volume and distribution in the neck; insufficient iliac artery diameter, and excessive iliac or aortic tortuosity. It is the responsibility of the operating surgeon to ensure that for each selected device, the instructions for use (IFU) are understood and appropriate for the planned repair. Experienced operators, with careful planning, may knowingly place devices in off-label circumstances, depending on the patient-specific anatomic and physiologic risk assessment, with the expectation of reasonably long-term results. In off-label applications, however, the onus is on the surgeon to confirm that sufficient proximal and distal fixation and sealing zones exist to ensure a reasonable result.[7]
- Femoral access must also be evaluated with ultrasound or CT imaging to determine if the patient is a candidate for percutaneous repair. The "preclose" technique (see the following text) can be used for arteriotomy closure for devices up to 21 French (Fr) in diameter. Contraindications to percutaneous repair include calcification of the anterior femoral artery wall, diameter less than 7 mm, the presence of an aneurysmal femoral artery, and excessive scaring at the access site.
- The superior mesenteric artery (SMA) and celiac arteries should be examined for patency and the presence of flow-limiting stenosis or occlusion; if found, revascularization of the SMA and celiac artery should be considered prior to attempted EVAR, or open repair is considered as an alternative approach. In planning for EVAR, attention must be paid to the status of the inferior mesenteric artery and the total visceral vascularity assessed in terms of consequences of obligate inferior mesenteric artery (IMA) coverage during EVAR. Occasionally, depending on anatomic circumstances, custom fenestration or parallel grafting options may be considered as alternatives, allowing for EVAR management despite the presence of significant celiac or SMA disease. The latter options again, however, should only be considered by operators experienced in these techniques or facile with rapid open conversion when indicated to preserve intestinal perfusion.
- Facilities are an essential consideration. Fixed imaging is the preferred option for procedural guidance and aortography, preferably when available in a "hybrid" operating room configuration. This is especially true when tolerances are low regarding IFU status and related anatomic considerations. Anesthesia can be either general or local with conscious sedation, depending on the habitus of the patient, their suitability for conscious sedation, and the potential likelihood of open conversion. In our practice, all patients are consented for open conversion, even though in practice this happens in less than 1% of cases.

ENDOVASCULAR ANEURYSM REPAIR STANDARD

Percutaneous Access

- Using ultrasound guidance to determine the location of the femoral bifurcation and potential presence of anterior calcified atherosclerotic plaque, bilateral common femoral arteries (CFAs) are accessed with 0.018-in micropuncture kits. Femoral arteriography is performed to confirm suitability of the selected access site within the CFA prior to serial dilation.
- A 0.035-in general purpose wire (e.g., Bentson, Cook Medical, Bloomington, IN) is advanced into the aorta through the micropuncture sheath and 11-cm, 7-Fr sheaths are exchanged over the Bentson into the external iliac arteries (EIA) under continuous fluoroscopic guidance. Full intravenous anticoagulation is established with unfractionated heparin (at least 100 units/kg) and confirmed by subsequent determination of activated clotting time (ACT) greater than 250 seconds.

Preclose Technique

- In all circumstances, the surgeon should consult the respective IFUs for all devices employed during these procedures.
- While the assistant maintains direct compression proximal to the inguinal ligament to maintain hemostasis, the 7-Fr sheaths are individually removed over each respective wire and replaced with a Perclose ProGlide™ (Abbott, Abbott Park, IL) device. This is back-loaded on the wire and advanced until the guidewire exit line on the device. The wire is then temporarily removed and the device advanced until pulsatile blood is visualized through the pilot tube lumen. The first device is turned to the 10 o'clock position and foot plate activated. Holding back tension on the device, the suture is deployed, and the ends are removed from the device and controlled with a padded suture clamp. After the wire is repositioned through the wire port into the aorta under fluoroscopic guidance, the foot plate is released and the device is backed out of the femoral artery. Pressure is reapplied over the puncture site during this maneuver (**FIG 1**).
- A second Perclose ProGlide™ (Abbott) device is back-loaded on the wire and the aforementioned steps are repeated with the device turned to the 2 o'clock position.
- After both ProGlides™ (Abbott) are deployed, the 7-Fr sheath is reformed and replaced over the wire to maintain hemostasis. The suture clamps are positioned consistent with the clockface orientation of each suture placement.
- The procedure is then repeated for the contralateral femoral access site.

Delivery and Deployment of Endograft

- Wire exchange is performed through a guiding catheter (e.g., 100-cm Glidecath™, Terumo Medical, Somerset, NJ) for a stiffer access wire (e.g., Lunderquist™, Cook Medical). Serial dilation is preformed over the stiff wire, under fluoroscopic guidance, to gently distend and enlarge the respective arteriotomy sites. Following dilation to at least 14 Fr, the primary and secondary access sheaths are advanced under fluoroscopic guidance into the aorta.

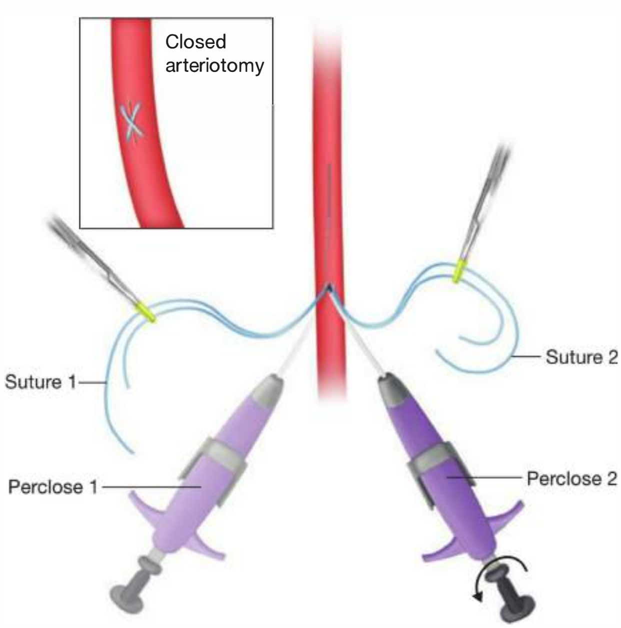

FIG 1 ● Preclose technique. Two ProGlides™ are deployed, one at the 10 o'clock position and the other at the 2 o'clock position before beginning serial dilation maneuvers and deployment of delivery catheters. Once the procedure is complete, and large diameter devices are removed, both knots are seated to close the arteriotomy (see inset). Until closure, the free sutures are controlled on suture boots. Once the procedure is complete, both knots are pushed down to close the arteriotomy.

- The main body endograft is placed up the ipsilateral iliac artery to the level of the renal arteries. Laterality of main body deployment is determined based on the tortuosity and diameter of the access arteries, as well as the desired angle at which the main body will interface with the renal arteries. The main body should be oriented so that the gate deploys in anterolateral fashion for easy contralateral limb access. The image intensifier should be adjusted to limit parallax by accounting for some degree of anterior angulation (usually in the range of 10%, occasionally more) and lateral angulation in the surgical neck, based on preprocedural assessment from the reformatted CT aortogram (**FIG 2A**).
- An Omni Flush catheter (AngioDynamics, Latham, NY) is placed up the contralateral iliac artery to the level of the renal arteries. The gantry position is then confirmed to be appropriate for the patient's anatomy, ensuring that the image plane is orthogonal to the takeoff of the lowest renal artery. Usually, a "20 for 10" contrast run is performed during breath-hold under magnification views, delivering 10 mL of contrast at a rate of 20 mL per second, to confirm the device position vis-a-vis the renal artery origins.
- The main body endograft is then deployed according to the IFU, with the proximal fabric margin positioned just below the lowest renal artery. Deployment continues until the contralateral gate is fully open (although techniques may vary between devices). Depending on the device-specific IFU, the main body may be resheathed and repositioned, if necessary, to obtain optimal positioning (**FIG 2B**).
- Repeat aortography is performed to ensure adequate placement. The side-hole, aortic flush catheter is withdrawn into the aneurysm through the proximal landing zone, over a wire. If the device uses suprarenal stent fixation, the suprarenal stents are deployed when main body placement is deemed sufficient. Care should be taken to prevent pulling the main body of the endograft down into the aneurysm.

Gate Cannulation

- The contralateral sheath is placed 1 to 2 cm distal to the contralateral gate. Using an Omniflush™ (Angiodynamics) or Glide™ catheter (Terumo), the gate is cannulated with an angled Glidewire™ (Terumo). When successful, the Omniflush catheter should be exchanged over a wire and reintroduced into the endograft. The tip is allowed to reform by withdrawing the wire and the curled flush catheter is spun 360 degrees several times to confirm gate cannulation. Failure to confirm this step may result in deployment of the contralateral limb outside of the gate, likely generating "endotrash" (e.g., graft limb free in the aneurysm, outside the main body, which will not remain in circulation) (**FIG 2C**).
- If the contralateral gate cannot be successfully cannulated using standard guidewire and catheter techniques (different-shaped catheters should be employed, as well as repositioning the sheath in relation to the contralateral gate), cannulation may be accomplished by advancing a snare up the contralateral sheath into the aneurysm and engaging the main body endograft bifurcation with a Sos Omni or similar curved catheter. The ipsilateral wire is then advanced through the gate, to be snared from the contralateral side. Once the wire is withdrawn through the contralateral sheath, a catheter may be back-loaded and advanced into the main body, which in turn allows an exchange to a stiffer wire through the gate. When necessary, a wire can also be advanced from brachial artery access for the same purpose.

Limb Extension

- Retrograde iliac angiography is performed through the sheath, with the gantry position in the contralateral oblique position. This will identify the origin of the internal iliac artery. Once this is confirmed, distance from the gate to the internal iliac is measured using a marker catheter and an appropriately sized limb is chosen.

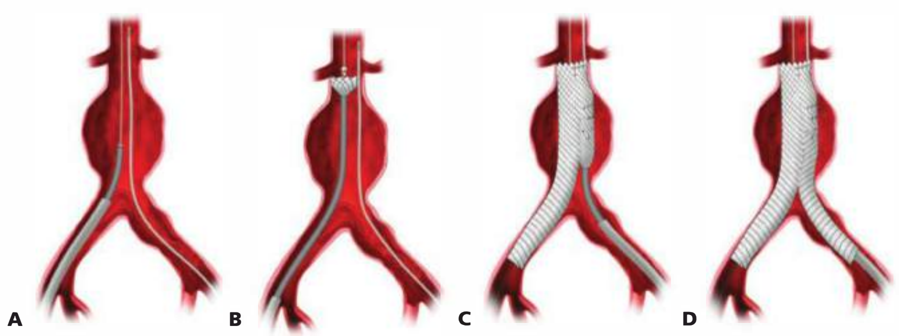

FIG 2 ● Delivery and deployment of endograft. **A.** The main body is brought up the ipsilateral iliac artery to the level of the renal arteries. An Omni Flush catheter is brought up the contralateral iliac artery and an angiogram is performed. **B.** The main body endograft is deployed under fluoroscopic guidance until the contralateral gate is opened. **C.** The contralateral gate is cannulated. **D.** An extension limb is placed proximal to the iliac bifurcation on the contralateral side and the ipsilateral endograft is finished being deployed (one docking limb systems) or an extension limb is placed (two docking limb systems) to the level of the ipsilateral iliac bifurcation.

For three-piece bifurcated devices (e.g., TriVascular Ovation™, Cook Zenith™), this procedure has to be performed on both sides. Optimal limb deployment maintains sufficient contact with the gate to maintain seal (see respective IFU) and sufficient distal coverage to completely exclude the common iliac artery without impinging on the origin of the internal iliac artery (**FIG 2D**).

- Occasionally, when the distance required for proper limb placement does not precisely correlate with the sizes available, the next size–longer limb may be deployed into the gate and slowly along its length. During deployment (once out of the gate), continued upward pressure on the deployment handle is maintained to encourage the graft to take a somewhat more serpiginous route, taking up some of the additional leak. Partial coverage of the ipsilateral internal iliac artery orifice is also appropriate when deployment can be precisely monitored in the contralateral oblique gantry position.

Balloon Molding

- An appropriately sized semicompliant balloon (e.g., Coda™, Cook Medical) is expanded with dilute contrast solution at all three landing zones and overlap areas within the gate(s) as appropriate for the specific device (**FIG 3**). When existing common iliac artery stenosis is present, kissing balloons should be deployed to obtain optimal internal diameter and prevent limb kinking or occlusion. Similarly, the aortic bifurcation should also be dilated when necessary. Occasionally, self-expanding bare metal nitinol stents may be deployed at areas of stenosis or from the distal limb into external iliac artery, to prevent kinking of the endograft or native external iliac artery distal to the device.

Completion Arteriography

- Completion arteriography is performed with higher volume and longer injection time to completely fill the endograft, ensure limb patency, and identify endoleaks (**FIG 4**). All type I or III endoleaks, when present at the end of the case, should be addressed with additional maneuvers to ensure seal. This may include deployment of proximal endograft cuffs, prolonged molding balloon inflation time, or, on occasion, placement of embolism coils in recalcitrant leaks. When small leaks persist, even when anatomic coverage seems adequate, anticoagulation should be reversed and sheaths removed with the plan for follow-up CT aortography within a few days. Care should be taken to carefully evaluate the nature of all leaks (type, volume, location in regard to lumbar branches, status of graft limb deployment, adequacy of molding, etc.) before secondary interventions are considered for persistent leaks. The majority of type II endoleaks resolve in the first year. In our practice, we never resort to deployment of a large diameter, balloon-expandable stent in the proximal neck—accurate sizing and deployment of this stent may be difficult and "stretching" the proximal orifice of the main body in this way may damage the graft, without sufficient assurance that the proximal type I leak will be adequately addressed.

Closure

- The contralateral sheath is removed over the wire and manual pressure is held. The previously placed preclose polypropylene sutures are deployed sequentially in each access site and cinched down with a knot pusher over a wire. When initial hemostasis appears adequate, the wire is removed and slightly more pressure is applied to the knot pusher. After both sutures are deployed in one groin, determination is made as to which of the two appears to provide more effective hemostasis and manual pressure is held to this suture for 5 additional minutes. This is repeated for the ipsilateral side.
- Procedural anticoagulation is reversed once all sheaths and clamps are removed. It is essential to wait for final introducer device removal before reversing the anticoagulation, because the large diameter sheaths used to deliver EVAR devices may almost entirely occlude the ipsilateral external iliac artery, causing potentially catastrophic graft limb and iliac artery thrombosis in the absence of full anticoagulation.

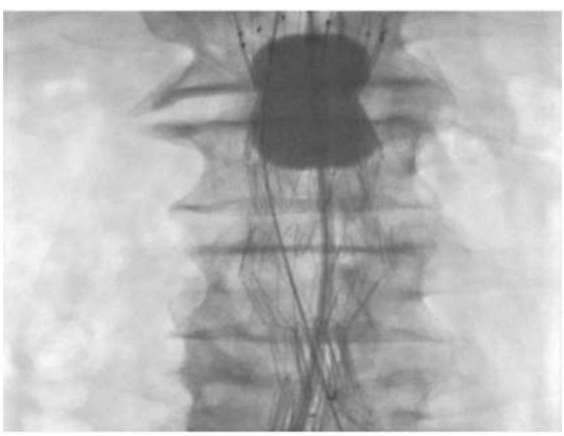

FIG 3 ● Balloon molding. A semicompliant balloon is inflated at proximal and distal landing zones as well as at all overlapping endografts.

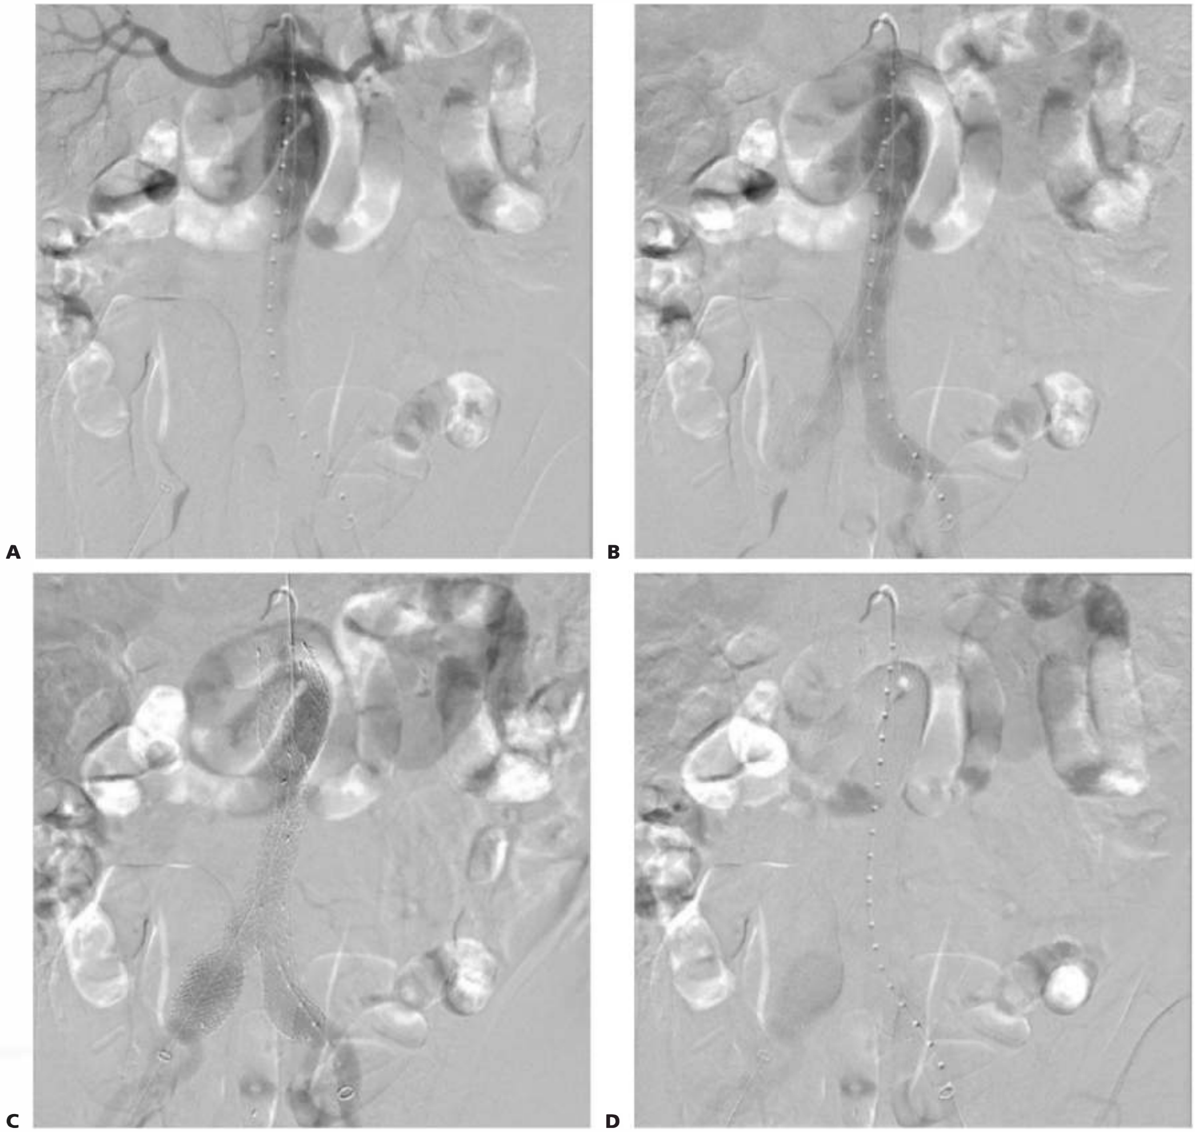

FIG 4 ● Completion arteriography. Special attention is paid to ensure the renal and iliac arteries are patent, as well as to identify if an endoleak is present. The endograft itself should be scrutinized for any evidence of limb kinking. **A.** Renal artery patency confirmed. **B.** No Type 1A endoleak confirmed. **C.** External and internal iliac artery patency confirmed and endograft itself should be scrutinized for any evidence of limb kinking. **D.** No type 1B, 2, 3, or 4 endoleak identified with delayed imaging.

ENDOVASCULAR ANEURYSM REPAIR FOR RUPTURED ANEURYSMS, OR REVAR

Percutaneous Access

- Bilateral CFA access is obtained under local anesthesia. The preclose technique (described in the previous section) can be employed when time and conditions permit, but if not possible, the case can proceed percutaneously initially, with conversion to open femoral closure when the endograft is fully deployed and internal bleeding has stopped.
- Rapid catheter and guidewire exchanges are performed, with sheath upsizing as noted in the previous section. The use of intravenous anticoagulation is controversial in this setting—again it is highly dependent on the hemodynamic status of the patient, presence of active bleeding, and existing consumptive coagulopathy. Often when treating ruptured aneurysms, the case begins without anticoagulation, which is subsequently instituted once the main body and extension limbs are deployed.
- In the case of rupture procedures, preoperative CT aortography may not exist or may not provide sufficient

anatomic detail to guide deployment. In this circumstance, catheter arteriography with a marker flush catheter should be employed to determine path lengths, landing zones, and optimal graft sizing.

Aortic Balloon Control

- Following access and wire exchange, a Lunderquist™ (Cook Medical) or similar stiff wire is advanced into the aorta, over which a 14-Fr × 55-cm braided sheath is advanced to the level of the renal arteries. Once localization is confirmed, the sheath is sutured to the skin at the access site.
- A semicompliant balloon (Coda™, Cook Medical) or similar aortic occlusion balloon is directed to a position immediately proximal to the visceral arteries under fluoroscopic guidance (**FIG 5**). Once positioned, it can be maintained in the deflated site until or unless the patient's hemodynamic status requires inflation and aortic occlusion.
- Once bilateral therapeutic sheath access is obtained and the deflated occlusion balloon is positioned properly, general anesthesia may be induced.

Endograft Delivery and Deployment

- Aortography is performed through the contralateral sheath below the balloon to localize the origins of the renal arteries.
- The main body endograft is placed up the ipsilateral sheath to the level of the renal arteries. It should be oriented so that the gate deploys in anterolateral fashion.
- The main body endograft is then deployed according to the IFU, just distal to the lowest renal artery. Deployment continues until the contralateral gate is fully deployed (**FIG 6**).
- The ipsilateral limb of the endograft is cannulated and the sheath advanced into the main body of the endograft.
- A second Coda balloon is placed in the ipsilateral sheath and inflated in the main body (**FIG 7**). The first balloon is deflated and removed through the contralateral sheath. Balloon placement should be performed in such a way that time without balloon coverage is kept to an absolute minimum. Retroperitoneal hemorrhage can continue at a rapid rate throughout this procedure, and in the absence of external bleeding, neither the surgeons nor the anesthesiologists may appreciate true magnitude of blood loss and circulatory reserve. Under these circumstances, hemodynamic collapse can be precipitous and, unfortunately, calamitous, unless an occlusion balloon is properly positioned and immediately inflated at the first indication of rapid hemodynamic deterioration.

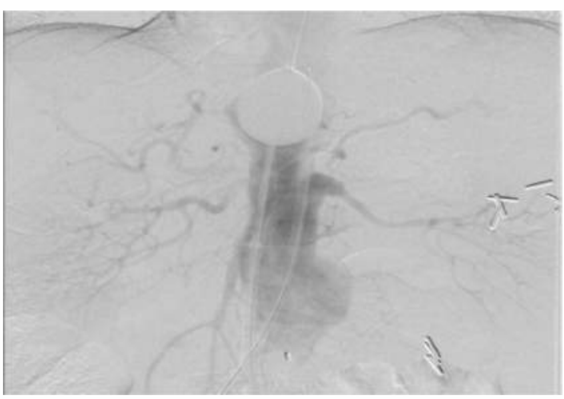

FIG 5 ● Aortic balloon control for REVAR. A semicompliant balloon is placed up the contralateral iliac artery proximal to the celiac trunk. It can be inflated depending on hemodynamic instability.

FIG 6 ● Main body deployment for REVAR. After an angiogram is performed to identify the renal arteries and aortic neck, the main body is deployed up the ipsilateral iliac artery. This can be done with the semicompliant balloon inflated.

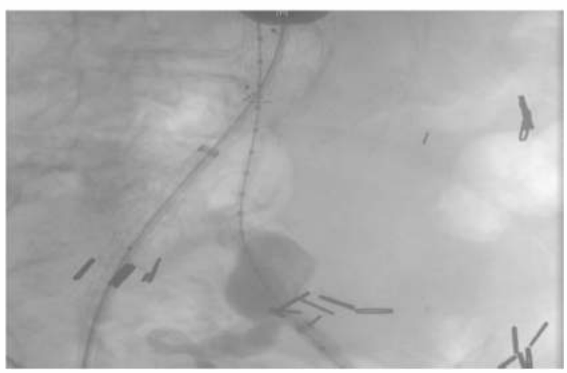

Figure 7 ● Balloon exchange and gate cannulation for REVAR. The entire ipsilateral gate is deployed prior to contralateral gate cannulation. A second semi-compliant balloon is placed up the ipsilateral endograft limb (top of image) and placed into the main body of the endograft. It can be inflated depending on hemodynamic instability. The first semi-compliant balloon is removed and the sheath is brought to distal to the contralateral gate to prepare for gate cannulation. Retrograde angiography with a marking catheter is performed through the contralateral sheath to identify the iliac bifurcation and desired limb extension length.

Gate Cannulation

- Gate cannulation proceeds in a standard fashion during REVAR.

Limb Extension

- Limb extension proceeds in a standard fashion during REVAR. Time awareness is critical during standard EVAR steps to ensure that aneurysm sealing is accomplished in the most expeditious manner possible.

Balloon Molding

- Coda™ balloon (Cook Medical) molding is performed at all seal zones to optimize hemostasis. Only after molding is complete is hemostasis assured.

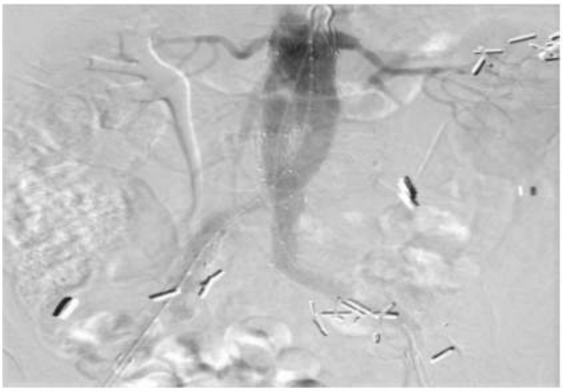

FIG 8 ● Completion aortography for REVAR.

Completion Aortography

- Completion aortography is performed as previously described. Attention should be paid to all the usual considerations, including presence and nature of endoleaks, iliac limb or arterial kinking, sufficient overlap in the landing zones to meet IFU, and so forth (**FIG 8**).

Closure

- Closure proceeds as indicated for standard EVAR, with caveat that if ProGlides were not deployed prior to percutaneous access, then surgical incisions will need to be made to expose the femoral artery sites for control and closure under direct vision as the therapeutic sheaths are withdrawn.

PEARLS AND PITFALLS

Access	▪ Ultrasound guidance is essential to limiting access complications. Visualize the needle tip entering the anterior artery wall, in an area deemed appropriate for access.
Gate cannulation	▪ In general, main body should be advanced through the more tortuous of the two iliac arteries to allow a more "straight shot" for the contralateral gate cannulation. This preference is not always practical, however, and laterality may need to be decided based on more practical considerations (e.g., Is the tortuosity sufficient to prevent main body positioning and deployment altogether?).
Tortuous iliacs	▪ Perform the completion aortogram with soft catheters instead of stiff wires in place. Stiff wires may straighten out a tortuous vessel, which may end up kinked when the wires are removed and lead to limb occlusion. Also, retention of stiff wires at the time of completion aortography may mask the development of type I proximal endoleaks, which may develop situationally when stiff wires are removed.
Closure	▪ Tie down the sutures of the closure device with the wire in place. If there is still significant bleeding, either deploy another closure device or place an occlusive sheath and proceed with open conversion of the femoral artery closure under more controlled circumstances.
Ruptures	▪ Outcomes are vastly improved when REVAR protocols are established and practiced. Abdominal compartment syndrome is a real and frequent complication following REVAR—if there is any indication that ventilation pressures are rising or abdominal pressures are significantly elevated at the end of the procedure by measuring bladder pressure, strong consideration should be given to decompressive laparotomy at the initial setting.

POSTOPERATIVE CARE

- Patients should remain supine for a minimum of 3 hours and are free to ambulate thereafter. Most elective EVARs can be discharged on postoperative day 1 or 2. For cases well within the IFU, same-day surgery is now a reality and can safely be offered to patients who can remain in reasonably close proximity to the hospital the evening after surgery.
- Following REVAR, consideration should be given to decompressive laparotomy whenever abdominal pressures are elevated at the end of the initial procedure. When decompressive laparotomy is performed, free peritoneal blood should be evacuated but retroperitoneal hematomas should not be explored or evacuated. Abdominal wound suction systems should be deployed to control drainage and provide a moist environment for intestinal viability. Dressing changes should be performed daily or every other day until the wound can be safely closed.
- Initial postprocedural CT aortography is performed at 1 month to document presence or absence of endoleaks

FIG 9 ● Postoperative imaging. 3-D reconstruction of a CT aortogram in a patient who have undergone successful EVAR at 1 month follow-up.

and graft position and confirm visceral perfusion (**FIG 9**). Follow-up imaging is performed with either ultrasound +/− noncontrast CT scanning or by CT aortography, based on the last known status of endoleaks (presence or absence), symptomatic status, and comorbid conditions such as chronic renal insufficiency. In general, we prefer serial ultrasound evaluations, with CT scanning reserved for aneurysms which are enlarging following endografting or evidence of significant changes in endoleak volume or location.

OUTCOMES

- All-cause mortality is similar in patients undergoing open or EVAR for AAA at 2 years.[3,8,9]
- There is higher perioperative survival in patients undergoing EVAR, which is sustained for several years.[3] The loss of this is due to late ruptures in the EVAR group.
- Secondary interventions are similar in open and EVAR.[3]

COMPLICATIONS

- Endoleak
- Delayed rupture
- Renal dysfunction
- Thromboembolism
- Limb occlusion
- Colon ischemia
- Abdominal compartment syndrome (ruptured EVAR)

Chapter 24

Advanced Aneurysm Management Techniques: Management of Internal Iliac Aneurysm Disease

W. Anthony Lee

DEFINITION

- Iliac aneurysm is defined as an iliac artery whose diameter is 20 mm or more. Iliac aneurysms are present in up to 20% of abdominal aortic aneurysms,[1] and common iliac aneurysms occur far more frequently than internal iliac aneurysms.
- Isolated iliac aneurysms represent less than 5% of all aortoiliac aneurysms.
- External iliac aneurysms are extremely rare and mostly either associated with underlying connective tissue disorders or represent traumatic pseudoaneurysms.

DIFFERENTIAL DIAGNOSIS

- Differential diagnoses of iliac aneurysm are limited to true degenerative aneurysms, which are most common; mycotic, traumatic, or surgical pseudoaneurysms; or aneurysmal enlargement of the false lumen from a primary dissection.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most iliac aneurysms are clinically silent (asymptomatic). Rarely, in very thin individuals with large aneurysms, a pulsatile aneurysm may be palpable on physical examination. Even more rarely, a patient being evaluated for hydroureter may be determined to have an iliac aneurysm. Ureteral obstruction in this circumstance derives from perianeurysmal inflammation (similar to retroperitoneal fibrosis) rather than mechanical compression by the aneurysm.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Although a plain abdominal x-ray can detect an aortoiliac aneurysm if there is heavy mural calcification, the most common imaging modalities include ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI).
- Thin-cut (1 mm), intravenous contrast-enhanced, spiral CT (CT arteriogram) represents the "gold standard" for diagnosis and anatomic evaluation of abdominal aneurysms. Even in patients with stage III/IV chronic kidney disease, high-quality imaging may be obtained relatively safely using reduced volumes of isoosmolar, nonionic contrast with multidetector (32, 64, 128, or 220) scanners, particularly following preprocedural intravenous hydration. The CT dataset is rendered into three-dimensional (3-D) images for dimensional postprocessing, a critical requirement for complex endovascular case planning.
- Conventional arteriography adds little to the identification and analysis of iliac aneurysms; penetrating ulcers may appear like saccular aneurysms, and large aneurysms with circumferential mural thrombus may appear to have a normal contour.

SURGICAL MANAGEMENT

- In general, iliac aneurysms are repaired when they reach 30 mm in diameter, become symptomatic, or rupture.
- Due to the relatively inaccessible location of iliac aneurysms, situated deep in the pelvis, as well as densely adherent pelvic veins posterior to the arteries and frequent co-occurrence of calcific occlusive disease, conventional surgical repair is challenging and fraught with risk of significant hemorrhage. Thus, evolving endovascular methods of repair have largely supplanted open surgical reconstruction.
- A variety of off-label devices and hybrid techniques have been applied to iliac aneurysm management. The variability derives, in large part, from uncertainty regarding the need to preserve antegrade internal iliac artery flow in most patients. Indications for internal iliac preservation remain controversial due to the added complexity, cost, and uncertain benefit derived from such procedures; analysis of the relative merits of intentional unilateral occlusion versus preservation in the management of iliac aneurysm disease is beyond the scope of this chapter.

Preoperative Planning

- As in all things endovascular, high-quality imaging is critical for precase planning and, as previously mentioned, CT arteriography is optimal for this purpose. Using a combination of axial imaging and 3-D postprocessing, complete evaluation should, note the following:
  - Locations, diameter, and length of proximal and distal landing zones
  - Iliac artery tortuosity and angulation
  - Presence and severity of associated occlusive disease
  - Ipsilateral and contralateral internal iliac artery patency
  - Status of the ipsilateral deep femoral artery
  - Concomitant abdominal or thoracic aortic pathology
- In general, landing zones are sited in nonaneurysmal arterial segments, manifesting minimal occlusive disease, with relative absence of angulation or tortuosity. The allowable diameter range for treatment may vary, depending on the particular device to be deployed. In all circumstances, reference should be made to the "Instructions for Use" included in the package insert.
- Device selection is based on the need for durable aneurysm exclusion and endograft fixation, accomplished with the fewest component pieces possible.
- This chapter focuses on endovascular and hybrid management strategies for the iliac bifurcation in the context of large common or internal iliac aneurysms. Standard techniques suffice for management of smaller (<24 mm) aneurysms that do

not involve the bifurcation, either in isolation or associated with larger proximal aortic aneurysms.

Positioning

- Nearly all endovascular aortoiliac aneurysm repairs are performed with the patient in the supine position, with both arms tucked. The operative team stands on the patient's right, with the C-arm brought in from the left. Although some operators prefer to access the left groin from the left side of the table, for a right-handed operator, it is ergonomically more natural to access both groins from the right.
- Electrocardiogram (EKG) leads and other monitoring cables and lines are positioned so that they are not in the x-ray beam and do not entangle the C-arm gantry.
- The left arm should be available for brachial artery access when necessary; it is not routinely prepped into the surgical field.

ENDOVASCULAR COMMON ILIAC ARTERY ANEURYSM REPAIR WITH INTERNAL ILIAC ARTERY OCCLUSION

- After obtaining bilateral femoral access, a shepherd's hook–type (e.g., Omni™ Flush) side-hole catheter is advanced from the contralateral side for pelvic arteriography. Typical injection technique is 10 to 15 mL contrast at 15 mL per second. Following satisfactory anatomic delineation, a steerable hydrophilic 0.035 guidewire (e.g., angled Glidewire®, Terumo) is advanced through the same catheter into the ipsilateral external iliac artery. Following exchange for a stiffer guidewire (e.g., Rosen®), the flush catheter and contralateral femoral sheath are removed and replaced with a 45-cm 6-French (Fr) guide sheath (e.g., Balkan® or similar braided sheath), positioning the tip in the distal third of the common iliac aneurysm (**FIG 1**).
- A 65-cm 4-Fr angled catheter (e.g., Kumpe®) is advanced through the sheath and, under digital subtraction roadmapping guidance, directs the hydrophilic guidewire into the ipsilateral internal iliac artery (**FIG 2**). The catheter is then advanced securely into either the anterior or posterior divisions. The C-arm gantry is positioned at approximately 30 degrees contralateral anterior-oblique for optimal visualization during this maneuver. With access secured, the 6-Fr sheath is then advanced over the 4-Fr catheter into the proximal internal iliac artery.
- A selective internal iliac arteriogram is obtained through the 6-Fr sheath, and the angle catheter is retracted to the first bifurcation of the internal iliac artery. Typically, distal access is maintained with the wire during this maneuver.
- [Alternate technique] Depending on anatomic considerations (e.g., tortuosity, iliac bifurcation angle, internal iliac branch anatomy, etc.), ipsilateral access may be

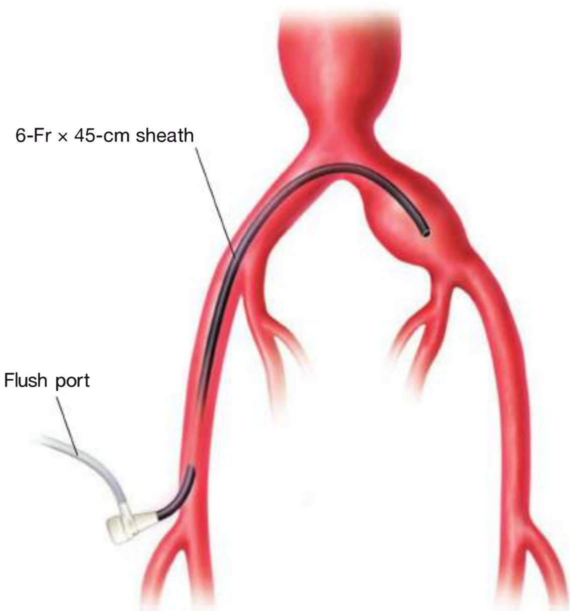

FIG 1 ● A 45-cm, 6-Fr guide sheath is introduced from the contralateral femoral access. This provides a stable platform for interval angiography, selective catheterization, and coil embolization of the internal iliac artery.

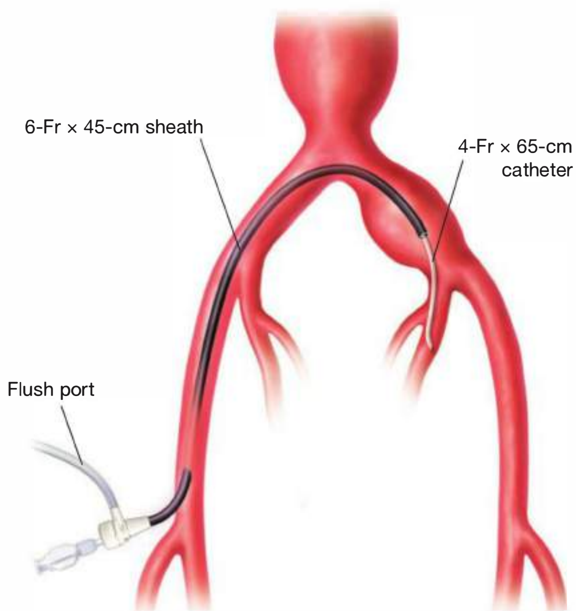

FIG 2 ● A 65-cm, 4-Fr angled catheter is used to selectively engage the internal iliac artery. Typically, the catheter is used in combination with a soft-tipped angled hydrophilic guidewire. After the guidewire crosses the origin of the internal iliac artery, it is advanced deep into any one of its distal branches, and the catheter advanced over the guidewire. The hydrophilic guidewire is removed, and an angiogram is performed through the catheter to confirm correct position in the main trunk of the internal iliac artery. The 6-Fr guide sheath may be optionally advanced closer to the origin of the artery before removing the guidewire to gain additional stability.

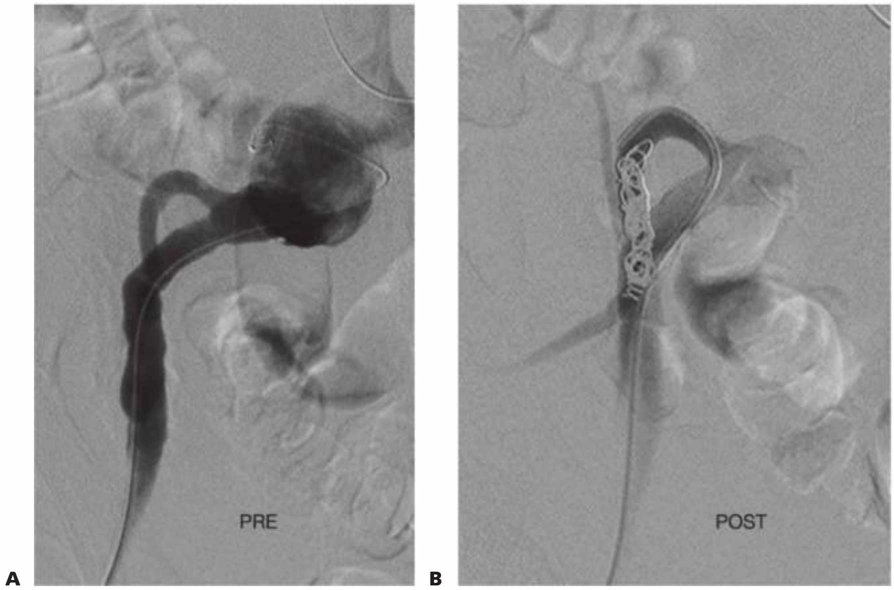

FIG 3 ● **A,B.** When using the ipsilateral approach, a variety of catheter shapes may be used depending on the angle of the internal–external iliac bifurcation and the luminal diameter of the common iliac aneurysm. The three most useful are the shepherd's hook, Cobra®, and right-angle curved catheters.

feasible. In this case, a 25-cm, 6-Fr sheath is advanced from the ipsilateral femoral artery. A 4- or 5-Fr appropriately shaped catheter (curve or reverse curve) directs the hydrophilic guidewire into the internal iliac artery (**FIG 3**). If a shepherd's hook catheter type is employed, the hook may be reformed either in the iliac aneurysm or in the aorta, depending on their respective luminal diameters. The ipsilateral approach is more demanding technically and is not recommended when concomitant internal iliac aneurysm embolization is also indicated.

- Size-appropriate platinum occlusion coils are deployed through the 4-Fr catheter into the main internal iliac artery trunk, with care taken to avoid placement or distal migration into arborizing branches or reflux back into the main iliac circulation. Alternative vascular occlusion devices may also be used for internal iliac embolization, including hydrogel coils and nitinol mesh (e.g., Amplatzer®) plugs. Interval arteriograms are obtained using small volume hand injections through the sheath or catheter to guide deployment and confirm positioning. Complete occlusion of the target artery during deployment is not necessary or even desirable. Following subsequent endograft deployment over the internal iliac artery orifice, in the absence of antegrade flow, the extensive surface area of the coils induces rapid thrombosis following reversal of anticoagulation at the end of the procedure. Usually less than five coils will suffice to ultimately induce complete occlusion.
- [Alternate technique] The presence of an internal iliac aneurysm, either with or without an associated proximal common iliac aneurysm, deserves special consideration. In these situations, more extensive embolization of the internal iliac circulation will be necessary to prevent retrograde (type II) endoleak. Individual internal iliac branches must be separately embolized at the initial procedure (**FIG 4**).

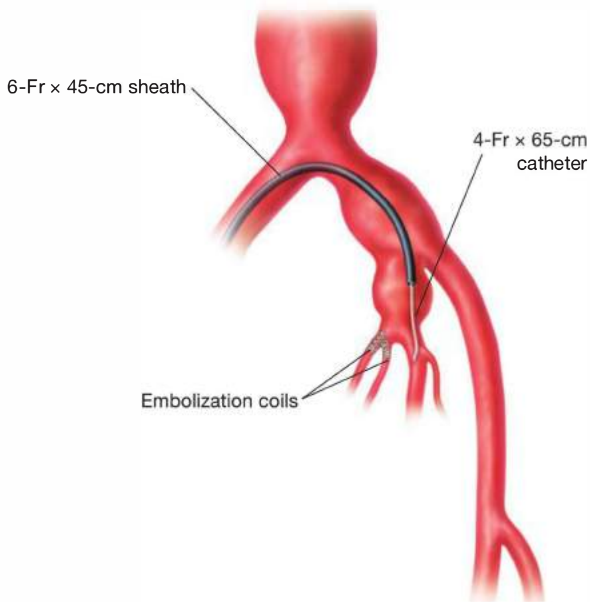

FIG 4 ● In the setting of ipsilateral concomitant internal iliac aneurysm treatment, the contralateral approach should be used, and guide sheath advanced well within the internal iliac artery itself. Individual branches arising from the internal iliac aneurysm may prove difficult to identify and catheterize. Multiple projections of the C-arm gantry, both in lateral oblique and craniocaudal directions, should be employed to visualize the branches.

If left untreated, due to collateral pelvic flow, these branches unfortunately remain patent following endograft deployment, severely limiting options for secondary procedures. Complete branch vessel embolization can be time consuming and tedious, due to the sheer number, anatomy and sizes of the branches that must be occluded, requiring patience, expert catheter and guidewire skills, and excellent intraoperative imaging.

- [Alternate technique] When the common iliac aneurysm tapers to a funnel near the iliac bifurcation, the so-called sleeve technique may be employed to occlude the adjacent internal iliac artery. In this method an appropriately sized aortic cuff is deployed into the distal common iliac artery and over the internal iliac artery origin. The distal end of this cuff is partially extended into the external iliac artery. The iliac limb is next passed through the aortic cuff and deployed normally from its proximal landing zone and into the external iliac artery 20 mm distal to the aortic cuff (**FIG 5**). The putative benefit of this technique is avoidance of potential atheroembolization that may occur during standard coil occlusion techniques from catheter manipulation, which some speculate is the cause of ischemic complications following internal iliac artery occlusion.
- Following internal iliac occlusion, subsequent aneurysm exclusion procedures vary as functions of landing zone and aneurysm anatomy. Endograft deployment nearly always follows management of the internal iliac artery in some form or another. In the typical scenario, following internal iliac embolization, the endograft positioning and deployment proceeds in the standard fashion except for extension of the ipsilateral distal landing zone beyond the iliac bifurcation to the external iliac artery. At least 20 mm of purchase into the external iliac artery is recommended.
- In the unusual case of an isolated common iliac aneurysm without aortic involvement, with a proximal uninvolved segment at least 20 mm in diameter and 15 mm in length, a short endograft may be deployed to bridge the proximal common and external iliac arteries.[2] Device options for this approach include either the "off-label" deployment of an aortouniiliac converter graft or placement of a flared or "bell bottom" iliac endograft limb that has been previously deployed, reversed, and reloaded into the delivery sheath at the back table (way off-label). These adaptations are often necessary because although nonaneurysmal, the common iliac artery is still too large to securely seat the proximal end of most iliac limbs. To obtain a satisfactory proximal seal, the distal flared segment, commonly available in diameters up to 24 mm, is deployed proximally by simply reversing the limb in the sheath (**FIG 6**).

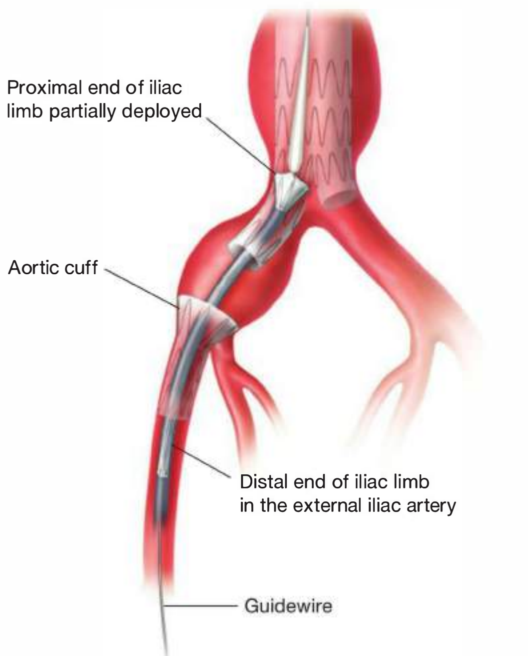

FIG 5 ● Note that in this technique, the distal segment of the common iliac aneurysm must funnel down so that the aortic cuff will coapt securely against the internal iliac orifice. The aortic cuff should be expanded following deployment with a compliant molding balloon to securely seat in position to prevent subsequent inadvertent dislodgement when advancing the iliac limb delivery system.

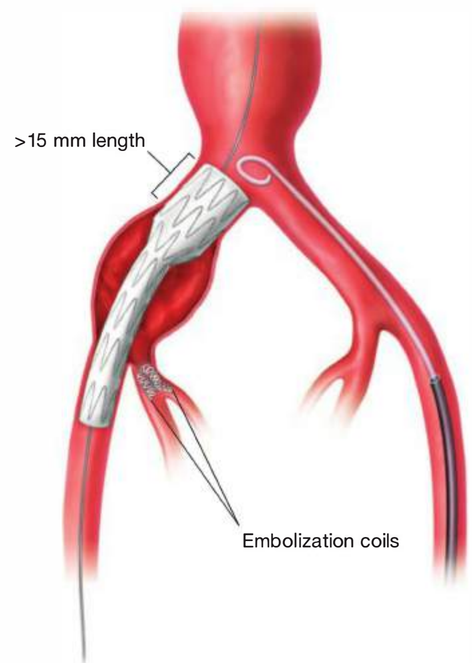

FIG 6 ● Not all endograft systems have an aortouniiliac device or converter. Similarly, not all endografts can be deployed ex vivo and resheathed. Currently, the only system is the Zenith Flex® (Cook, Bloomington, IN). If the origin of the contralateral common iliac artery is partially covered and flow compromised for any reason, a bare metal balloon-expandable stent should be deployed in a "kissing" manner.

ENDOVASCULAR COMMON ILIAC ARTERY ANEURYSM REPAIR WITH INTERNAL ILIAC PRESERVATION

- These techniques specifically pertain to common iliac aneurysms without an associated ipsilateral internal iliac aneurysm. In cases of an internal iliac aneurysm (see exception below), preservation methods are not possible and selective branch occlusion (see above) and endovascular exclusion are necessary.
- Indications for internal iliac artery preservation may include the following:
  - Routine revascularization as procedural preference
  - The presence of contralateral internal iliac occlusion
  - Active patient with concern/potential for buttock claudication
  - Diabetic with diseased ipsilateral deep femoral artery (reduced potential collateral supply)
  - Prior thoracic endograft repair (concern regarding anterior spinal artery collateral flow arising from the internal iliac circulation and potential for postoperative paraplegia)
- The simplest internal iliac preservation technique involves deployment of flared or so-called bell-bottom devices. Although anecdotally applied to larger aneurysms, conventionally, this technique is limited to common iliac artery aneurysms with 24-mm or shorter diameter distal landing zones. As an off-label modification of this technique, for common iliac aneurysms with larger or poorly defined distal landing zones, the maximal diameter flared iliac limb is intentionally deployed approximately 2 cm proximal to the internal iliac artery orifice. An aortic extension cuff without a proximal uncovered stent (typically 28 mm) is then deployed halfway into the unsecured iliac limb and flared out into the distal aneurysm, essentially creating a larger landing zone than that conventionally available (**FIG 7**). Although strictly speaking, cuff deployment is essentially in the aneurysm itself; late outcomes from these procedures appear favorable, with a low reported incidence of migration or type Ib endoleak.
- Direct internal iliac artery revascularization can also be accomplished by surgical bypass from or transposition to the ipsilateral external iliac artery distal to the ipsilateral endograft limb. Like all open vascular procedures, exposure is the most critical requirement for technical success.
- Proper incision placement and entry into the retroperitoneal space is tantamount to gaining adequate and safe iliac bifurcation exposure and minimizing postoperative discomfort. For these exposures, the primary surgeon stands on opposite side of the table. The incision is centered over either lower quadrant and starts at a paramedian location at level of the umbilicus and gently curves toward the midline over the first third of the distance from the umbilicus to the symphysis pubis (**FIG 8**). Exposure proceeds through the anterior rectus sheath following the hockey-stick shape of the skin incision. Care is taken not to divide the rectus muscle—this is a complete "muscle-sparing" technique. The sheath itself is incised at least 3 to 5 cm medial to the semilunar line. Keeping the rectus muscle intact reduces incisional hernia risk and decreases postoperative pain.
- The rectus muscle is dissected away from the sheath and retracted medially. The retroperitoneal space is developed below the arcuate line (linea semicircularis) just superior to the inferior epigastric vessels, which are

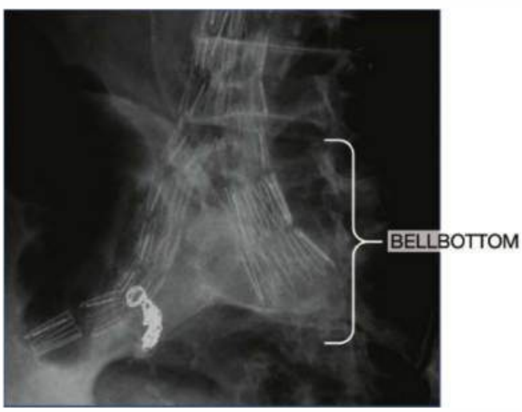

FIG 7 ● In this instance, the patient had bilateral common iliac aneurysms. The right side was large and left was smaller. The right internal iliac artery was occluded and the iliac limb extended to the external iliac artery. The bell-bottom technique was able to be used for the smaller left common iliac aneurysm because it was only 24 mm.

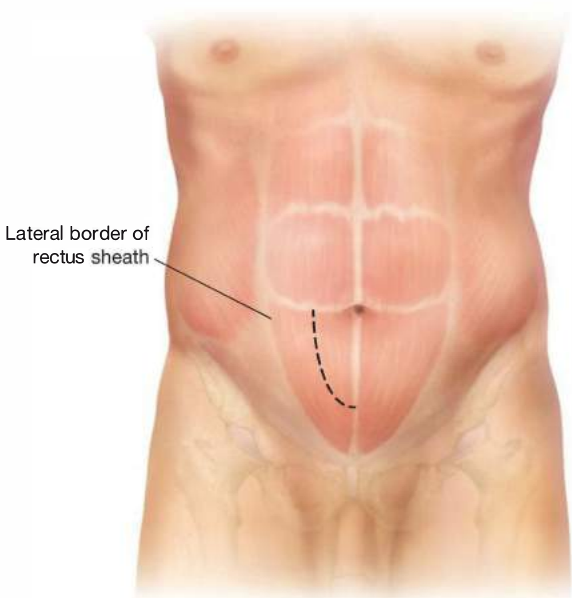

FIG 8 ● In some patients, the distance between the umbilicus and the symphysis pubis may be quite short. If so, the longitudinal segment of the incision is extended more inferiorly than depicted in this diagram. The most important technical point of this exposure is to place the incision sufficiently medially as the lateral border of the rectus sheath is not palpable and there are no obvious surface landmarks.

preserved and gently swept inferiorly. In women without prior hysterectomy, the round ligament of the uterus is often encountered as a fibrous cord during this exposure and is divided between ties. The peritoneal sac is swept bluntly medially until the external iliac artery and the distal half of the common iliac aneurysm are exposed. The ureter is visualized crossing the iliac artery and should be left undisturbed. Self-retaining retractors (e.g., Bookwalter®) are placed at this point.

- Choice of retractors and proper placement are essential for procedural success. The retractor post is placed on the opposite side about the level of the costal margin, and a small round ring is fixed and centered directly over the incision. A Balfour® blade is placed over the inguinal ligament, and a medium Kelly® blade oriented toward the opposite shoulder. A narrow malleable blade is oriented medially to retract the bladder. Following retractor placement, if the incision was sited properly, the iliac bifurcation should be positioned directly in the center of the surgical field.
- The midsegment of the external iliac artery is exposed and controlled. The internal iliac artery is next isolated from the surrounding tissue, from its origin to the bifurcation of the anterior and posterior divisions, which are individually controlled. No attempt should be made to expose anything more than a small anterior aspect of the distal common iliac aneurysm during this maneuver.
- The internal iliac artery origin is ligated with 0-polypropylene suture, and the anterior and posterior divisions of the internal iliac artery are controlled independently. Additional small branches arising from the main trunk are clipped for hemostasis. The internal iliac artery is divided as proximally as possible, and the stump closure is reinforced and imbricated with a 5-0 polypropylene suture (**FIG 9**). The distal internal iliac artery is then mobilized from the subjacent internal iliac vein.
- The patient is systemically anticoagulated at this point. An 8-mm × 10-cm graft knitted, collagen-impregnated polyester graft is anastomosed to the distal stump of the internal iliac artery in an end-to-end manner. The graft is occluded at its open end and distal control released to test anastomotic leaks. The graft is then recontrolled just proximal to the distal anastomosis.

FIG 9 ● When the incision is properly positioned, the iliac bifurcation should be located directly in the center of the wound. The common iliac aneurysm is minimally exposed to allow the stump of the divided internal iliac artery to be safely oversewn.

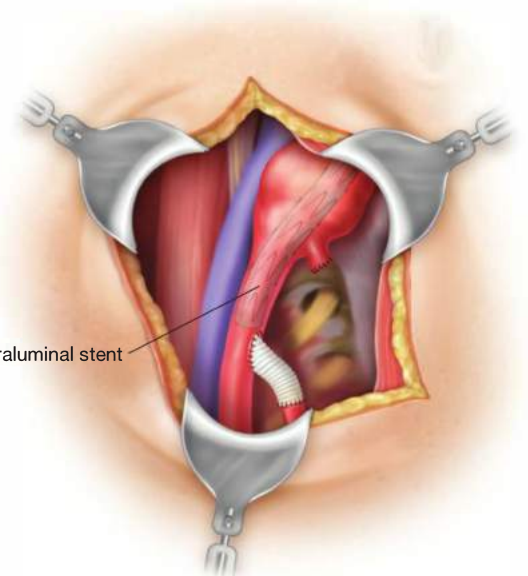

FIG 10 ● An 8-mm graft is anastomosed to the distal end of the internal iliac artery first. Due to the deep nature of this artery, this anastomosis can be difficult. An open ("parachute") anastomotic technique can be helpful in visualizing the suture line throughout placement. The distal anastomosis is tested for hemostasis and any leaks completely repaired before the proximal anastomosis is performed, as the former may be difficult to see once the latter is completed. The external iliac anastomosis is performed at least 5 cm distal to its origin along its posteromedial aspect.

- A segment of the ipsilateral, adjacent external iliac artery, at least 5 cm distal to its origin, is next mobilized and controlled. Following creation of a posteromedial arteriotomy, the graft is trimmed and beveled to length and anastomosed to the external iliac artery in an end-to-side manner. The graft is flushed routinely and flow restored to the internal and external iliac arteries (**FIG 10**).[3]
- A large clip is sewn transversely at the heel of the external iliac artery anastomosis to establish a fiducial point for the internal iliac bypass. After hemostasis is confirmed, the retractor system is removed and retroperitoneal contents allowed to collapse back into the wound. The endovascular portion of the procedure completed through femoral artery access sites in a standard fashion.
- After endograft deployment and satisfactory completion aortography, the retroperitoneum is reinspected for hemostasis following reversal of anticoagulation. The anterior rectus sheath is closed with a running 1-0 PDS suture, followed by closure of Scarpa's layer and skin.
- [Alternate technique] Occasionally, the common trunk of the internal iliac artery is long and runs parallel to the course of the external iliac artery for some distance. If sufficient length is present, the internal iliac artery may

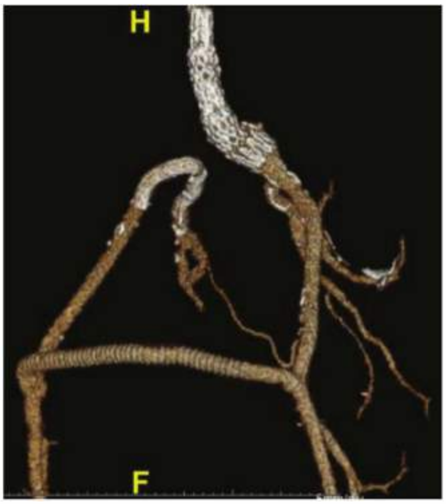

FIG 11 ● Note that an endovascular external-to-internal iliac bypass has been created on the right side which also excludes the common iliac aneurysm. The durability of this bypass is compromised given its reliance on retrograde perfusion through the femoral–femoral bypass graft, the angulated nature of the graft position, and the propensity for one or both ends to "back out" of the origin and target arteries, given sufficient time, pressure, and movement.

be transposed to the external iliac artery, as long as the anastomosis is tension-free.

- [Alternate technique] Another hybrid approach is available to preserve internal iliac flow. In this method, a covered self-expanding stent (e.g., Viabahn®, W. L. Gore, Flagstaff, AZ) is deployed to provide retrograde flow from the external to internal iliac artery, ipsilateral to the common iliac aneurysm to be excluded. An aortouniiliac endograft is then deployed from the contralateral side, and the procedure completed with a femoral–femoral bypass graft (**FIG 11**). Several circumstances limit the general applicability of this technique, including an acute external–internal iliac bifurcation angle and significant diameter discrepancy (>2 mm) between the two arteries. Also, the durability of this technique is not well established and may be limited by the propensity of the covered stent to back out of either the origin or destination artery or kink. This technique also requires advanced catheter and guidewire skills and a large device inventory to reliably complete the procedure.
- [Alternate technique] More recently, a variation of the chimney (parallel) stenting technique has been described for complete endovascular repair of common iliac aneurysms.[4] In this technique, the proximal brachial artery is exposed through an axillary incision to allow safe introduction of a long (90 cm) braided 9-Fr sheath. Briefly, after the bifurcated main body endograft is deployed, the long 9-Fr sheath is advanced from the left brachial artery, through the main body, and positioned into the ipsilateral common iliac artery. The internal iliac artery is catheterized, followed by wire exchange for a stiff wire. A covered self-expanding stent graft (e.g., Viabahn®), sized for the target internal iliac artery diameter, is deployed from the ipsilateral iliac gate to the internal iliac artery landing zone. A second covered self-expanding stent graft is advanced from the ipsilateral femoral artery access retrograde into the aneurysm and proximal external iliac artery and deployed at the same level as prior internal iliac artery stent graft. Both stent grafts are expanded within the ipsilateral iliac limb of the aortic endograft using a kissing-balloon technique. This procedure can be repeated for the contralateral side in cases of bilateral common iliac aneurysms (**FIG 12**). Care should be taken during this maneuver to deploy each stent graft sequentially, rather than simultaneously, in order to position the covered stents accurately relative to each other.
- [Alternate technique] Although only available under an investigational device exemption (IDE), U.S. Food and Drug Administration (FDA)–approved clinical trial at the current time, an iliac branch device (IBD) is under

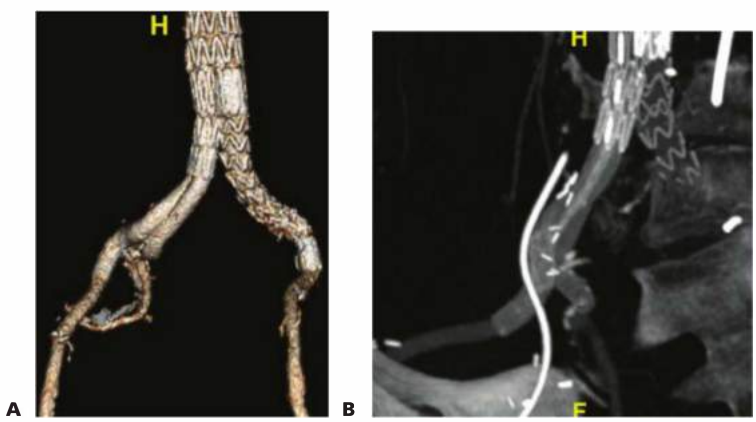

FIG 12 ● Like all "chimney" techniques, the proximal seal is dependent on the length of the parallel segment. In this instance, it should be more than 5 cm to promote thrombosis of the "gutters" between the parallel stents. It is not uncommon for a small type III endoleak to be seen on the completion angiogram with the patient anticoagulated.

TECHNIQUES

development for total endovascular repair of common iliac aneurysms (**FIG 13**). Briefly, this bifurcated device is inserted ipsilateral to the common iliac aneurysm prior to main body deployment. It is designed to be used in conjunction with a standard bifurcated aortic endograft. The partially constrained branch in the investigational device and adjacent internal iliac artery are catheterized from the contralateral side employing a preloaded catheter in the delivery system and cross-femoral guidewire access. A bridging covered stent is advanced from the branch to the internal iliac artery. Following this, a standard bifurcated endovascular aneurysm repair is completed in the usual manner.[5]

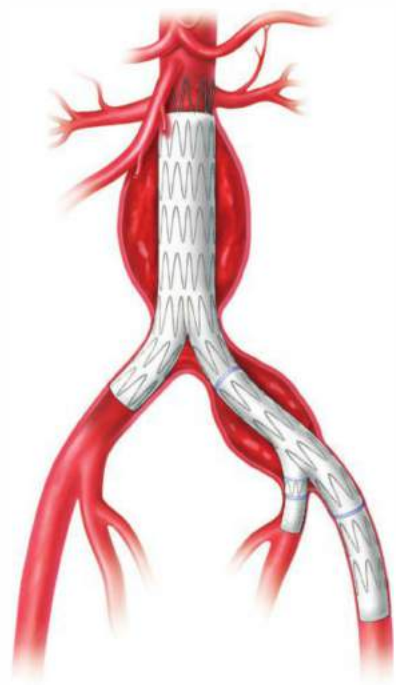

FIG 13 ● This figure depicts the IBD used in the repair of a left common iliac aneurysm. A covered stent is required to bridge the iliac branch to the native internal iliac artery. Although this bridging stent is typically delivered from the contralateral side, it may also be introduced through the left brachial artery.

PEARLS AND PITFALLS

Choose the right procedure for the right patient.	▪ Although perfusion is optimally maintained to at least one internal iliac artery, preservation should be attempted selectively, weighing the risks and benefits of potential ischemic complications associated with intentional occlusion vs. the additional complexity and long-term durability issues associated with preservation techniques.
External-to-internal iliac bypass exposure	▪ Make sure the longitudinal segment of the skin incision is sufficiently medial to the lateral edge of the rectus to accommodate a single layer fascial closure. The preserved rectus muscle provides a natural barrier against postoperative abdominal wall hernia formation.
Use a cross-over introducer sheath for internal iliac embolization.	▪ The cross-over sheath allows for intermittent contrast injection and stabilization of the embolization catheter. Internal iliac sheath access also minimizes the probability that deployed coils may reflux retrograde into the axial iliac circulation, requiring often prolonged and frustrating attempts at retrieval.
Pelvic bleeding	▪ The internal iliac vein is posterior and adherent to the artery and may be the source significant, unanticipated hemorrhage if injured during circumferential arterial dissection.
Inflow to the internal iliac bypass	▪ Choose a site on the external iliac artery sufficiently distal to its origin so that the stent graft can land in a segment free from kinking and prevent subsequent development of an ipsilateral type Ib endoleak.

POSTOPERATIVE CARE

- Postoperative care is similar to a standard endovascular aneurysm repair. A complete blood count and a basic metabolic panel are checked the following morning.
- If the procedure was performed entirely using endovascular techniques, oral intake is started immediately, Foley catheter is removed, and patient is encouraged to ambulate and discharged on following postoperative day.
- If the procedure involved a surgical internal iliac revascularization, the patient is started on clear liquids and advanced as tolerated. The retroperitoneal approach is not typically associated with a clinically significant ileus, and the muscle-sparing exposure is well tolerated. Patients may be discharged typically on the second postoperative day.

OUTCOMES

- Ipsilateral hip and buttock claudication develops in as many as 40% of patients following acute internal iliac artery occlusion. Fortunately, more severe forms of postprocedural pelvic ischemia, although potentially lethal, occur extremely rarely. Although claudication symptoms, when present, are reported to improve within 6 months following the procedure, this improvement may be attributable to lifestyle alteration (e.g., walking less) rather than collateral vessel formation. It is generally agreed, however, that complete symptom resolution rarely occurs.

- Internal iliac bypass grafting (surgical or endovascular) effectively maintains pelvic perfusion, with excellent long-term patency. Most patients enjoy a symptom-free postoperative course in perpetuity. Thus, in active individuals, as a general recommendation, internal iliac circulation should be preserved whenever possible.

COMPLICATIONS

- Complications for management of common iliac aneurysms can be a result of internal iliac revascularization or occlusion techniques.
- The main complication associated with revascularization is bleeding. This can occur intraoperatively from venous injury and/or postoperative anastomotic or other arterial sources. Other less common complications include ureteral injury, bowel injury, ipsilateral leg ischemia, and early graft thrombosis.
- Complications associated with acute occlusion of internal iliac artery include the spectrum of ischemic symptoms ranging from hip and buttock claudication to more severe forms such as perineal necrosis, ischemic sacral plexopathy, and vasculogenic impotence.
- The internal iliac artery serves as an important outflow branch in maintaining patency of the iliac limb after endovascular aneurysm repair. Iliac limbs whose distal landing zone is placed in the external iliac artery may have an increased risk of thrombosis. However, this is not an indication for any additional antiplatelet or anticoagulation treatments beyond what is customary.

Chapter 25

Occlusive Disease Management: Isolated Femoral Reconstruction, Aortofemoral Open Reconstruction, and Aortoiliac Reconstruction with Femoral Crossover for Limb Salvage

Nathan Itoga E. John Harris, Jr.

DEFINITION

- Aortoiliac occlusive disease falls under the umbrella of peripheral artery disease where atherosclerosis and chronic plaque accumulation leads to diminished blood supply to distal arterial beds.
- The aortic bifurcation near the level of the L4 disc space is one of many areas of decreased shear stress and is an area of early atherosclerosis.
- Peripheral arterial disease (PAD) is usually classified into inflow and outflow disease.
- The infrarenal aorta and iliac vessels are of larger caliber and are classified as inflow vessels.
- The infrainguinal outflow from the common femoral artery is via the profunda femoral and superficial femoral arteries.
- The patterns of arterial stenosis and occlusion can be broken up into five types (Table 1). When a combination of both inflow and outflow disease exists, treatment is focused on the aortoiliac system first or femoral artery occlusive disease. Outflow occlusive disease is addressed in Part 6, Chapters 26–28, 31–33.

Table 1: Type of Lower Extremity Disease Patterns

	Distribution	Notes
Type 1	Confined to the distal infrarenal aorta and common iliac arteries	10% of disease patterns—found in younger female patients. Long-term patency after bypass is lower when done in patients <50 years of age.
Type 2	Found within infrarenal aorta, common and external iliacs	Most common presentation of aortoiliac disease
Type 3	Occlusive disease in the aortoiliac segment is combined with femoropopliteal or tibial disease.	Found commonly in critical limb ischemia
Type 4	Isolated superficial femoral and popliteal artery	
Type 5	Diffuse disease in the femoral popliteal and tibial vessels	

DIFFERENTIAL DIAGNOSIS

- Neurogenic claudication is frequently confused for arterial claudication. Neurogenic claudication is variable—some good days, some bad—whereas arterial claudication is very consistent. Neurogenic claudication can be relieved by the use of spinal support while walking, such as a shopping cart, or wheeled walker. These aids do not influence arterial claudication symptoms.
- Osteoarthritis of the hips can be frequently confused with arterial claudication. Like arterial claudication, pain is brought on by activity and relieved by rest and is more common with increasing age.
- Venous claudication from chronic venous outflow obstruction is described as a bursting type pain, comes on at longer distances, requires a longer rest period that requires leg elevation, and is frequently associated with leg swelling and discoloration.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of aortoiliac occlusive disease can readily be made from a patient's clinical history and physical examination.
- Patient's with aortoiliac disease have up to a 50% risk of concomitant coronary artery disease with the same risk factors of smoking, hypertension, lipid abnormalities, diabetes mellitus, male gender, increased age, and family history.
- The disease burden in the internal and external iliac blood supply leads to a variety of clinical presentations which is most notable for Leriche syndrome which comprises the symptoms of buttock claudication, impotence in men, muscle atrophy, and absent or diminished femoral pulses.
  - Claudication is the most common presenting symptom and is not limited to the buttocks but can occur in the hip, thigh, and, rarely, in the calf muscles.
  - Impotence as an isolated symptom in men should be evaluated for other possible causes. Impotence is only seen in 30% of men with decreased hypogastric perfusion as there are abundant collaterals from the mesenteric, profunda, and lumbar arteries.
  - Ankle–brachial indices (ABI) are usually diminished but rarely lower than 0.5 in isolated aortoiliac occlusive disease for the same reason cited earlier. It is rare to see critical limb ischemia, which encompasses rest pain and/or

tissue loss, in the setting of isolated aortoiliac disease as there are multiple collaterals through the ilioprofunda system.
- Severe common femoral disease, with both superficial femoral and profunda femoral artery high-grade stenosis or occlusion, can mimic aortoiliac occlusive disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasound studies available in noninvasive vascular laboratories can help aid in diagnosis and assess the degree of PAD.
- ABI measurements can be supplemented by exercise, where a decrease in 15% of the ABI is considered significant as a decrease in peripheral resistance during exercise leads to diminished blood flow distal to the point of stenosis or obstruction.
- Duplex ultrasound for the aortoiliac system is difficult and is limited by body habitus and bowel gas. With an experienced technician, arterial disease of the intraabdominal vessels can be detected with greater sensitivity.
- For vascular surgeons, computed tomography angiography (CTA) is the noninvasive imaging study of choice for preoperative planning. Considerations for kidney disease and contrast dye allergies need to be taken into account. The evaluation usually involves the abdomen pelvis and runoff to the feet. It is difficult, especially in tall patients, to evaluate the thoracic aorta during one contrast bolus due to timing of the contrast injection. A CTA study provides accurate estimation of luminal flow and with good visualization of degree of calcification.
- Magnetic resonance (MR) angiography is also useful but is found to, at times, overestimate the degree of stenosis, and motion artifacts may limit the quality of the study.
- Direct arteriography under fluoroscopy is considered the gold standard, but improvements in CTA approach this accuracy in evaluating PAD.
- Arteriography may be difficult in the setting of an iliac occlusion and may need to be performed through the descending thoracic artery using a radial or brachial artery approach.
- Some surgeons may forego computed tomography (CT) studies and proceed with a contrast digital subtraction angiogram in the setting of a reliable history and physical and/or noninvasive ultrasound testing. This may limit the amount of contrast dye the patient is exposed to by proceeding directly with endovascular intervention. Like CTA, catheter-based arteriographic studies should include infrainguinal outflow of the femoral, popliteal, and tibial vessels, in addition to the abdominal and pelvic views.
- Although rarely used, pressure catheters can also be used during arteriography to identify significant lesions with a mean arterial pressure drop of 5 to 10 mm Hg across the stenosis considered significant.
- Preoperative imaging is essential in preoperative planning. The degree of aortoiliac disease in combination with infrainguinal and tibial occlusive disease needs to be considered in choosing the appropriate intervention for the patient.
- Graft selection, location of cross-clamping, and enlarged collaterals need to be accounted for prior to surgery.
- Identifying the degree and extent of arterial occlusive disease also enlightens the decision between an open or endovascular approach.
- The Trans-Atlantic Inter-Society Consensus (TASC) Classification (**FIG 1**) is a multispecialty consensus approach to managing aortoiliac occlusive disease. Routinely, TASC A and B lesions are treated with endovascular approaches with balloon angioplasty and/or stenting. TASC C and D lesions have a better outcome with an open approach.

SURGICAL MANAGEMENT

- Before surgical management is pursued, medical management should be initiated due to the high incidence of coronary artery disease with peripheral artery disease.
- Patients should be advised to quit smoking; placed on a regular walking program, ideally supervised; and started on statin therapy and aspirin when appropriate and tolerated.
- Preoperative anesthesia visits should include inquiries into cardiac, lung, and renal systems to evaluate overall operative risk.
- Age and comorbidities should be factored into decisions regarding an open versus endovascular approach, as should procedural durability and invasiveness of the intervention.
- The aims of therapy in aortoiliac occlusive disease are to relieve symptoms and, in cases of critical limb ischemia, prevent limb loss. Revascularization of the aortoiliac system can be done in a variety of endovascular and open approaches. The choice of procedure depends on the disease pattern, patient risk factors, available resources, and surgeon experience.
- We describe three common operative interventions for inflow disease: aortobifemoral bypass, femoral–femoral bypass, and femoral endarterectomy.

TYPE A Lesions

- Unilateral or bilateral stenosis of CIA
- Unilateral or bilateral single short (<3 cm) stenosis of EIA

TYPE B Lesions

- Short (<3 cm) stenosis of infrarenal aorta
- Unilateral CIA occlusion
- Single or multiple stenoses totaling 3-10cm involving the EIA not extending into the CFA
- Unilateral EIA occlusion not involving the origins of internal iliac of CFA

TYPE C Lesions

- Bilateral CIA occlusions
- Bilateral EIA stenoses 3-10cm long not extending into the CFA
- Unilateral EIA stenosis extending into the CFA
- Unilateral EIA occlusion that involves the origins of internal iliac and/or CFA
- Heavily calcified unilateral EIA occlustion with or without involvement of origins of internal iliac and/or CFA

TYPE D Lesions

- Infrarenal aortoiliac occlusion
- Diffuse disease involving the aorta and both iliac arteries requiring treatment
- Diffuse multiple stenoses involving the unilateral CIA, EIA, and CFA
- Unilateral occlusions of both CIA and EIA
- Bilateral occlusions of EIA
- Iliac stenoses in patients with AAA requiring treatment and not amenable to endograft placement or other lesions requiring open aortic or iliac surgery

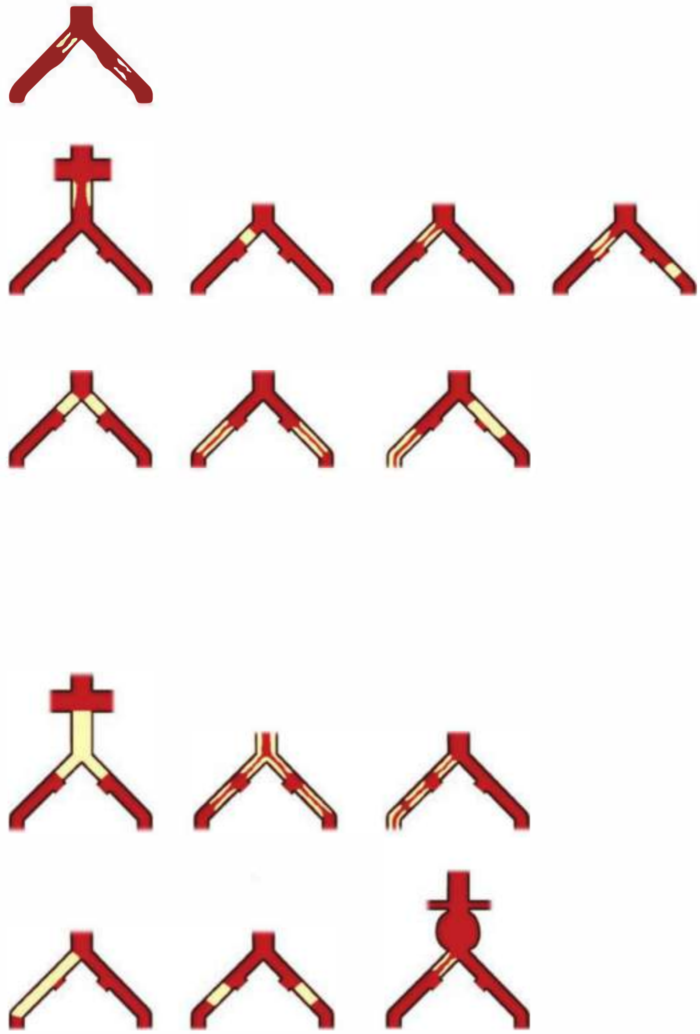

FIG 1 ● TASC II Classification scheme for iliac disease. (Adapted from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II]. *J Vasc Surg*. 2007;45[suppl S]:S5–S67.)

ISOLATED FEMORAL RECONSTRUCTION FOR LIMB SALVAGE WITH POSSIBLE ENDOVASCULAR INTERVENTION

First Step—Landmarks

- The patient is placed prone on the operating table, with a soft bump under the knee and the leg slightly abducted and externally rotated. The inguinal ligament marks the transition point from the external iliac artery to the common femoral artery and is identified by connecting the anterior superior iliac spine to the pubic symphysis. The common femoral artery is usually located over the medial third of the femoral head but may be difficult to palpate in aortoiliac occlusive disease. Pre- or intraoperative ultrasound can be used to identify the common femoral as well as the bifurcation into the superficial and profunda arteries.

Second Step—Incision and Exposure

- Two types of incisions can be made to expose the common femoral artery. A vertical incision above the common femoral artery and bifurcation allows for greater access to the proximal and distal vessels in extensive disease. An oblique incision is better for cosmesis and is made cephalad to the groin crease and is acceptable in focal isolated lesions and in obese patients.
- After a skin incision is made, the subcutaneous tissue is then dissected with electrocautery with careful attention to ligate superficial crossing vessels to control bleeding and ligating lymphatics to prevent seroma formation.

A self-retaining retractor is used to help expose the tissues and is repositioned as the dissection proceeds deeper. Once the femoral sheath is identified and entered the femoral artery lies lateral to the femoral vein. The distal external iliac artery, the common femoral artery, the proximal profunda femoral and superficial femoral arteries are circumferentially dissected with scissors and tagged with a vessel loop or moist umbilical tape using a right angle. Other arterial side branches may be identified and are controlled with vessel loops or temporary clips but rarely ligated in occlusive disease.

Third Step—Clamping

- Before clamping of the arteries, heparin is given intravenously as a weight-based bolus at 100 units/kg and allowed to circulate for 3 minutes. Heparin has a half-life of approximately 90 minutes and is checked periodically with activated clotting time (ACT) measurements. A range of 250 to 350 is desirable and 1,000 to 3,000 units boluses can be given periodically to maintain this level of anticoagulation. Gaining proximal and distal control of the femoral arteries can be done with a variety of clamps. An angled Novare clamp or femoral C-clamp can be used at the proximal common femoral artery. Next, a profunda clamp is used to clamp the profunda femoral artery and the superficial femoral artery. Clamps are placed on soft areas of the artery past the area of the high plaque burden. Side branches can be controlled with vessel loops pulled tightly around the artery and clamped with a hemostat or temporarily clamped with a medium or large clip.

Fourth Step—Endarterectomy, Tacking sutures

- A longitudinal incision is made along the exposed common femoral artery using a no. 11 blade scalpel followed by Potts scissors. The adventitia is grasped with vascular forceps and a freer elevator is used to dissect the plaque away from the adventitia. The plaque is removed with blunt dissection unless sharp dissection is needed to dissect the plaque off the posterior wall. Tacking sutures with 7-0 Prolene are used to secure the remaining plaque to the posterior wall to avoid a dissection plane and emboli (**FIG 2**).

Fifth Step—Patch Angioplasty

- Rarely is the common femoral artery closed primarily after endarterectomy as this decreases the artery diameter. Patch angioplasty with bovine pericardium, polyester (Dacron), or saphenous vein is used. A patch is cut out to match the length of the endarterectomy incision with tapering at the proximal and distal edges to facilitate a curved end of the ellipse. The patch is secured with 6-0 Prolene suture. A parachute technique or three knots is used to anchor the patch at the proximal or distal end. The patch is then sewn with a running suture line. Before the patch is completely sewn in, back-bleeding is performed from the profunda artery, superficial femoral artery, and common femoral artery. Repair sutures with 6-0 or 7-0 sutures can be made in the case of suture line bleeding. Once the patch is in place, a micropuncture kit can be used to access the common femoral artery if endovascular therapies in a retrograde fashion are planned for the iliac arteries (**FIG 3**). In the case of extensive profunda femoral arterial occlusive disease, this artery should be exposed beyond the extent of any palpable plaque, and a separate arteriotomy, endarterectomy, and patch angioplasty of the superficial femoral and the profunda femoral arteries are performed (**FIG 4**). In the situation where extensive endarterectomy yields an adventitia that is too thin, the femoral bifurcation can be reconstructed with prosthetic graft material (**FIG 5**).

Sixth Step—Closure

- If an endovascular technique is performed in the same operation, simple Prolene stitches can be used to close the sheath access site. Careful attention is then made to ensure hemostasis. The femoral sheath may or may not be closed over the vessels, but careful attention must

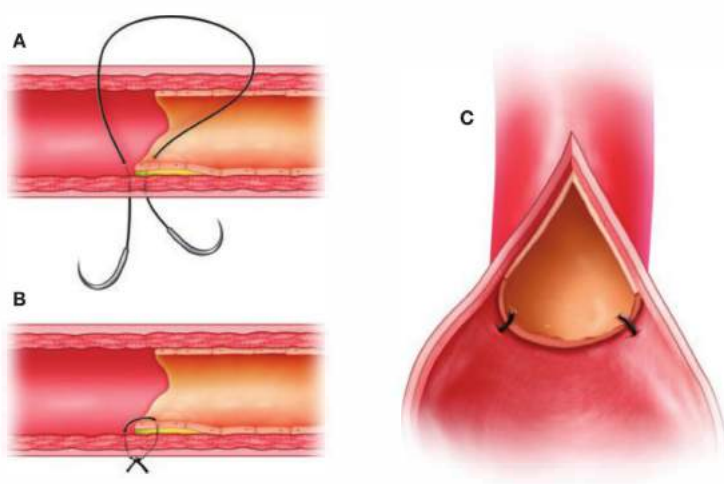

FIG 2 ● A single 7-0 Prolene U-stitch is applied through the endarterectomy/intima interface **(A)**, then ligated **(B)**, with the sutures typically placed at 4 o'clock and 8 o'clock positions **(C)**.

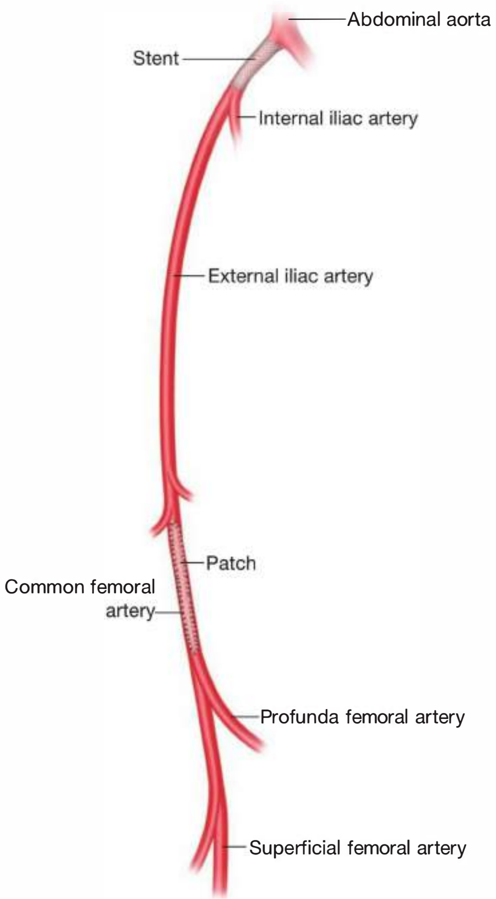

FIG 3 ● A common femoral patch angioplasty extending from the iliofemoral junction onto the origin of the superficial femoral artery (SFA), below a common iliac artery (CIA) stent.

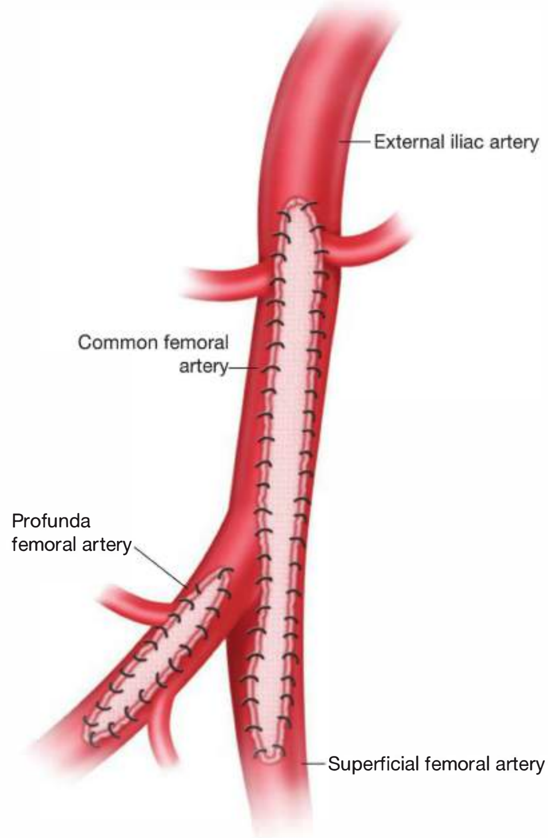

FIG 4 ● An extended femoral endarterectomy. The patch extends form the external iliac artery (EIA), across the entire common femoral artery (CFA) onto the proximal superficial femoral artery (SFA). A separate endarterectomy and patch angioplasty of the profunda femoral artery (PFA) is also depicted.

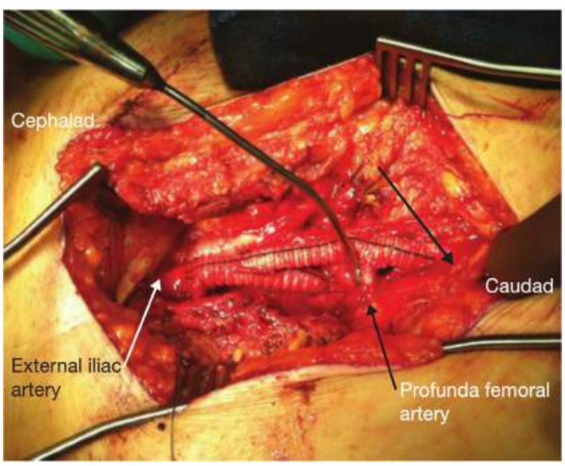

FIG 5 ● Femoral artery reconstruction with external iliac to deep femoral bypass with 8-mm Dacron and femoral to superficial femoral bypass with 6-mm Dacron. The inguinal ligament is mobilized cephalad for exposure.

be made to approximate tissues to close dead space to prevent seroma formation. Usually, a three-layer closure is used. At the end of the operation, femoral and distal flow should be checked with pulse palpation and continuous wave Doppler insonation. We do not routinely employ completion angiography or duplex ultrasonography. Protamine may be given, depending on the time of last heparin bolus or according to the intraoperative ACT reading. Approximately 10 mg is given for every 1,000 units of heparin given, adjusted for time decay and the heparin half-life or can be estimated off the last ACT measurement.

AORTOFEMORAL OPEN RECONSTRUCTION

Positioning

- The patient is supine, with a soft bump under the left hip for a retroperitoneal exposure and the table slightly flexed, or straight supine on a flat table for a transabdominal approach. The entire abdomen; the perineum, blocked with a sterile drape; and the groins and both legs are circumferentially prepped and draped into the sterile field.

First Step—Exposure of Femoral Vessels

- The femoral vessels are typically exposed first through bilateral longitudinal or oblique incisions to minimize the time which the abdomen is open. The crossing vein off the femoral vein beneath the inguinal ligament must be ligated or carefully avoided as this may be injured when the graft is tunneled from the abdomen later in the operation. After a soft spot is identified for anastomosis in the common femoral artery, or the profunda femoral artery when the superficial femoral artery is occluded, and adequate circumferential exposure is achieved, the common femoral artery along with superficial femoral and profunda artery are tagged with vessel loops or moist umbilical tape. The groin incision is then packed with an antibacterial saline-soaked gauze to avoid desiccation.

Second Step—Exposure of the Aorta

- A transperitoneal approach is routinely used to expose the infrarenal aorta, although a retroperitoneal approach may also be used. A longitudinal midline incision is made from just below the xiphoid process to a few centimeters below the umbilicus or down to the symphysis pubis when iliac arterial exposure will be required. Subcutaneous tissue is dissected and the abdomen is entered between the rectus muscles. With routine CTA preoperatively, a thorough abdominal exploration is discouraged, which will minimize postoperative ileus. The transverse colon is retracted cephalad, and the small bowel is shifted to the patient's right side and packed in soft, moist lap sponges to the right. The ligament of Treitz is taken down and the duodenum is mobilized to the right. A self-retaining retractor is then placed to sweep the bowel to the right with a moist laparotomy pad. The retroperitoneal tissue overlying the aorta is dissected, and the aorta is exposed superiorly to the level of the left renal vein. Extra retractors are used as needed for exposure. Distal control of the infrarenal aorta will be necessary if an end-to-side aortic anastomosis is planned. Preoperative imaging and manual palpation of the aorta identify a soft spot for the proximal anastomosis. Accessory renal arteries and the inferior mesenteric artery should be identified and be evaluated if reimplantation is necessary. Endarterectomy of the origin of the reimplanted visceral vessels is recommended, and extra aortic tissue is used as a Carrel patch. Lumbar arteries should also be identified and controlled with suture ligation or a vessel loop with care to avoid excessive bleeding. Depending on the type of aortic occlusive disease, an end-to-side or an end-to-end anastomosis will be fashioned and the dissection necessary is dictated by this decision. In general, an end-to-end anastomosis is more favorable hemodynamically, yet with preserved inferior mesenteric or iliac arteries, an end-to-side anastomosis may be more feasible.

Third Step—Tunneling

- After adequate exposure of the aorta is achieved, focus turns to making tunnels for the femoral limbs of the bypass. Tunnels should track directly along the anterior aspect of the external iliac artery and by elevating soft tissues and ensuring ureters remain anterior. Moist umbilical tapes or Penrose drains are passed with a smooth aortic clamp to mark the tunnels.
- Graft selection can also be made at this time with an 18 × 9-mm or a 16 × 8-mm graft used for males and a 14 × 7-mm or 12 × 6-mm graft typically used for females. Typically, a polyester (Dacron) graft is used, although others prefer polytetrafluoroethylene (PTFE). Prior to aortic clamping, heparin is given intravenously, as explained earlier with a target ACT range of 250 to 350.

Fourth Step—Clamp Placement

- The choice of clamp depends on the approach if end-to-side anastomosis or an end-to-end is chosen. The patency is similar for both approaches and, in most cases, is made by surgeon preference. For an end-to-end anastomosis, the proximal clamp is placed just below the renal arteries if the disease pattern does not obligate suprarenal clamping, with as little dissection of the renal artery origins as possible. The distal infrarenal aorta is then divided and oversewn in two layers with 4-0 Prolene suture. The proximal aortic cuff may require endarterectomy, which is performed up to the proximal clamp. For an end-to-side anastomosis, two aortic clamps are used or a side-biting Satinsky clamp is used to obtain proximal and distal control. With flush occlusion of the aorta at the

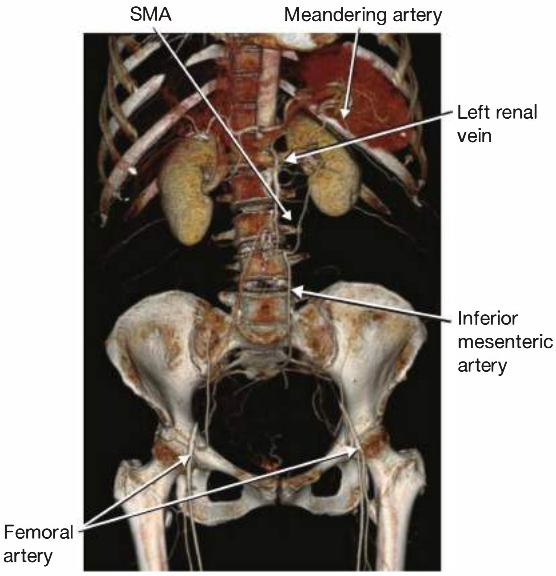

FIG 6 ● CTA identifying flush aortic occlusion at the level of the renal arteries, just deep to the left renal vein, with reconstitution of both common femoral arteries. Note the collateral network from the superior mesenteric artery (SMA), through the meandering artery to the inferior mesenteric artery (IMA), and into the pelvis, which has no hypogastric arterial flow.

level of the renal arteries (**FIG 6**), suprarenal dissection is required, with mobilization and control of the origins of the renal arteries, which are controlled with doubly passed silastic loops so that they may be occluded during endarterectomy to prevent atheroma embolization. A suprarenal clamp is placed to allow thromboendarterectomy of the infrarenal aortic cuff, then the clamp is moved caudally prior to graft anastomosis.

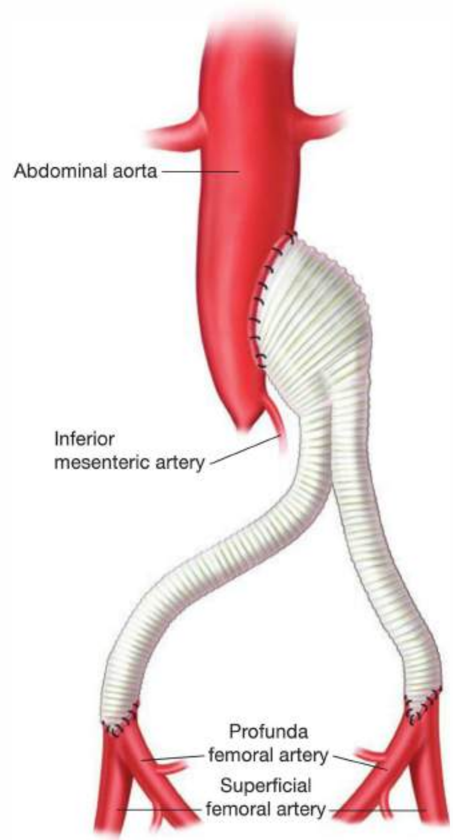

FIG 7 ● With a patent infrarenal aorta and inferior mesenteric artery (IMA), an end-to-side aortic anastomosis is depicted, positioned laterally as mentioned. With iliac occlusions, an end-to-end femoral anastomosis is depicted bilaterally.

Fifth Step—Proximal Anastomosis

- In the case of the end-to-end anastomosis, the technique is straight forward and the graft diameter should match the remaining aortic diameter. In the side-to-side anastomosis, the graft is cut at a bevel to maximize the amount of blood flow and the arteriotomy is laterally placed to allow the graft to enjoy a more retroperitoneal position to minimize the chance for development of an aortoenteric fistula (**FIG 7**). The graft is sewn in place with running 3-0 or 4-0 Prolene sutures using a parachute technique or securing the suture with three knots, starting from the posterior wall to visualize the placement of each stitch. The graft limbs are then clamped and the proximal clamp is then released to check for suture line bleeding. Repair sutures can be used for any suture line bleeding with 4-0 or 5-0 sutures on a pledget as needed. The abdomen is then packed and attention is then turned to the femoral anastomoses. In some instances, where a single internal iliac artery is patent, but the distal aorta or proximal common iliac artery is diseased, we will directly revascularize the internal iliac artery with the bifurcated graft limb and then jump graft down to the femoral position (**FIG 8**).

Sixth Step—Graft Tunneling

- Using the umbilical tape or Penrose drain as a guide, a smooth aortic clamp is then used to tunnel each graft limb from the abdomen into the femoral incision. The graft is then pulled gently through the tunnel above the external iliac vessels and below the ureter. Care must be taken to minimize kinking and redundancy in the graft tunnels. Once tunneled the graft limbs are flushed to confirm adequate inflow, reclamped in the abdomen and flush with heparinized saline solution.

Seventh Step—Distal Anastomosis

- Clamping of the femoral artery is then performed as described earlier so that the common femoral artery, superficial femoral artery, and profunda femoral artery are controlled. A longitudinal incision is then made with a no. 11 blade followed by Potts scissors to approximate the graft limb. The graft is then cut on a taper to allow a natural reimplantation angle into the common femoral artery with minimal tension. The anastomosis is then completed as an end-to-side fashion with 5-0 or 6-0 Prolene suture in a running fashion. In some situations, where retrograde external iliac flow is not possible, an end-to-end femoral anastomosis is preferred to either the common femoral or the profunda femoral artery (**FIG 8**). The same procedure is completed for the contralateral limb.

Eight Step—Closure

- After hemostasis is achieved, careful attention is made to ensure the anastomoses are securely done and dead space is closed to prevent seroma formation and minimize groin infections. Protamine may be given as described earlier.

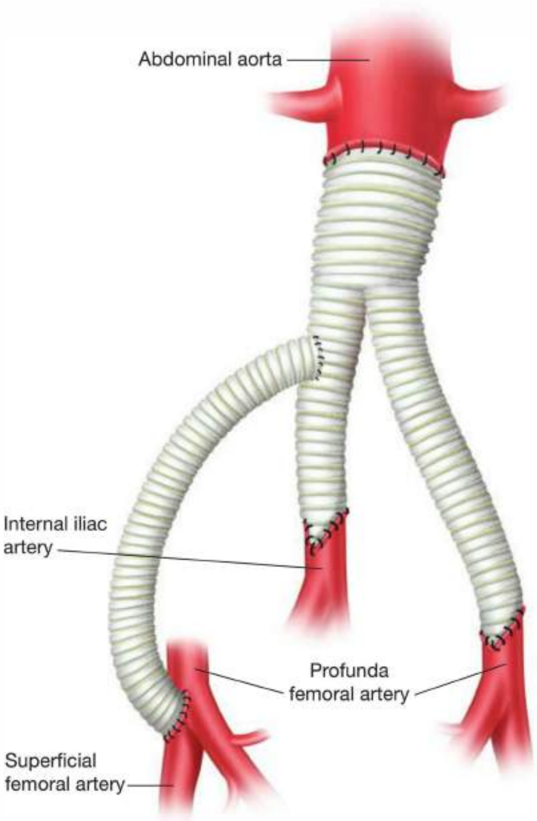

FIG 8 ● An end-to-end aortic anastomosis is depicted. In this case, an isolated internal iliac artery (IIA) was present and preserved with end-to-end anastomosis from the right limb of the bifurcated graft. A jump graft is then brought off this limb to the right common femoral artery (CFA). With occlusion of the left superficial femoral artery (SFA), the left limb is performed in end-to-end fashion to the profunda femoral artery (PFA).

AORTOILIAC RECONSTRUCTION WITH FEMORAL CROSSOVER

- This technique can be used to restore blood flow to a lower limb when one of the iliac arteries is obstructed and the contralateral iliac arteries are patent. The surgical procedure can also be used in conjunction with an endovascular procedure, for example, angioplasty and/or stenting of the nonoccluded iliac vessels. Groin incisions are made in an oblique or longitudinal fashion. Control of the common, superficial femoral, and profunda femoral arteries are performed as previously described. Endarterectomy of the common femoral artery is performed as necessary if there is significant plaque burden. The suprapubic tunnel is made with blunt dissection using a blunt-ended hemostat or one's fingers. The key is to create the tunnel just anterior to the abdominal fascia. Either a blunt tunneling device or a long aortic clamp can be used to pass the graft from one side to the other in the subcutaneous tissue, avoiding entry into the peritoneal cavity. The anastomosis is performed so the graft sits in a curved configuration over the suprapubic tissue (**FIG 9**). Meticulous attention is given to closure to avoid kinking or compression of the graft and to avoid dead space that can lead to problematic seromas and the possibility of soft tissue infection, with subsequent graft infection.

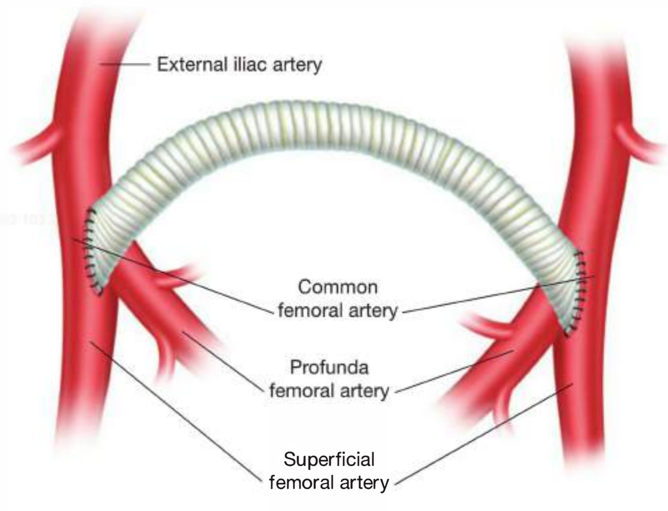

FIG 9 ● A right to left common femoral artery to common femoral artery (CFA) is depicted. Ideally, the graft extends over the origin of the profunda femoral artery (PFA) onto the origin of the superficial femoral artery (SFA).

PEARLS AND PITFALLS

Isolated femoral reconstruction	■ Care must be taken to be certain that proximal and distal atherosclerotic plaque is not causing residual stenosis. ■ Patch angioplasty is critical to the success of this procedure. ■ Distal tacking sutures should be employed generously.
Aortofemoral reconstruction	■ Adequate exposure is critical to success. ■ Localized endarterectomy at both proximal and distal anastomotic sites is generally required. ■ Tunneling errors can lead to late complications and early graft failure.
Femoral–femoral crossover	■ Adequate inflow and outflow must be assured for success. ■ Concomitant femoral endarterectomy should be used freely. ■ Tunneling and closure errors frequently cause early graft failure.

POSTOPERATIVE CARE

- Patients are admitted to a cardiac monitored floor postoperatively as patients are at high risk for or have documented coronary artery disease. Immediately, postoperative vascular checks are performed with high frequency to assess early graft thrombosis requiring reintervention or initiation of anticoagulation. Patients are encouraged to ambulate 4 to 6 hours after the operation, with adequate pain control a point of focus. When the abdomen is entered, in the case of aortobifemoral grafting, patients are kept from an oral diet until bowel function returns. While anticoagulation is not routinely used for graft patency, aspirin is standard, and subcutaneous heparin is given for secondary prevention of deep vein thrombosis (DVT).

OUTCOMES

- See Table 2.

Table 2: Long-term Outcomes for Aortoiliac Disease

Type of Operation	Patency Rates
Femoral endarterectomy with iliac stenting	5-year patency—iliac stenting without femoral endarterectomy—66%; iliac stenting without femoral endarterectomy—88%
Aortobifemoral bypass	5-year primary patency, 90%–93%; 5-year secondary patency, 87%–97%; 10-year patency, 72%–94%; 15-year patency, 63%–82%
Femoral–femoral bypass	5-year patency rate, 42% to 88%; weighted average, 66%

COMPLICATIONS

- Early
  - Hemorrhage
  - Early thrombosis

  - Infections
  - Colon ischemia
  - Femoral nerve injury
- Late
  - Aortoenteric fistula
  - Restenosis, thrombosis of graft
  - Anastomotic pseudoaneurysm
  - Sexual dysfunction
  - Spinal cord ischemia
  - Graft infection

Chapter **26**

Occlusive Disease Management: Iliac Angioplasty and Femoral Endarterectomy

Venita Chandra

DEFINITION

- Multilevel atherosclerotic occlusive disease involving the distal aorta, iliac vessels, and common femoral arteries is a common occurring pathology seen often by vascular surgeons. Traditional approaches to this disease process involved open surgical reconstruction with an aortobifemoral bypass or iliofemoral bypass. Recently, however, there has been a paradigm shift toward endovascular and hybrid approaches. Combining femoral endarterectomy with endovascular iliac stenting is an increasingly common minimally invasive approach to this problem, providing an effective alternative to open strategies with the potential of shorter hospitalizations and decreased morbidity. Compared to iliac stenting alone, proper evaluation of femoral disease and, if indicated, a hybrid approach with concomitant femoral endarterectomy have been associated with increased durability of endovascular aortoiliac interventions.[1]

PATIENT HISTORY AND PHYSICAL FINDINGS

- Aortoiliac and femoral occlusive disease can present, as with all peripheral arterial diseases (PADs), in a variety of ways.
- The typical presentation of aortoiliac occlusive disease includes claudication of the buttock and upper thigh and erectile dysfunction. When multilevel vascular disease occurs, as in the case of combined aortoiliac and femoral occlusive disease, distal lower extremity symptoms such as calf claudication, rest pain, and tissue loss may ensue.
- Typical physical exam includes the absence or diminution of femoral pulses. Other than the peripheral pulse assessment, the physical exam can demonstrate other signs of PAD such as cool digits and active wounds.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The initial evaluation of a patient with PAD should involve noninvasive evaluation of peripheral blood flow with arterial waveforms and ankle–brachial indices (ABIs) (**FIG 1**). These studies provide objective data regarding the extent of occlusive disease; however, they do not provide adequate anatomic data for preoperative planning.
- Once the degree and physiologic impact of the disease are determined by noninvasive testing, high-resolution anatomic imaging via either computed tomographic angiography (CTA) or magnetic resonance angiography (MRA) should be obtained for surgical planning.
- CTAs are currently the gold standard for preoperative planning. They have the advantage of providing information regarding the degree and location of stenosis as well as the anatomy of the arterial wall (including degree of calcification and presence of aneurysms). Three-dimensional reformatting can provide additional valuable information (**FIG 2**). CTAs, however, are limited by the fact that they involve the use of contrast as well as radiation exposure. MRAs avoid radiation exposure and contrast often, however, at the risk of reduced anatomic precision. Gadolinium magnetic resonance (MR) contrast also entails risk of long-term renal dysfunction.

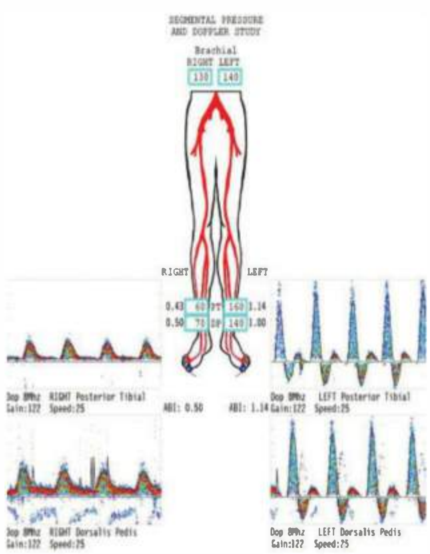

FIG 1 • Arterial waveforms and ABIs for a patient with aortoiliac disease. Note the monophasic waveforms on the right.

FIG 2 • CTA with 3-D reconstruction demonstrating diffuse aortoiliac as well as femoral occlusive disease.

- Catheter-based diagnostic aortography also provides anatomic data; however, this study has a number of limitations including the fact that it is an invasive procedure with potential complications. In addition, arteriograms only provide an understanding of the luminal anatomy, occasionally obscuring features such as aneurysms, inclusion cysts, or periarterial inflammation. Particularly for aorto-iliac-femoral disease, preprocedural CTA has the ability to identify significant common femoral disease that may benefit from concomitant open endarterectomy at the time of catheter-based intervention. Alternatively, relying on catheter-based arteriography as the primary diagnostic modality may reduce overall contrast burden, radiation exposure, and need for additional procedures if common femoral level intervention is not required. In general, careful preprocedural physical examination and duplex imaging may suffice to help determine whether the additional cost, risk, and inconvenience of CTA are justified prior to catheter-based intervention for aortoiliac arterial occlusive disease.

SURGICAL MANAGEMENT

- As with all patients with PAD, initial treatment approach should include comprehensive assessment and management of concomitant cardiovascular disease risk factors. Details regarding maximal medical management of PAD are beyond the scope or purpose of this chapter; at a minimum, however, consideration should be given to beginning statin and antiplatelet therapy prior to intervention, along with consideration of beta blockade and angiotensin receptor blocker or converting enzyme inhibitor therapy in selected patients.
- Regardless of medical or anesthetic risk, however, all patients with critical limb ischemia should be considered candidates for revascularization when limb loss is a distinct possibility. Despite platitudes to the contrary, major limb amputation above or below the knee is not necessarily a "safer" surgical alternative to multilevel hybrid revascularization. Indications for intervention for intermittent claudication are somewhat more complicated, however. The risks of a procedure are weighed against the potential gain; typically, only patients with severe lifestyle-limiting claudication who have failed nonoperative strategies are offered surgical revascularization.

Preoperative Planning

- Determining the anatomic distribution of disease is essential to obtaining optimal results. The imperative for precision imaging cannot be emphasized enough—if you cannot appreciate the full extent of disease, you cannot expect to comprehensively address it. As in all aspects of vascular surgery, the biggest disappointments, both during and after the procedure, usually arise from underestimating the extent of underlying disease.
- The Trans-Atlantic Inter-Society Consensus (TASC) II guidelines provide a classification scheme based on anatomic patterns of disease (**FIG 3**).[2] The recommendations of the TASC II guidelines is an endovascular management for TASC A and B iliac lesions, whereas open surgical reconstruction is recommended for TASC C and D lesions in good-risk patients. Frequently, however, patients with multilevel disease as seen in TASC C and D lesions have more virulent atherosclerotic processes that often make them poorer surgical candidates. In addition, the development of an increasingly sophisticated armamentarium of endovascular tools and strategies are leading more and more vascular surgeons to attempt endovascular revascularization, even for patients with TASC C or D lesions. Further updates of the TASC classification guidelines are under review and will likely be published in the near future, highlighting the dynamic nature of surgical management of this challenging condition.
- Targeted perioperative risk assessment should be undertaken in appropriate patients, particularly those with reduced exercise tolerance, known or suspected congestive heart failure, clinically significant pulmonary disease, exercise-induced angina, arrhythmias, or those with recent history of myocardial infarction. The presence of additional relevant comorbidities, including diabetes, reduced glomerular filtration rate, iodinated contrast allergies, thrombophilia or coagulopathic disorders, concomitant bacterial infection, or liver disease should also be identified and, when present, evaluated.

Positioning

- Patients are generally placed in the supine position, either in a hybrid operating suite with fixed imaging capabilities or on a radiolucent table with a mobile imaging unit (C-arm) in a traditional operating room environment.
- Positioning should be arranged in such as way as to ensure adequate exposure of the entire aortoiliac and femoral vasculature, with room on either side of the patient to rotate the imaging unit to various angles in order to obtain appropriate oblique images. In angiographic parlance, in many important circumstances (such as identifying and protecting the origin of the ipsilateral internal iliac artery), "one view is no view."

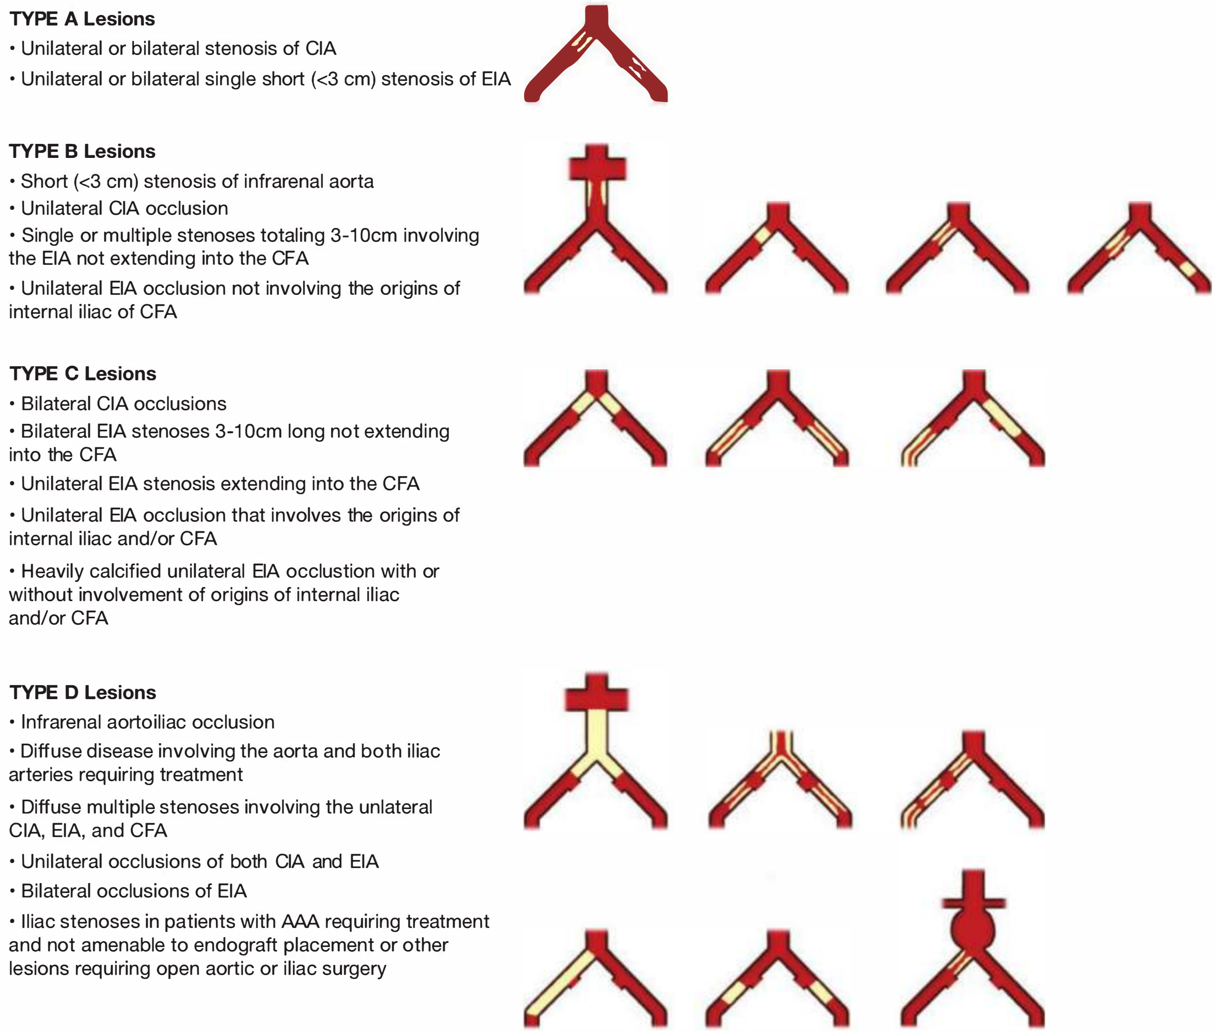

FIG 3 ● TASC II Classification scheme for iliac disease. (Adapted from Norgren L, Hiatt WR, Dormandy JA, et al. Inter-Society Consensus for the Management of Peripheral Arterial Disease [TASC II]. *J Vasc Surg*. 2007;45[suppl S]:S5–S67.)

FEMORAL ENDARTERECTOMY

First Step

- For extended femoral endarterectomy (often requiring exposure of the proximal deep femoral artery as well as the entire length of common femoral artery), optimal exposure is obtained via a longitudinal incision placed directly over the femoral artery (**FIG 4**). The inguinal ligament should be identified by palpation of the pubic tubercle and anterior superior iliac spine (an oblique line between these two structures is the typical course of the inguinal ligament) and used as a guide for femoral localization. Typically, the femoral artery is located approximately one-third the distance from the pubic tubercle to anterior superior iliac crest. Even when no pulse is palpable, a firm calcified linear mass can usually be palpated in this area. Alternatively, duplex ultrasound or fluoroscopic imaging may be used to ensure accurate placement of the incision. Failure to incise directly over the common femoral artery may increase risk for chronic lymphatic drainage, delayed or complicated wound healing, and femoral nerve or venous injury. Although oblique femoral incisions have gained in popularity, especially when used to obtain femoral access for proximal aneurysm repair, these often do not provide exposure sufficient for comprehensive endarterectomy as previously detailed.
- The subcutaneous tissues are divided, ligating any lymphatic channels that are encountered. The inferior edge of the inguinal ligament is identified and the common femoral artery is exposed through the femoral sheath as it exits underneath the inguinal ligament.

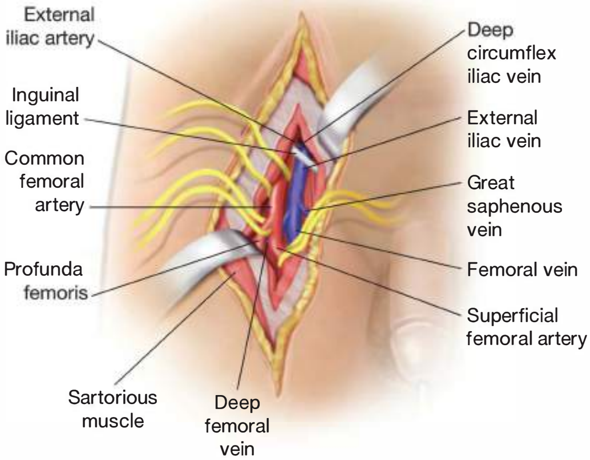

FIG 4 ● Typical longitudinal femoral artery exposure and anatomy. CFA, common femoral artery; EIA, external iliac artery; EIV, external iliac vein; GSV, greater saphenous vein; DCIV, deep circumflex iliac vein; SFA, superficial femoral artery.

Second Step

- Full circumferential dissection of the distal external iliac artery (under the inguinal ligament), the common femoral artery, the superficial femoral artery, and the origin of the deep femoral artery and its initial branches are obtained sequentially (**FIG 4**).
- The individual arteries should be assessed for areas of calcification and extensive plaque burden. Soft sections with minimal calcification, or plaque limited to the posterior arterial wall, should be identified for consideration of clamp placement as appropriate for the planned procedure.
- The inguinal ligament may be divided for adequate exposure of the distal external iliac artery when necessary to ensure adequate endarterectomy When considering the relative margin of distal endarterectomy versus proximal stent placement, it is important to avoid stent placement across the inguinal ligament, as this may greatly reduce long-term patency of the procedure as well as complicate stent delivery through an ipsilateral retrograde sheath. In general, operators should err of the side of more extensive proximal endarterectomies as opposed to distal extension of external iliac stents.
- Careful ligation of the circumflex iliac vein as it crosses over the external iliac artery under the inguinal ligament should be considered to prevent accidental tearing of the vessel during clamping.
- External iliac collaterals, like the epigastric artery or circumflex iliac artery, should be preserved during dissection and endarterectomy whenever possible to ensure optimal long-term outcome.

Third Step

- Once exposure is complete, the common femoral artery can be punctured under direct vision with advancement of a wire under fluoroscopic guidance across the iliac lesion (**FIG 5**).
- This eliminates the possibility of creating a retrograde dissection when a wire is passed after the endarterectomy is performed, as well as the need to puncture the endarterectomy patch to gain access.
- If the disease burden is confined to the common iliac artery or only the proximal external iliac artery, then iliac stenting can proceed at this point, prior to proceeding with the endarterectomy. Occasionally, however, the amount of femoral disease burden is so great that the sheath will be occlusive or otherwise impair runoff, which may limit the ability to obtain digital subtraction angiography (DSA) images during or after stent placement. So consideration should be given to initial

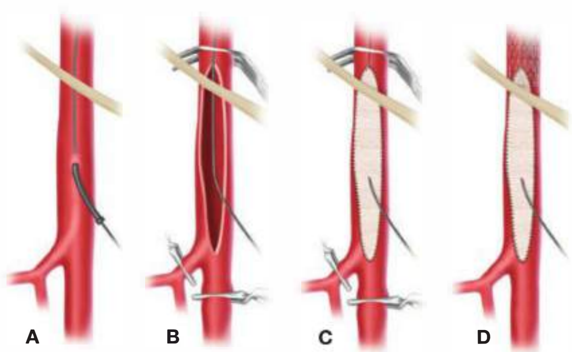

FIG 5 ● Technique for concurrent femoral endarterectomy and iliac stenting. **A.** Direct puncture of common femoral artery and advancement of wire under fluoroscopic guidance. **B.** With wire across iliac lesion, clamp proximal and distal and proceed with arteriotomy. **C.** After endarterectomy, patch is sewn in. Prior to completion of patch center, the distal portion of the patch is punctured with an 18-gauge needle and the wire is passed through the patch. **D.** After completion of the patch, flow is restored and a sheath can be advanced over the wire and iliac stenting can proceed. For patients with distal external iliac disease, the iliac stents can be carried down into the proximal portion of the endarterectomy and patch.

endarterectomy depending on individual anatomic circumstances.

- When retrograde wire passage is not possible due to extensive proximal plaque burden, tortuosity, or other anatomic considerations, antegrade passage from the contralateral iliofemoral system (obtained via either percutaneous or open femoral access) or left axillary or brachial access may be attempted. Obviously, longer sheath/catheter/guidewire combinations will be needed for these procedures and positioning considerations will be affected as well (e.g., arm will need to be exposed and prepped on a radiolucent surface). Once antegrade wire is accomplished, this may be used to deliver treatment devices directly or snared and externalized through the ipsilateral femoral access for retrograde intervention as originally planned.

Fourth Step

- Leaving the wire in place, systemic anticoagulation is accomplished with sufficient doses of unfractionated intravenous heparin administration and proximal and distal femoral control is obtained with vascular clamps. Especially proximally, a padded clamp should be chosen to allow the external iliac artery to be clamped over the existing wire to prevent or minimize wire-related injury.
- A longitudinal common femoral arteriotomy is performed to expose the full extent of femoral disease that needs to be addressed to ensure adequate runoff from the iliac intervention. This can almost always be accomplished within the femoral incision itself without need for additional distal femoral bypass procedures, unless extensive forefoot gangrene is present as a consequence of multilevel arterial occlusive disease. Extended deep femoral endarterectomy is highly effective in achieving suitable runoff when few other revascularization options may be available (**FIG 4**).
- The arteriotomy can extend onto either the superficial or deep femoral artery. Occasionally, an eversion endarterectomy of the deep femoral artery can be performed when the arteriotomy extends onto the superficial femoral artery. Alternatively, the arteriotomy may be extended down the deep femoral artery when the superficial femoral artery is chronically occluded. Selection of the reconstruction technique is influenced by the occlusive pathology, level of debility, indications for revascularization, and optimal revascularization strategy (**FIG 6**).

Fifth Step

- Carefully, an endarterectomy plane is developed between the plaque and remaining mural media or adventitia using a Penfield dissector or Beaver blade. The plane most typically is developed within or exterior to the media, leaving the adventitia intact. Failure to appreciate the appropriate endarterectomy plane may weaken the adventitia, leading to bleeding or postoperative hematoma or pseudoaneurysm formation. Care should be taken to dissect the plaque away from the remaining arterial wall, not vice versa. The endarterectomy plane is developed on each side of the vessel and advanced posteriorly until the planes meet in the midline. Following this maneuver, the plaque is transected flush with the arterial wall. Care should be taken to achieve good

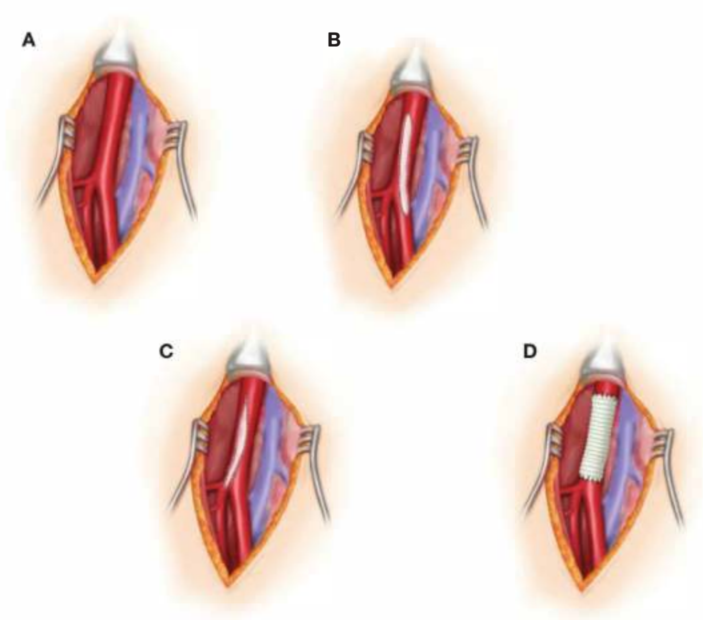

FIG 6 ● Various femoral endarterectomy closure strategies. **A.** Typical anatomy; occasionally, primary repair can be considered if common femoral artery is of adequate size. **B.** Arteriotomy and patch extended onto superficial femoral artery; deep femoral artery endarterectomy can be performed using an eversion technique. **C.** Arteriotomy and patch extended onto deep femoral artery. Particularly useful in chronically occluded superficial femoral artery (SFA). **D.** Interposition repair of common femoral artery; can syndactylize deep femoral artery and SFA if needed.

quality and minimally diseased endpoints in both the superficial and deep femoral arteries as necessary (**FIG 7**). Tacking sutures, as commonly employed during carotid endarterectomy, may also be necessary in the femoral artery to ensure adequate endpoints. Particularly in the case of the deep femoral artery, care should be taken to extend the endarterectomy well past the mass of common femoral artery–related plaque. This may require exposing the deep femoral artery well beyond its initial branches, dividing crossing branches of the deep femoral vein, and avoiding excessively deep placement of self-retaining retractors to limit the possibility of traction injury to femoral nerve branches.

- Often, significant posterior plaque extends proximally well into the external iliac arteries. As previously discussed, care should be taken in deciding at which point the endarterectomy should end versus distal extension of iliac stents (**FIG 5**).

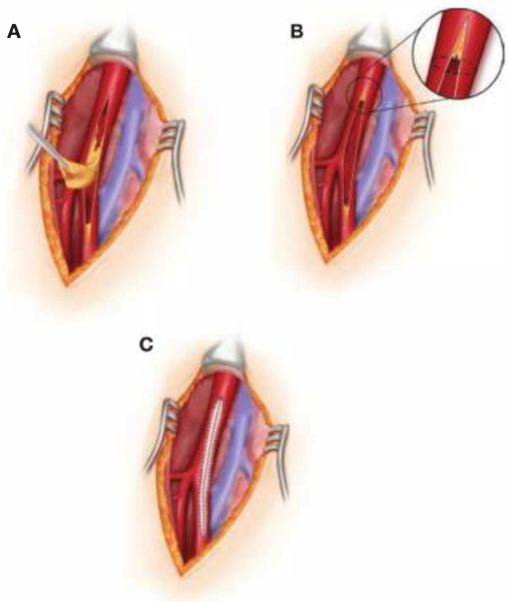

FIG 7 ● Femoral endarterectomy technique. **A.** Longitudinal arteriotomy and development of endarterectomy plane. **B.** Ensure adequate endpoints on either end. **C.** Patch closure.

Sixth Step

- Once the full extent of plaque has been removed and suitable irrigation performed to identify and eliminate remaining mobile fragments of residual media, patch angioplasty should be performed typically using running 5-0 polypropylene suture initiated at both the proximal and distal endpoints and tied in the middle. Bovine pericardium, extruded polytetrafluoroethylene (ePTFE), and polyester or autogenous vein segments all may represent reasonable patch options, depending on individual circumstances. In general, autogenous vein is more resistant to infection, whereas prosthetic patch options are available off the shelf in a variety of configurations. ePTFE patches tend to bleed more through their suture holes following placement, although this tendency may be tempered by use of ePTFE patches. Currently, our preference is to use bovine pericardial patch as the default choice in the absence of infection or other contraindication (e.g., patient objection due to religious reasons) (**FIG 6**).
- Rarely, when arterial wall integrity appears compromised following endarterectomy, femoral interposition grafting may be performed in lieu of patch angioplasty. Interposition grafting may also be a good choice when the femoral plaque burden is so great that endarterectomy is impractical; in this case, an interposition graft (ePTFE or knitted polyester) can be placed instead of a patch. This can be configured in any number of ways:
  - Distal anastomosis to distal common femoral artery
  - Distal anastomosis to syndactylized superficial and deep femoral arteries (**FIG 6**)
  - Distal anastomosis to superficial femoral artery with reimplantation of the deep femoral artery
  - Distal anastomosis to the deep femoral artery with reimplantation of superficial femoral artery
  - Distal anastomosis to the deep femoral artery only, when the superficial femoral artery is already occluded

Seventh Step

- Before completion of patch closure, the middle or distal portion of the patch is punctured with an 18-gauge needle and the back of the previously placed wire is routed through the needle. Patch closure is then completed and the clamps removed; at this point, an appropriately sized sheath can be advanced over the wire, through the patch, in preparation for iliac stenting.

COMMON ILIAC STENTING

First Step

- Typically, a 6- or 7-Fr sheath is adequate for iliac stenting. Once the sheath is placed after completion of the patch, appropriate arteriogram images are obtained.
- For distal aorta and proximal common iliac disease, often the best approach is passage of a flush catheter into the aorta and a power-injected aortogram.
- For primarily iliac disease, retrograde arteriography through the femoral sheath is usually sufficient to obtain adequate iliac opacification.
- Contralateral anterior oblique (15- to 30-degree) projections are typically chosen for visualization of the respective iliac systems to ensure identification of the origin of the ipsilateral internal iliac arteries. Also, the full extent of disease burden may be most adequately addressed by multiple obliquities in any circumstance.

- A marking catheter may be used to assist in length measurements and "buddy" wires may also be placed from contralateral femoral access. Every effort should be made to maintain perfusion to the hypogastric arteries.

Second Step

- Selection of the appropriate balloon and stent diameter is of great importance. Slight oversizing of 5% to 10% is recommended, except in the case of heavily calcified lesions, where oversizing may predispose to arterial rupture.
- Optimal target vessel diameter may be estimated preoperatively by measurements from the CTA, particularly looking at the diameter of adjacent or contralateral normal arterial segments. Similarly, diameter and length measurements may also be obtained during the hybrid procedure itself. Generally speaking, common iliac artery target diameters may range from 7 to 10 mm, depending on gender, body habitus, and burden of disease. External iliac artery diameters range from 5 to 8 mm under similar qualifications.
- Balloon "predilation" may facilitate stent placement and assist with stent sizing.
- Mild pain during dilation is to be anticipated and indicates stretching of the adventitia; excessive or persistent pain, however, may indicate arterial compromise or rupture. In the latter circumstance, consideration should be given to additional placement of a covered stent when contrast extravasation is present on arteriography and not immediately controlled with extended balloon deployment. In the retroperitoneum, unlike the lower extremities, tamponade will not likely limit further bleeding and extended balloon deployment may not be advisable as definitive treatment. When general anesthesia is required for the concomitant endarterectomy, this warning sign may not be present and completion arteriography should be carefully scrutinized for indications of iliac artery compromise or contrast extravasation.
- There are numerous commercially available stents to choose from, many of which are specifically indicated for iliac arterial intervention (e.g., "on label"). Appropriate diameter and length stents generally fall into two categories, balloon-expandable or self-expanding and can be covered or uncovered (e.g., with adherent graft material).
- The length of the balloon or stent should cover the entire length of the diseased area.
- Balloon-expandable stents have the advantage of higher precision of placement and greater radial strength; however, they are less flexible than self-expanding stents. As a general rule of thumb, balloon-expandable stents are best suited for common iliac artery lesions where "kissing" stents in the contralateral iliac artery may be needed to deal with excessive plaque burden or calcification or the aortic bifurcation may need to be "advanced" into the distal aorta to completely ensure adequate luminal recanalization. Alternatively, external iliac lesions are often best treated with self-expanding stents, which by their nature are more flexible and compliant with the radius of curvature present in this artery. Exceptions exist for both indications, however, and device placement should be individualized to specific anatomic and clinical requirements.

Third Step

- In the setting of bilateral or even unilateral proximal common iliac artery disease or distal aortic disease, bilateral aortic bifurcation balloon dilation and stenting should be completed simultaneously to protect the contralateral common iliac artery from dissection, plaque dislodgement, or subsequent embolization. This is generally referred to as "kissing" stents.
- Balloon-expandable stents are typically used for these proximal common iliac lesions and they may be deployed well into the distal aorta, essentially "advancing the aortic bifurcation."

Fourth Step

- For common iliac lesions immediately adjacent to the aortic bifurcation, after precise arteriographic localization of the aortic and iliac bifurcations and extent of plaque burden, appropriately sized stents are selected. Uni- or bilateral sheaths of sufficient diameter for the selected stents are advanced into the distal aorta. When common iliac lesions are not strictly "orificial," concomitant contralateral stenting is generally not required. Again, careful angiographic assessment should be made to determine the extent of plaque burden present at the origin of the common iliac arteries to make this determination.
- Appropriately sized balloon-expandable stents are advanced within the sheaths and positioned across the respective lesions. The sheaths are then pulled back to expose the entire stent; this sequence prevents accidental dislodgement of the stent off the balloon, attempting to cross the lesion, and limits the risk of plaque embolization during stent passage.
- Once both stents are positioned appropriately, they are inflated simultaneously to achieve the kissing configuration (**FIG 8**).

Fifth Step

- Completion arteriography, typically through a pressure injection in the distal aorta through "side-hole" or flush catheters, is obtained to confirm stent placement, evaluate degree of residual stenosis, and rule out complications such as dissection or thrombus/embolization.
- When pressure measurement are required, pull-back pressures are obtained with the goal of eliminating pressure gradients across the treated lesion at rest or limiting to less than 15 mmHg following injection of a distal vasodilator such as papaverine.

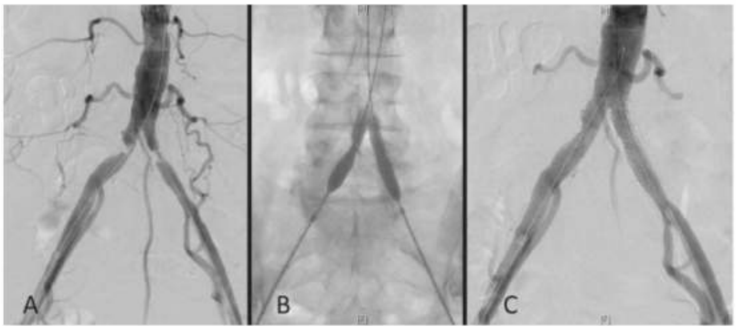

FIG 8 ● Bilateral common iliac artery stenosis treated with kissing stent technique. **A.** Initial aortogram demonstrating high-grade bilateral proximal common iliac stenosis. **B.** Balloon dilation demonstrating waist in balloon at location of stenosis. **C.** Completion aortogram with bilateral kissing iliac stents, raising the aortic bifurcation by a few centimeters.

EXTERNAL ILIAC ARTERY STENTING

First Step

- When the external iliac artery is diseased, particularly the distal segment, self-expanding stents are typically used due to the increased tortuosity of these vessels and the increased flexibility of self-expanding stents as opposed to balloon-expandable stents.
- The same principles exist in terms of sizing, although for self-expanding stents, 10% to 20% oversizing is typically recommended in the respective instructions for use (IFU).

Second Step

- Deployment of self-expanding stents does not require advancement of the introducer sheath past the lesion. The self-expanding stents usually are mounted on a carrier and constrained. The stents should be positioned across the lesion and deployed.
- Close fluoroscopic monitoring should occur during deployment, as self-expanding stents tend to be far less precise in positioning in comparison to balloon-expandable stents and typically may advance across the lesion during deployment.

Third Step

- Predilation and postdilation may be performed as necessary with appropriately sized balloons before and after stent deployment.
- In the setting of very distal external iliac artery disease or incomplete distal external iliac endarterectomy (as described earlier), the distal end of the stent may be carried down to the level of the endarterectomy, again with care to be taken to avoid crossing the inguinal ligament as previously described (**FIG 5**).

Fourth Step

- Just as in common iliac stenting, completion arteriograms should be performed, and pressure gradients may be obtained as necessary to confirm sufficient resolution of the stenosis.

Fifth Step

- Usually, a single-repair stitch can be used to close the patch sheath access site, regardless of the diameter of the sheath used for stent deployment.
- Once hemostasis is achieved, the sheaths removed, and anticoagulation reversed with protamine injection, the femoral exposure should be closed with a multilayer, anatomic closure with absorbable suture.

PEARLS AND PITFALLS

Occluded iliac artery strategies	
Reentry devices	■ When attempting to cross an occluded segment with catheter-guidewire combinations, a subintimal plane may be developed. This subintimal technique is appropriate as long as the true lumen can once again be regained prior to entering the aorta. In some circumstances, this reentry may be challenging. In these situations, reentry devices can be employed. These devices have nitinol cannula that can be advanced through the device and used to puncture into the true lumen; a 0.014-in wire is then advanced. Free passage of the wire indicates true lumen access, which is confirmed by contrast injection. The passage can then be dilated and stented in a conventional manner (**FIG 9**). Care should be taken to attempt reentry before the dissection plane is advanced too far proximally into the distal aorta, as this may compromise the ability to properly deploy balloon-expandable stents and/or compromise inferior mesenteric arterial flow. Similarly, reentry systems should be used with caution in the iliac arterial system to avoid perforation and retroperitoneal bleeding.

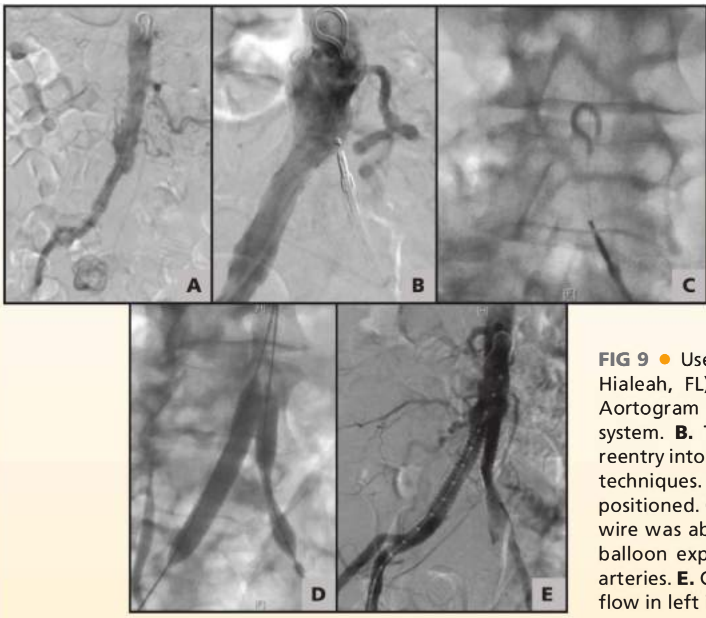

FIG 9 ● Use of an Outback® reentry catheter (Cordis Corporation, Hialeah, FL) in treatment of a chronic total iliac occlusion. **A.** Aortogram showing complete occlusion of the left iliac arterial system. **B.** The majority of the occlusion was crossed; however, reentry into the true aortic lumen was unsuccessful using traditional techniques. The Outback® reentry catheter was advanced and positioned. **C.** After advancement of the reentry needle, a 0.014-in wire was able to be passed into the aorta. **D.** Retrograde kissing balloon expandable stent placement into bilateral common iliac arteries. **E.** Completion aortogram demonstrating reconstitution of flow in left iliac system.

Alternative approach	■ Antegrade approach from either a brachial or contralateral femoral access sometimes provides more "pushability" across recalcitrant lesions and may be more successful at obtaining wire access. This is particularly true when a small invagination is apparent angiographically in the ipsilateral common iliac artery (when totally occluded). Once the occlusion or stenosis is traversed, the wire can be snared from the ipsilateral femoral and an ipsilateral sheath can still be advanced to complete the procedure as previously described from the ipsilateral femoral access. This is generally advisable as compared to attempted stent placement from left brachial access, due to proximity and control issues, as well as the availability of suitably sized stents on long delivery catheters.
Severe calcified disease strategies	■ In patients with significant atherosclerotic burden, care should be taken during the intervention to minimize atheroembolization. Use of covered stent grafts can be considered in these scenarios. Additionally, as an added benefit of the hybrid approach, flushing maneuvers of the patch angioplasty site may be performed to eliminate embolic debris.
Arterial rupture	■ Cover with stent graft. Consider proximal balloon occlusion.
Arterial dissection	■ Extend stent if flow limiting dissection.

POSTOPERATIVE CARE

- Following femoral endarterectomy and iliac stents, patients are usually monitored in the hospital for 1 to 2 days.
- Postoperative antithrombotic management is not well studied in this population; however, most surgeons treat patients with dual antiplatelet therapy such as aspirin and clopidogrel, with a loading dose of clopidogrel followed by a daily dose, for the first 6 weeks following the procedure. Long-term antiplatelet management is usually achieved with acetylsalicylic acid (ASA) alone, except in circumstances of aspirin allergy.
- Routine follow-up with arterial duplex and ABIs is important to monitor for continued patency and potential need for secondary intervention.

OUTCOMES

- Early and long-term results of concomitant common femoral artery endarterectomy and iliac stenting have been excellent. One-year primary patency and primary-assisted patency rates have been reported to be 84% and 97%, respectively.[3] Five-year primary, primary-assisted, and secondary patency rates were 60%, 97%, and 98% in a recent report of 171 patients.[4]
- There is some evidence that covered stent grafts may have improved patency compared to bare metal stents, particularly in TASC C and D lesions.[4,5]
- Iliac artery stenting combined with open femoral endarterectomy also appears to be equally effective as open surgical revascularization. Piazza and colleagues[6] found similar 30-day morbidity and mortality as well as primary patency at 3 years when comparing a 10-year cohort of patients treated in both manners. These similarities were maintained even after stratification for TASC group.

COMPLICATIONS

- Contrast nephropathy
- Wound complications, including infection, dehiscence, seroma formation, and nerve entrapment

- Arterial rupture
- Arterial dissection
- Embolization

Chapter **27**

Management of the Infected Femoral Graft

Matthew Mell

PATIENT HISTORY AND PHYSICAL FINDINGS

- The symptoms of an infected femoral graft can vary widely, from a chronically draining wound to sepsis and hemodynamic collapse.
- Symptoms may have been present from hours to weeks.
- Physical examination should include inspection of the surgical wounds and graft tunnels for induration, erythema, tenderness, open wounds, aneurysmal degeneration of the graft or anastomosis, or drainage.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- When possible, causative organisms should be identified prior to surgery to aid in choosing appropriate systemic antibiotics and the optimal surgical approach.
- Prior to surgery, detailed imaging with computed tomographic angiography (CTA) can provide critical information for developing a cohesive plan for surgical exploration and graft removal and replacement.
- Computed tomography (CT) can accurately identify anatomic signs of infection, including abscess or anastomotic aneurysm. CT can also provide clues to the extent of infection.
- CTA provides high-resolution imaging of the aorta and runoff vessels, which will aid in determining the options for revascularization, including in situ reconstruction, obturator bypass, or ilioprofunda bypass.
- Radionuclide scans may provide evidence for graft infection when other imaging studies are nondiagnostic.

SURGICAL MANAGEMENT

- Aggressive and wide debridement of devitalized or infected tissue must accompany graft excision and replacement in the setting of infection.
- Partial or complete excision of infected prosthetic grafts is generally required to eliminate the infection.
- Excision of infected autogenous graft infections may be necessary when associated with sepsis caused by *Escherichia coli*, *Pseudomonas*, *Klebsiella*, or *Proteus* spp.
- Graft excision without reconstruction: Infected thrombosed grafts with adequate collateral circulation may require only excision without reconstruction.
- Excision and extraanatomic bypass is preferred with presence of severe sepsis and/or hemorrhage. Examples of extraanatomic bypasses include axillary-to-femoral bypass (**FIG 1**), obturator bypass, or cross-femoral bypass.
- In situ replacement: Low-grade infections without sepsis or invasive infection and those with distal occlusive disease may be best treated with in situ graft replacement.
- Graft replacement material
- Graft material should be considered prior to surgery to ensure availability.
- Potential options for graft material include the following:
  - Autogenous vein (saphenous vein, cephalic vein, basilic vein, superficial femoral vein [SFV])
  - Cryopreserved tissue (aorto-iliac-femoral artery, femoral vein, saphenous vein)
  - Prosthetic graft (rifampin-soaked Dacron™, polytetrafluoroethylene [PTFE])
- Consider the need for wound coverage:
  - Debridement of an infected groin wound may result in a large defect that either cannot be covered or closed. Muscle flaps can provide coverage of healthy well-vascularized tissue to protect the repair.
  - Small to medium defects can be covered with a sartorius muscle flap, which is divided from its attachment to the anterior superior iliac spine and mobilized medially to cover the wound.
  - A pedicled flap from the leg or abdominal wall may be required for larger wounds. These flaps include rectus femoris, rectus abdominis, tensor fasciae latae, or gracilis.

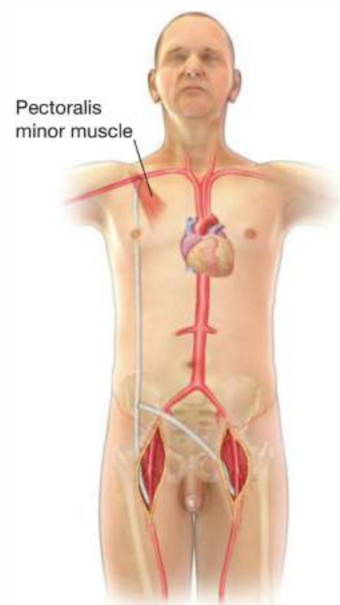

FIG 1 ● Figure 1: Axillo-femoral bypass. Note that the proximal graft is placed behind the pectoralis minor muscle.

GENERAL CONSIDERATIONS

- It is desirable when considering an extraanatomic reconstruction to revascularize before excising the infected graft. This can be accomplished with a bypass and tunnel performed across clean tissue planes. Once the bypass is completed and wounds closed, the groin can be explored and the infected graft removed. With this approach, the continuity between the superficial femoral and deep femoral arteries should be maintained by either oversewing the distal common femoral artery or anastomosing the profunda femoris artery (PFA) to the superficial femoral artery with proximal ligation (**FIG 2**).
- Debridement of the infected site must include removal of infected or necrotic tissue and complete excision of the anastomosis. Dissection may be aided by lack of incorporation of the infected graft but also may prove challenging from extensive scarring in the reoperative field. Sharp dissection techniques are critical to minimizing the risk of inadvertent injury to vessels or adjacent structures.
- It is important to send cultures of the perigraft fluid, tissue, and graft.[1] Instructions should be given to the microbiology lab to perform sonication of the graft to separate biofilm from graft and maximize the bacteriology yield.

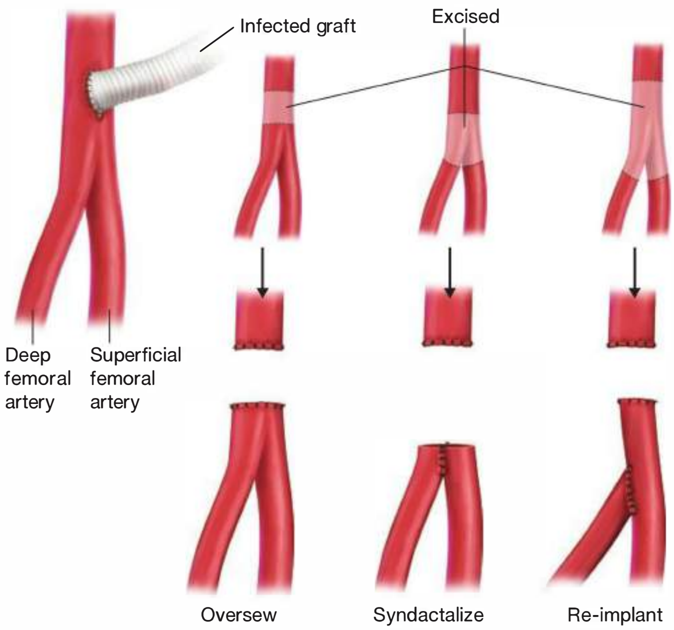

FIG 2 ● Surgical options for maintaining continuity of arterial flow to the profunda femoris artery after obturator bypass and common femoral artery ligation

OBTURATOR BYPASS

- Using the obturator foramen may be a useful approach for bypassing an infected groin through a sterile field.[2] A reinforced PTFE graft is best suited for this technique and can be used if sepsis has been controlled and the bypass can be performed without violating the infected field.
- The proximal anastomosis can be performed to the common iliac artery, external iliac artery (ipsilateral or contralateral), or previous graft if not infected (**FIG 3**). Exposure can be obtained through a standard retroperitoneal incision, by dividing the external and internal oblique and transversus abdominis muscles, identifying the preperitoneal space, and retracting the peritoneum medially with blunt dissection techniques. The obturator foramen is just posterior to the anterior ramus of the pelvis, although it may not be easily palpated due to the overlying obturator membrane.
- Distal anastomosis can be performed to the distal superficial femoral artery, the midportion of the PFA (see the following section, lateral approach to the Lateral Profunda Femoris Artery Exposure), or the popliteal artery. During this dissection, the adductor longus and magnus can be identified with the leg abducted and externally rotated. The tunnel will be placed deep to these muscles, which insert on the external surface of the obturator foramen.

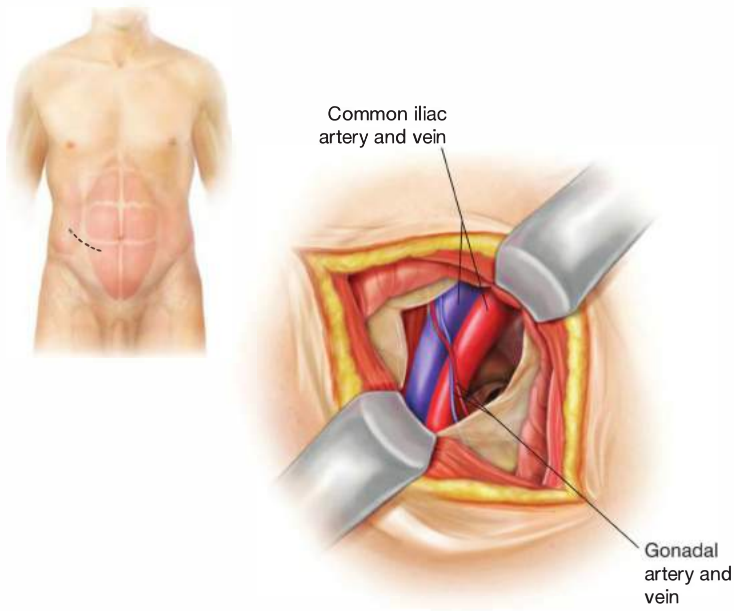

FIG 3 ● Operative incision for retroperitoneal exposure of the iliac artery. Peritoneum and its contents are retracted medially to aid in exposure.

- The tunnel should be performed in a cranial direction with a long aortic clamp or tunneling instrument (**FIG 4**). The instrument is passed deep to the adductor magnus while a hand is placed over the obturator foramen from the retroperitoneal incision. The instrument can be directed through the obturator foramen. The tunnel should be made through the lateral portion of the obturator foramen to avoid the obturator artery and nerve, which traverse anteromedially.
- Once the tunnel is made, the graft can be placed and the bypass performed. Once completed, the incisions should be closed and protected before proceeding with excision of the infected graft.

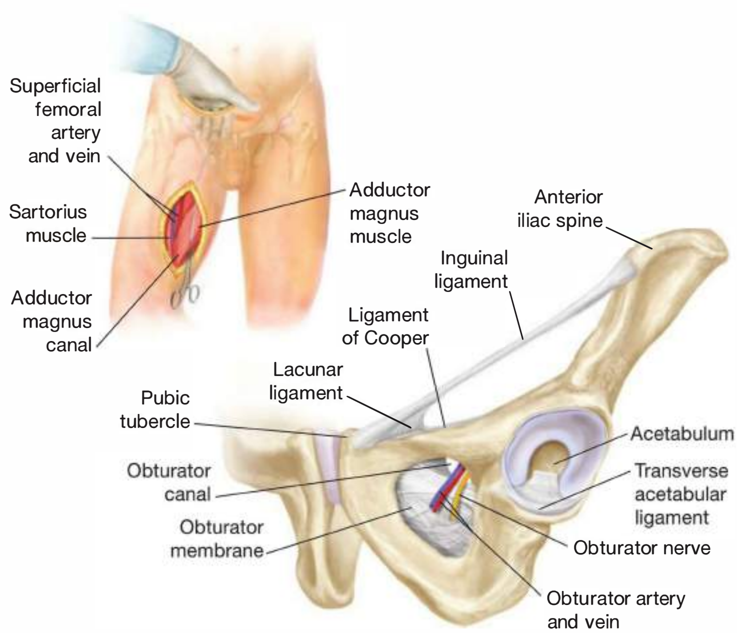

FIG 4 ● Exposure of the superficial femoral artery and tunneling for an obturator bypass. Left: creating the tunnel behind the adductor magnus muscle. Right: placement of the tunnel through the obturator membrane.

LATERAL PROFUNDA FEMORIS ARTERY EXPOSURE

- Another option for remote revascularization is to use the second portion of the PFA, exposed through a lateral incision.[3] This approach may be useful if the superficial femoral artery is occluded and the goal is to establish flow from the axillary artery via a tunnel medial to the anterior iliac spine and lateral to the femoral infection.
- The PFA is exposed through an incision placed along the lateral border of the sartorius muscle 4 to 6 cm below the anterior superior iliac spine (**FIG 5**). The sartorius and superficial femoral vessels can be retracted medially to expose the adductor longus. Its overlying fascia is divided, and with medial retraction, the PFA is exposed.

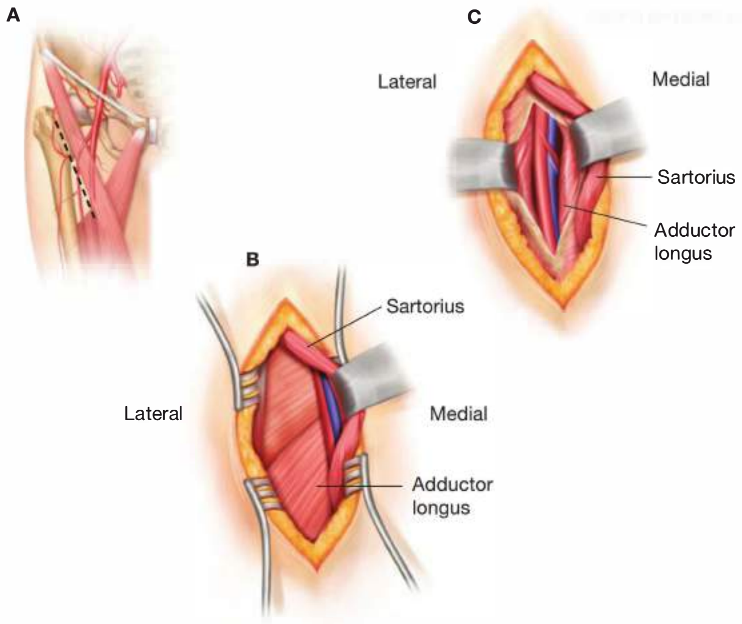

FIG 5 ● Lateral exposure of the profunda femoris artery. **A.** Incision along the lateral border of the sartorius muscle. **B.** Medial retraction of the superficial femoral artery and vein to expose the adductor longus. **C.** Fascial incision and medial retraction of the adductor longus to expose the profunda femoris vessels.

SUPERFICIAL FEMORAL VEIN HARVEST

- SFV can be a suitable graft for reconstruction, with a low incidence of recurrent or uncontrolled infection.[4] Preoperative evaluation should include duplex imaging of the SFV to exclude deep venous thrombosis and to determine the vessel diameter.
- Dissection can be performed through a standard anteromedial leg incision, or placed over the lateral border of the sartorius (**FIG 6**). The vein should be dissected from its confluence with the profunda femoris vein distally to obtain sufficient length for reconstruction. Care should be taken to preserve the profunda femoris vein and the common femoral vein and to stop the dissection at the adductor canal. These limits will preserve important collateral circulation between the profunda femoris and the popliteal vein, which will minimize postoperative leg edema.
- Once harvested, branches of the SFV should be doubly ligated or suture ligated a distance 2 mm from their junction with the SFV to prevent slippage of the ligature once the conduit is pressurized. The SFV can be used in a reversed manner or nonreversed after disrupting the valves.

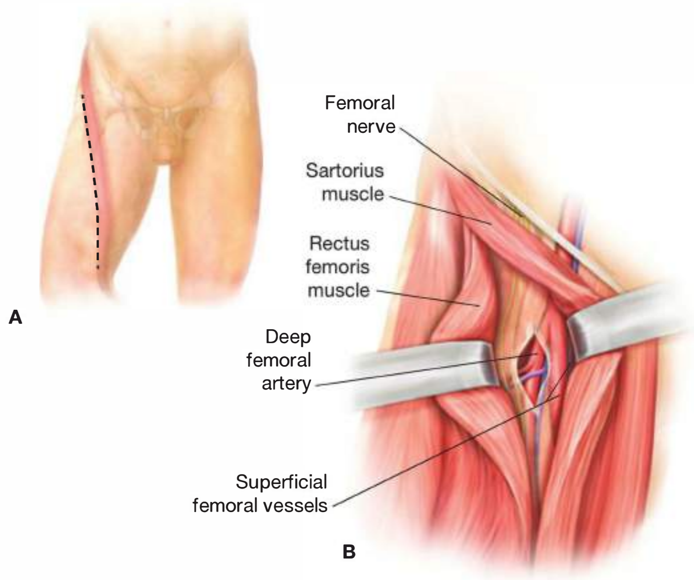

FIG 6 ● Exposure of the superficial femoral vein. **A.** Incision along the sartorius muscle. **B.** medial retraction of the sartorius to expose the superficial femoral vein.

CRYOPRESERVED GRAFTS

- Some studies have shown favorable results for cryopreserved allografts with regard to limb loss, recurrent infection, and survival compared with other in situ replacements.[5]
- When considering an allograft, greater than 24 hours may be required to locate suitable graft material and length if there is no on-site inventory.
- Grafts should be prepared immediately before implantation. The thaw-and-rinse process takes approximately 45 minutes.
- Ligated braches should be tested for hemostasis and suture ligatures placed if necessary. If using an aortoiliac homograft, it is easier to confirm hemostasis if the graft is placed with the lumbar branches facing anterior.
- Graft length should allow for a tension-free anastomosis. When possible, avoid allograft-to-allograft anastomoses.

PEARLS AND PITFALLS

Preoperative considerations	■ When possible, consideration should be made prior to surgery for the best option(s) of graft material, allowing time to obtain it if required. For autogenous vein, preoperative duplex is essential to determine the size and quality of the proposed conduit.
Proximal and distal vessel control	■ When possible, proximal and distal vessel control should be obtained through extension of the original incision or through separate incisions before dissecting the infected vessels. Remote bypass with subsequent removal of infected material may be preferable to in situ repair.
Intraoperative cultures	■ It is important to obtain Gram stain, aerobic, and anaerobic cultures of the perigraft fluid, perigraft tissue, and graft. The yield of the graft will be increased if sonication of the graft is performed in the microbiology lab prior to incubation.
Tunnels	■ Tunnels, when possible, should be placed in sterile fields.
Systemic antibiotic treatment	■ Broad-spectrum antibiotics should be initially considered for patients with severe sepsis. For those without sepsis, blood and wound cultures should be performed prior to starting antibiotics. Initial antibiotics should include coverage for methicillin-resistant *Staphylococcus aureus* (MRSA). After surgery, parenteral antibiotics should be considered for 4–6 weeks, especially for invasive infections or in situ repair.

POSTOPERATIVE CARE

- Antibiotics should be continued for at least 2 to 6 weeks, depending on the type of organism, and should be chosen based on antimicrobial sensitivity when available.
- Patients should be inspected daily for signs of infection, which may include fever, leukocytosis, erythema or drainage from the wound, or wound breakdown. Persistent infection should trigger consideration of wound exploration and re-evaluation of the antibiotic regimen.
- Drains, if placed, should be removed as soon as possible, based on quantity and appearance of fluid. Ongoing purulent drainage or continued fever and leukocytosis may indicate lack of source control, which may require wound exploration and washout.
- Arterial surveillance should be performed prior to discharge to confirm the integrity of the repair and establish a baseline for future surveillance examinations.

COMPLICATIONS

- Bleeding from the wound should raise immediate concerns of arterial disruption from persistent infection leading to tissue destruction. If present, patients should undergo arterial duplex and be considered for reexploration. Under these circumstances, complete evaluation of the arterial reconstruction (even if remote) is advisable as vascular resection and reconstruction may be required. At times, arterial ligation may be the only option for local control of sepsis.
- If not already performed, patients requiring reexploration and debridement for persistent infection will most often benefit from muscle flap coverage of the defect.

Chapter **28**

Surgical Exposure of the Lower Extremity Arteries

Luke X. Zhan Joseph L. Mills, Sr.

DEFINITION

- Chronic lower extremity ischemia, also known as peripheral artery disease (PAD), is a common condition managed by vascular specialists. The primary etiology is atherosclerosis. Atherosclerotic stenosis or occlusion of the peripheral arterial tree results in arterial insufficiency and end-organ (limb) ischemia. PAD is a major contributor to morbidity, reduced quality of life (QOL), and mortality in an increasing elderly demographic in the Western world.

DIFFERENTIAL DIAGNOSIS

- The challenge for the vascular specialist is to determine whether the nature and severity of presenting symptoms correlate with the degree of chronic arterial insufficiency present or whether alternative etiologies, such as neuropathy, inflammation, infection, lymphatic or venous disease, and repetitive trauma, are more likely responsible. Definitive diagnosis is derived from detailed historic and physical examination findings correlated with appropriately directed noninvasive vascular laboratory and adjunctive imaging studies.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with PAD may present with a spectrum of symptoms ranging in severity from none to varying degrees of claudication to severe or "critical" limb ischemia ("CLI" = ischemic rest pain, ulceration, and gangrene). Pulse palpation is an integral component of the physical examination. Femoral, popliteal, posterior tibial, and dorsal pedal pulses should be noted and graded (0 = absent; 1 = present but diminished; 2 = normal; 3 = enlarged, aneurysmal). Claudication is defined as muscular pain, cramping, aching, or discomfort in the lower limb, reproducibly elicited by exercise and relieved within 10 minutes of cessation. CLI has been traditionally defined as (1) persistent, recurring ischemic rest pain requiring opiate analgesia for more than 2 weeks and (2) ankle systolic pressure less than 50 mmHg or toe systolic pressure less than 30 mmHg (or absent pedal pulse in patients with diabetes).[1] Ischemic rest pain typically is nocturnal, worsens with elevation, and is relieved by dependency. Pedal pulses are absent; dependent rubor, elevation pallor, and calf muscle atrophy are frequent accompaniments. CLI also includes ischemic foot ulceration and gangrene in the setting of ankle systolic pressure less than 50 to 70 mmHg or toe systolic pressure less than 40 mmHg in patients without diabetes (<50 mmHg in diabetics).

SURGICAL MANAGEMENT

Indication

- All patients with PAD require comprehensive medical management and risk factor modification. Revascularization (either open bypass or endovascular intervention) is indicated in patients who remain symptomatic and significantly limited despite adequate risk factor modification, exercise, and medical management. The primary goal of intervention, in patients with lifestyle-limiting claudication, is to improve exercise tolerance and hence QOL. Patients with rest pain, tissue loss, and gangrene are at greater risk for limb loss and cardiovascular mortality (stroke, myocardial infarction) associated with systemic atherosclerosis than those who present with claudication alone. Revascularization in the CLI cohort is focused on wound healing and functional limb salvage as well as symptomatic relief and improvement in QOL.[2,3]

Preoperative Planning: Imaging and Risk Assessment/Mitigation

- The vascular specialist must first determine, given the underlying disease burden, the severity of ischemic and infectious complications as well as the patient's comorbidities, functional status, and anticipated longevity. Once it is decided that revascularization will improve the patient's functional status and QOL, these same variables, in concert with anatomic assessment of the location, extent, and severity of occlusive arterial lesions will determine whether endovascular, open, or hybrid revascularization options are indicated. When bypass is selected as the preferred revascularization option, the goals of preoperative planning involve delineation of diseased arterial segment(s), identification of the most appropriate arterial inflow source, selection of the optimal bypass target for maximal outflow and target bed perfusion, and selection of the best available conduit. In practice, conduit availability is almost always a critical, rate-limiting factor because good quality, autogenous vein conduit is preferred in almost every circumstance.
- Adequate preoperative planning depends on a thorough history and detailed physical examination.
- The delineation of the relevant arterial anatomy on the index limb is facilitated by high quality, noninvasive vascular laboratory studies (ankle–brachial index and toe pressure measurements). These are supplemented by arterial color duplex ultrasound imaging. Arterial duplex is extremely accurate in the assessment of iliofemoral and femoropopliteal arterial occlusive disease but less so for infrageniculate (tibial–peroneal) lesions. Duplex enables differentiation of stenosis from occlusion and determination of lesion length and degree of calcification. Cross-sectional imaging studies such as computed tomography angiography (CTA) or magnetic resonance arteriography (MRA) may add complementary information, but most experienced operators prefer the precision and resolution inherent in catheter-based, intraarterial contrast arteriography for definitive preoperative planning, especially when bypass will be required to distal calf or pedal targets.
- PAD is a coronary artery disease equivalent. Therefore, preoperative risk evaluation for overall cardiovascular-related mortality represents a component of preoperative planning.

In most patients with stable or minimally symptomatic coronary disease, preoperative risk-reduction efforts are best focused on optimizing medical management. Frequently, this includes statin and antiplatelet therapy, β-blockade, and optimization of hypertension management.

- The surgical plan should be tailored to each patient's needs based on extent of disease, conduit availability, and realistic long-term functional potential. Infrainguinal bypass may originate from the common, superficial, or deep femoral artery or the popliteal artery with a bypass target of the popliteal, tibial, or pedal/plantar arteries. The positioning, choice of incisions, and surgical techniques are dictated by type of bypass procedure deemed most appropriate under the circumstances.

- Refer to references 4 through 9 for this section.

FEMORAL VESSEL EXPOSURE

Positioning

- The patient is placed in supine position. A Foley catheter is inserted. Arms may be tucked to facilitate intraoperative prebypass and completion angiography.

Placement of Incision

- The common femoral artery (CFA) is located on a line between the pubic tubercle and anterior iliac spine, two fingerbreadths lateral to pubic tubercle. Palpation of the inguinal ligament and femoral pulse or direct arterial visualization with duplex imaging can localize the CFA bifurcation and guide optimal incision placement. Even when pulseless due to excessive calcification or occlusive disease, the CFA may be localized by reliance on anatomic landmarks and direct palpation, recognized as a firm tubular structure positioned within the femoral sheath.
- The vertical groin incision is most commonly employed to provide optimal access to the entire length of the CFA. This should be created coaxially along the artery itself, continued from the inguinal ligament distally, and aimed at the medial aspect of the knee. The incision can be extended superiorly or inferiorly to increase arterial exposure as necessary to achieve optimal inflow (**FIG 1**, *dashed line A*).
- Alternatively, especially in obese patients with substantial abdominal pannus, a curvilinear incision can be placed 1 cm below and parallel to the inguinal ligament to avoid potential skin maceration and wound complications that may accompany vertical incisions in this situation (**FIG 1**, *dashed line B*). Although the proximal superficial femoral and deep femoral arteries can be exposed via this incision, such a curvilinear or oblique incision limits further distal arterial exposure. It therefore would not be selected if an extensive common and deep femoral artery endarterectomy is anticipated as potentially necessary to optimize inflow.
- The incision is carried sharply through the subcutaneous tissue and superficial fascia.

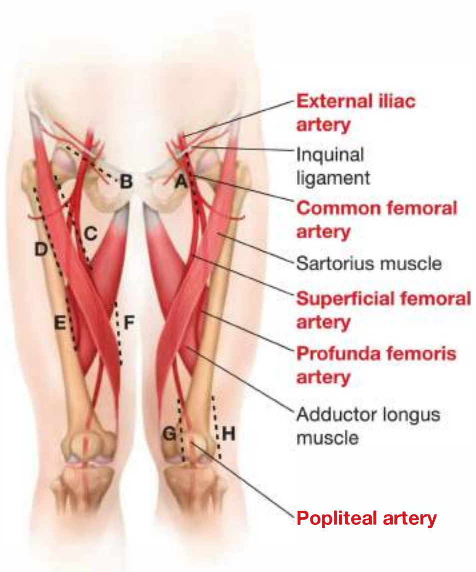

FIG 1 ● Placement of incisions for infrainguinal arterial exposure. Incisions *(A)* and *(B)*: Femoral vessel exposure at proximal thigh. Incisions *(C–F)*: Exposure of mid- and distal superficial and deep femoral arteries. Incisions *(G)* and *(H)*: Lateral and medial exposure of popliteal artery above the knee.

Dissection and Control of the Common, Superficial, and Proximal Deep Femoral Arteries

- Deep to the subcutaneous tissue and superficial fascia, the dissection is extended longitudinally, even when using an oblique incision, to optimize the length of femoral exposure. Depending on the depth of dissection and subcutaneous adiposity, self-retaining Weitlaner or cerebellar retractors are carefully placed to optimize exposure while avoiding traction injury to femoral nerve branches or the common femoral vein. Further dissection through the femoral sheath exposes the anterior surface of the femoral artery.
- The dissection plane should remain centered directly over the femoral artery. Encountering venous structures indicates medial deviation from the optimal plane; exposure of the iliopsoas muscle, femoral nerve fibers, or lymphatic vessels is an indication of lateral deviation. An increasing incidence of femoral incisional complications, including wound edge necrosis and separation, lymphatic leaks, femoral neuropraxia, and venous injuries are associated with incorrectly placed inguinal incisions for femoral exposure.
- Dissect directly along the CFA both proximally and distally. Placement of silastic vessel loops around the

femoral artery and its larger branches aids in retraction, dissection, and mobilization.

- Proximal dissection is continued along the CFA to the inguinal ligament. The inguinal ligament may be divided to aid in exposure or to enable extended endarterectomy. Caution is necessary in this area, as a prominent femoral vein tributary crosses anteriorly over the CFA in this area and is prone to injury if not identified, ligated, and divided early in the dissection. Inadvertent injury to this "vein of pain" produces retraction and troublesome bleeding. The medial and lateral femoral circumflex arteries, important collaterals in iliofemoral arterial occlusive disease, are identified at level of the inguinal ligament and individually controlled with removable clips or silastic vessel loops. Use of the former reduces clutter in the wound during endarterectomy or creation of the proximal anastomosis.
- As the dissection proceeds distally, an abrupt change in caliber marks the femoral bifurcation and the origins of the deep (also known as "profunda femoris" in Latin) and superficial femoral arteries (SFA). The latter continues distally in the same plane; the former usually courses posteriorly and laterally away from the femoral bifurcation. After silastic loops are placed on each vessel, gentle upward traction on the CFA or SFA may help bring the deep femoral artery into view. The lateral circumflex iliac vein may course anteriorly over the origin of the deep femoral artery and should be ligated and divided to optimize exposure and control of the first segment of this vessel (**FIG 2A**).
- Medial and distal dissection provides extended exposure of the proximal SFA (**FIG 1**, *dashed line F*). This vessel only occasionally has small branches in its proximal segment. A sensory branch of the femoral nerve may be present crossing the SFA from lateral to medial. Transection may result in medial thigh discomfort. Even extended femoral bifurcation dissections rarely require division of femoral nerve branches, which should be avoided to minimize postoperative paresthesias and dysesthesias.

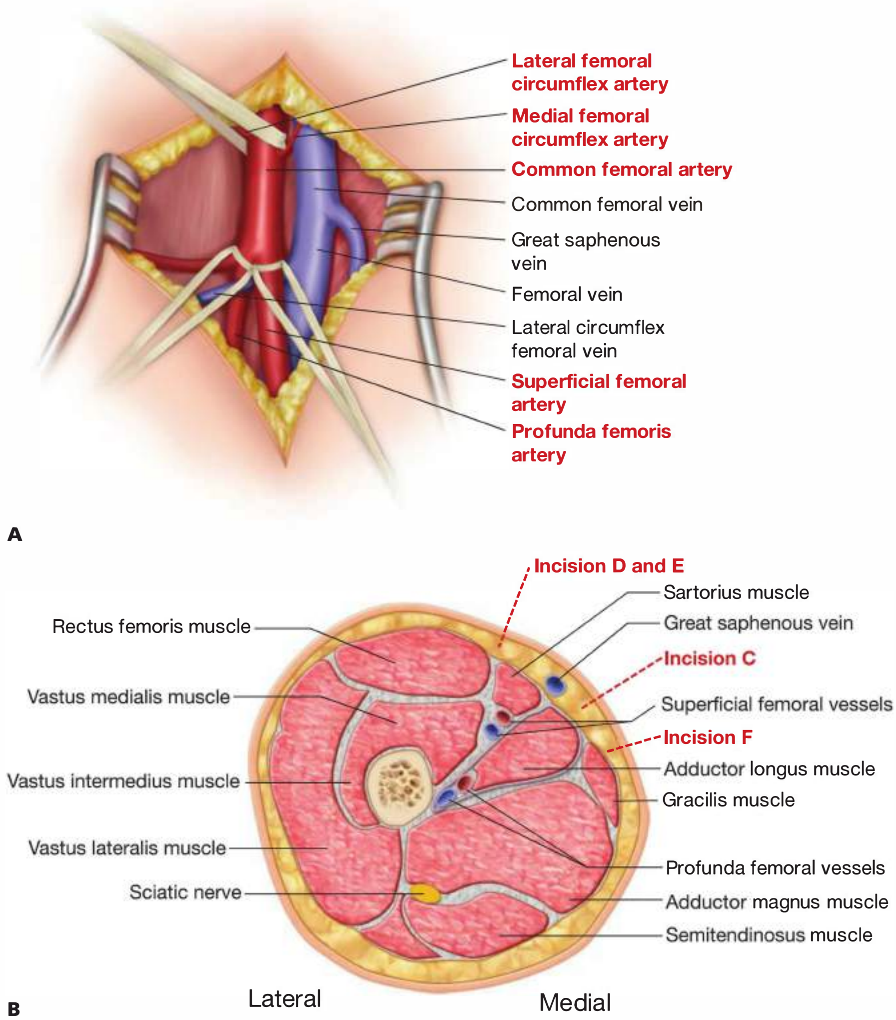

FIG 2 ● **A.** Exposure of femoral vessels at groin. **B.** Anteromedial and posterolateral approaches to expose middle and distal segments of the superficial and deep femoral arteries. Incisions *(C–F)* correspond to **FIG 1**.

Exposure of the Middle and Distal Segments of Deep Femoral Artery

- Exposure of the distal portions of the deep femoral artery often enables use of shorter vein conduit in distal leg bypass or may improve outflow from proximal revascularization procedures (iliac angioplasty and stenting or aortofemoral bypass). These segments are easily exposed from either posteromedial or anteromedial approaches (**FIG 1**, *dashed line C–F*). The approach should be dictated by the indication (inflow sources or outflow target); an additional consideration is the necessity to obtain exposure in a native field, either in the setting of prior dissection or femoral graft infection.
- Incisions are placed along either the medial (anteromedial approach; *dashed line C* and *F* in **FIG 1**) or lateral borders (posterolateral approach) of the sartorius muscle (**FIG 1**, *dashed line D* and *E*). The dissection plane is developed through the subcutaneous tissue and fascia, passing lateral or medial to the sartorius, respectively. Mobilize and retract sartorius muscle laterally or medially, depending on approach.
- The dissection is continued posteriorly, passing lateral to the superficial femoral vessels and accompanying nerve, to the space between the adductor longus muscle (medially) and vastus medialis (laterally) (**FIG 2B**, incisions *C–E*). The deep femoral artery and vein pass directly underneath.
- Dissection between adductor longus and vastus medialis muscle exposes the middle segments of the deep femoral artery. Crossing venous tributaries should be ligated and divided as necessary to provide optimal exposure. The more distal segments of deep femoral artery begin to course posterior to the femur beyond this point and are therefore less useful for bypass origination or destination.
- Alternatively, exposure between the adductor longus (anteriorly) and gracilis muscle (posteromedially) enables medial exposure of the deep femoral artery in the distal thigh (**FIG 1**, *dashed line F*; **FIG 2B**, incision *F*).

POPLITEAL ARTERY EXPOSURE

Medial Exposure of the Above-Knee Popliteal Artery

- Place patient in supine position. Rotate leg laterally, flex the leg, and place a bump underneath the knee joint.
- Place a 10- to 12-cm longitudinal incision along the groove formed between the edges of the vastus medialis (anteriorly) and the sartorius muscles (posteromedially) (*dashed line A* in **FIG 3A**). The incision is carried through the subcutaneous tissue and fascia. Place self-retaining retractor. Take care not to trap and injure the great saphenous vein and the saphenous nerve. The great

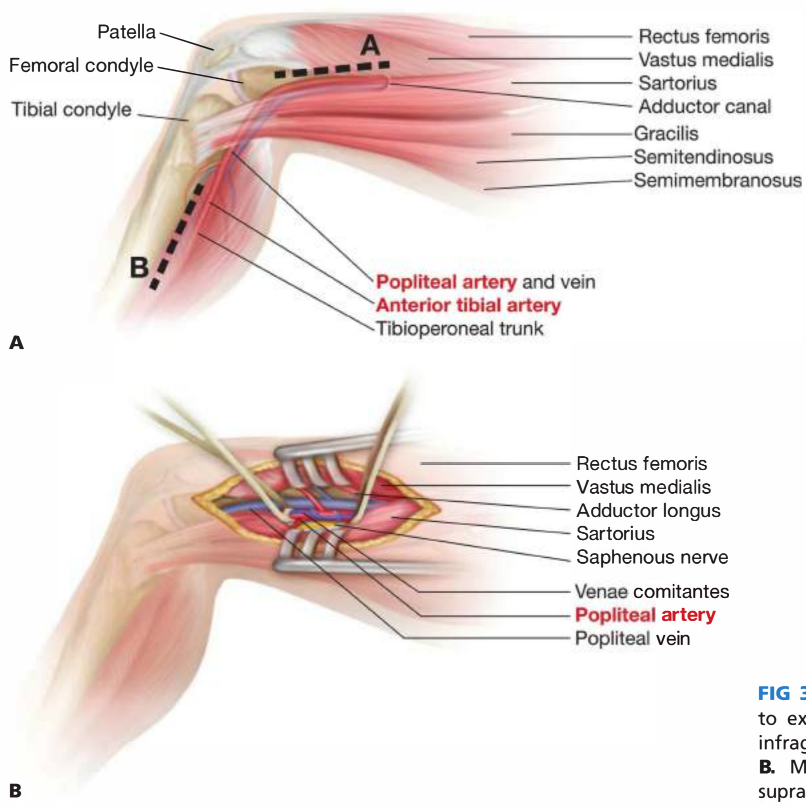

FIG 3 ● **A.** Incisions for medial approaches to exposure of the supra- (incision *A*) and infrageniculate (incision *B*) popliteal artery. **B.** Medial approach for exposure of the suprageniculate popliteal artery. *(continued)*

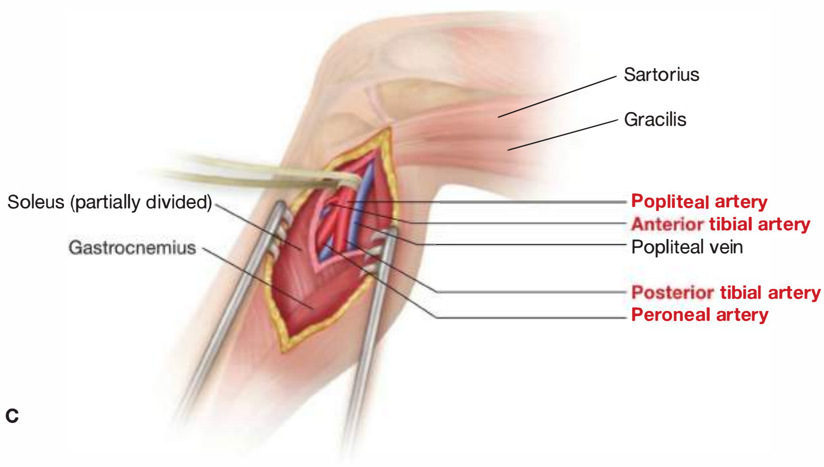

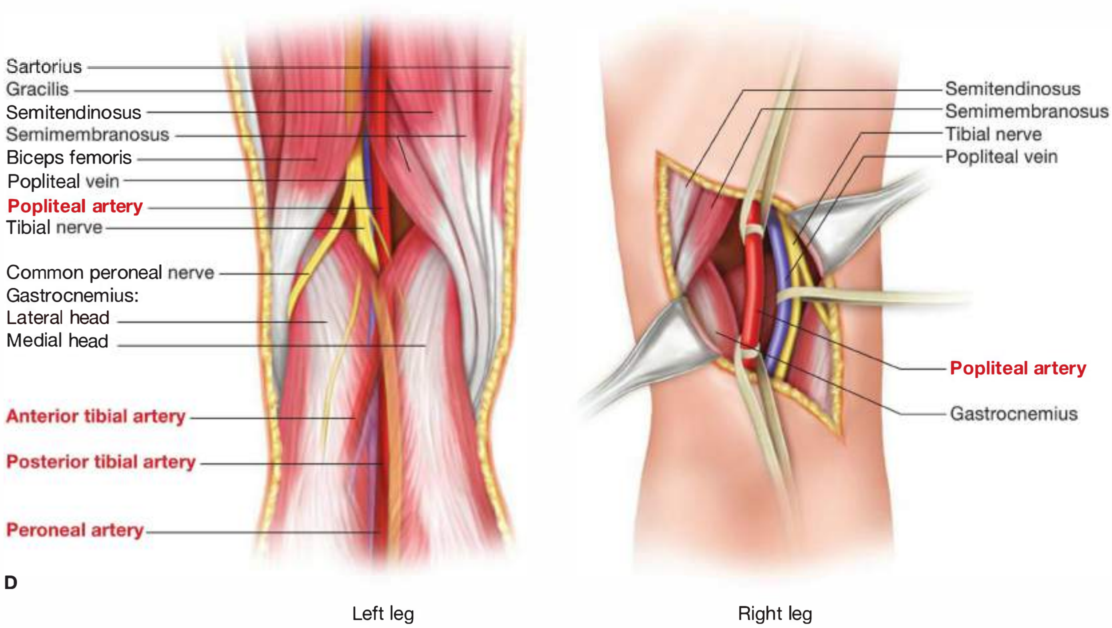

FIG 3 ● *(continued)* **C.** Medial approach for exposure of the infrageniculate popliteal artery and its branches. **D.** Posterior exposure of the popliteal artery.

saphenous vein is likely to be encountered more posteromedially to the incision in the subcutaneous tissue. The saphenous nerve may be encountered at distal end of the incision as it joins the saphenous vein near the medial aspect of the knee.

- Incise the deep fascia longitudinally and above the sartorius muscle to enter the popliteal fossa. The popliteal artery can be palpated up against the posterior surface of the femur (FIG 3B).
- The popliteal artery is often surrounded by multiple venous collaterals, or "venae comitantes" in Latin; the popliteal vein is usually posterolateral to the artery in this location. The popliteal and/or superficial femoral veins may be duplicated throughout the popliteal fossa and distal thigh. Isolation and control of the artery usually requires ligation and division of surrounding collateral veins.

Lateral Exposure of the Above-Knee Popliteal Artery

- Lateral exposure of the above-knee (AK) popliteal artery is useful in a variety of circumstances—for instance, axillopopliteal bypass or when the medial approach has previously been developed or is complicated by infection or injury.
- Place patient in supine position. Rotate leg medially, flex the knee, and place a bump underneath the knee joint.
- Place 10- to 12-cm longitudinal incision between the vastus lateralis and the biceps femoris muscles (*dashed line A* in FIG 4A). The incision is carried through the subcutaneous tissue and fascia.
- Make a generously cruciate incision ("T-ed") at both ends on the fascia lata to prevent bypass graft impingement by its dense fibers.
- Place retractor and enter the popliteal space. Sciatic nerve then popliteal vein will be encountered first before

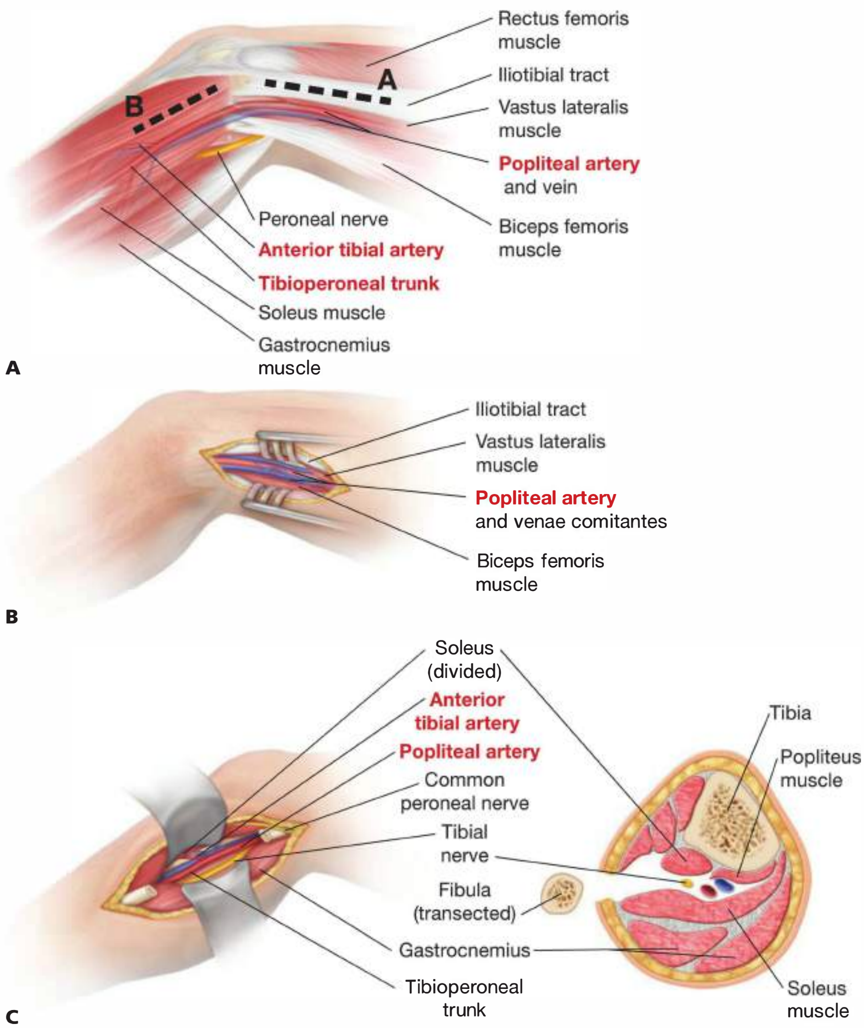

FIG 4 ● **A.** Incisions for lateral exposure of supra- and infrageniculate popliteal artery and its trifurcation. **B.** Lateral exposure of suprageniculate popliteal artery. **C.** Lateral exposure of infrageniculate popliteal artery and its trifurcation.

popliteal artery. Gently retract sciatic nerve downward. Then mobilize and retract popliteal vein to expose and control the popliteal artery.

Posterior Exposure of the Popliteal Vessels

- Posterior exposure may be the preferred approach for management of popliteal artery entrapment, popliteal cyst, focal popliteal artery aneurysm, or arterial injury following traumatic posterior knee dislocation. Although direct and relatively uncomplicated, posterior access is limited by the heads of the gastrocnemius muscle distally and the biceps femoris/"hamstring" muscles proximally; only focal, limited popliteal artery access is achievable through this incision.
- Patient is placed in prone position with pillow to prop up the lower leg and foot.
- The incision is S-shaped, across the posterior crease of the knee joint, with its superior extent beginning medially.
- The incision is carried anteriorly through the subcutaneous tissue and superficial fascia to enter the popliteal fossa. Exposure is maximized by mobilizing the popliteal artery between the two heads of the gastrocnemius muscle inferiorly and between semimembranosus and biceps femoris muscle superiorly.
- The muscles are gently retracted to expose the entire popliteal fossa. The tibial and common peroneal nerves are encountered superficially in this exposure. The popliteal artery is anterior, or deep to the vein, in the depths of the wound.
- It may be necessary to mobilize the popliteal vein with ligation and division of popliteal venous tributaries to fully expose the artery. Once the appropriate segment is exposed, silastic vessel loops are placed proximally and distally.

INFRAGENICULAR EXPOSURE

Medial Exposure of the Infragenicular Popliteal Artery and Its Branches

- The most common approach is a medial one (FIG 3A).
- Place patient in supine position. Rotate leg laterally, flex the leg, and place a bump underneath the knee joint.
- Make a longitudinal incision from below the edge of the tibia along the course of the great saphenous vein (*dashed line B* in FIG 3A).
- Carry the incision through subcutaneous tissue and fascia into the deep posterior compartment. The below-knee (BK) popliteal vessels reside deep in the wound and are partially covered by the origin of the soleus muscle.
- Division of the soleus origin medially (FIG 3C) will facilitate exposure of the tibioperoneal trunk, and origin of the anterior tibial artery, but is not really necessary for exposure of the popliteal artery itself. As was described for the posterior approach, the artery lies in close proximity to the popliteal vein and tibial nerve. Mobilization of the popliteal vein from the adjacent artery is necessary for sufficient exposure of all relevant structures, including the anterior tibial artery, tibioperoneal trunk, and derivative branches (posterior tibial and peroneal arteries). It is usually necessary to ligate and divide the anterior tibial vein at its confluence with the (often paired) popliteal vein to gain sufficient exposure to isolate and mobilize the more distal branches.
- Dissection must proceed deliberately to avoid injury to the neighboring tibial nerve and its distal branches.

Lateral Exposure of the Infragenicular Popliteal Artery and Its Trifurcation

- The lateral approach is rarely required but may be particularly useful to avoid scarring from a previous medial approach.
- Place the incision posterior to the head of the fibula and extend along the course of the fibula. Dissect directly onto fibula (incision is marked as *dashed line B* in FIG 4A). Note the location of the common peroneal nerve, which courses from posterior to anterior around the neck of the upper fibula just below its head, before it branches into the superficial and deep peroneal nerves.
- Circumferentially elevate the periosteum of the fibula and excise the exposed segment of the fibula with a saw. The popliteal vessels and branches are found directly beneath the fibular periosteum, with the artery usually located anterior to the posterior tibial nerve and the popliteal vein.
- Extending the dissection distally allows exposure and control of distal popliteal artery, as well as the origins of the anterior tibial and the tibioperoneal trunk.

Exposure of the Anterior Tibial Artery

- **Proximal segment**
  - The proximal segment of the anterior tibial artery is exposed in a fashion similar to the exposure for the infragenicular popliteal artery and its branches.
- **Middle segment**
  - The middle segment exposure of the anterior tibial artery is useful when there is limited length of autogenous vein.

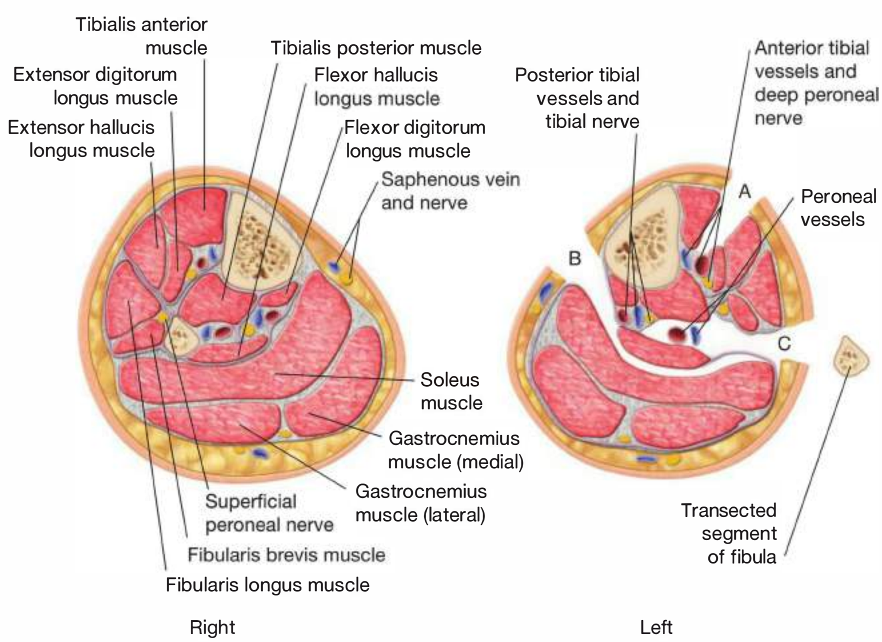

FIG 5 ● Exposure of anterior tibial, posterior tibial, and peroneal arteries at mid-lower leg.

- Place an axial incision in a vertical plane about two fingerbreadths lateral to the anterior edge of the tibia (**FIG 5A**).
- Deepen the incision between the tibialis anterior and the extensor hallucis longus muscles.
- The anterior tibial artery is superficial to the interosseus membrane between the cleft formed by these two muscles.
- Dissecting away the overlying collateral veins allows exposure and control of the middle segment of the anterior tibial artery. Use of a proximal sterile tourniquet during exposure of all the crural arteries may significantly accelerate the dissection while limiting bleeding from the numerous and redundant collateral veins.

Exposure of the Posterior Tibial Artery

- **Proximal segment**
  - The proximal segment of the posterior tibial artery is approached in a similar fashion to the exposure for the infragenicular popliteal artery and its branches and requires taking down the soleus muscle from the tibia.
- **Middle segment**
  - The middle segment exposure of the posterior tibial artery is useful when there is limited length of vein graft to bypass to the posterior tibial artery.
  - Incision is made just anterior to the soleus muscle. Divide the overlying soleus to expose the underlying vessels (**FIG 5B**).
  - The posterior tibial artery lies anterior to soleus muscle with the peroneal artery located laterally, in the same plane, between the soleus and tibialis posterior muscles.
  - Avoid injury to the tibial nerve, which commonly runs between the posterior tibial and peroneal vessels.

Exposure of the Peroneal Artery

- **Proximal and middle segments**
  - Exposure of the proximal segment of the peroneal tibial artery is via distal extension of the infragenicular popliteal artery approach.
- **Middle segment**
  - The middle segment may also be approached anterolaterally. The following description relates to lateral exposure requiring fibulectomy.
  - Place a vertical incision over the fibula at the desired level (**FIG 5C**).
  - Carry down the incision through the overlying muscle down to the fibula. Elevate the periosteum of the fibula circumferentially.
  - Transect the overlying segment of fibula. Incise the inner periosteal membrane. The peroneal vessels are found immediately beneath. The artery usually is anterior to flexor hallucis longus and posterior to the tibialis posterior muscles.
  - The peroneal artery is exposed and controlled after mobilization from circumferential collateral veins and the main peroneal vein.

EXPOSURE OF PEDAL VESSELS

Exposure of the Inframalleolar Posterior Tibial Artery

- Distal posterior tibial exposure enables pedal bypass at or below the ankle, which may be especially useful in patients with advanced diabetes.
- Make a longitudinal incision through skin and fascia at the midpoint between the medial malleolus and the Achilles tendon. If this exposure is used for an in situ bypass procedure, the incision should be sighted slightly more anteriorly to accommodate the anterior course of the great saphenous vein as it crosses the medial malleolus.
- Identify and divide the flexor retinaculum as needed to provide optimal exposure. The posterior tibial vessels are located between the flexor digitorum longus and flexor hallucis longus muscles/tendons.
- Place a small Weitlaner self-retaining retractor. The neurovascular bundle is usually enveloped by fatty tissue below the fascia.
- Dissection proceeds along the neurovascular bundle. The posterior tibial artery is usually anterior to the tibial nerve. There is typically a rich network of venous collaterals present. These may either be mobilized or (more commonly) divided to facilitate distal posterior tibial artery exposure.
- When more distal bypass targets are needed (e.g., prohibitive burden of disease in the posterior tibial artery itself), the dissection may be continued along the posterior tibial artery distally to the bifurcation of the medial and lateral plantar arteries. In all such cases, however, preoperative imaging is paramount to immediate and long-term surgical success, and only in rare circumstances should the operative plan be changed by unexpected findings at the time of surgery. The presence of luminal calcification alone, without substantial compromise to the target lumen diameter, is not a contraindication to bypass construction. When uncertainty is present regarding the optimal bypass target despite adequate preoperative imaging, consideration should be given to on-table, intraoperative arteriography to guide surgical decision making and confirm outcome. To this end, we perform all open bypass procedures in a hybrid operating room environment with high-quality imaging capabilities to ensure the optimal outcome of all procedures, regardless of the initial operative plan.

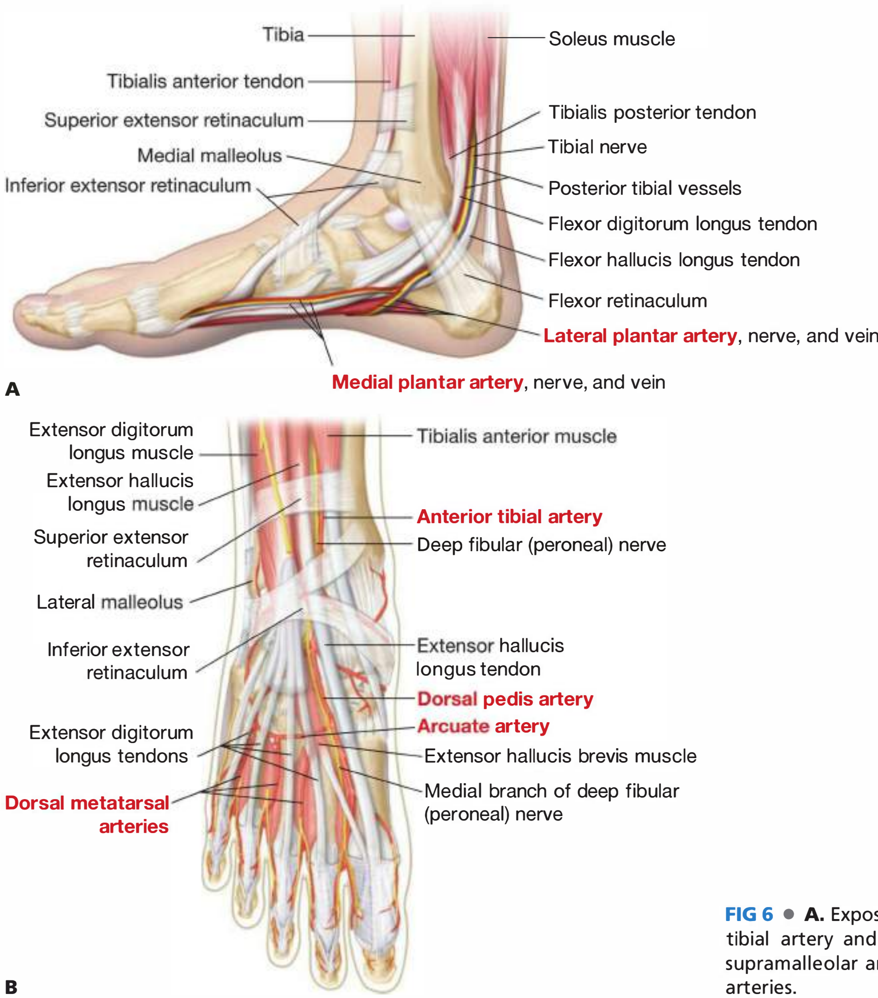

FIG 6 ● **A.** Exposure of inframalleolar posterior tibial artery and its branches. **B.** Exposure of supramalleolar anterior tibial and dorsal pedal arteries.

Exposure of the Supramalleolar Anterior Tibial Artery

- The distal anterior tibial artery may serve as a suitable distal bypass target, especially when substantial disease is present more proximally. It may also be preferable to bypass to this segment in the presence of a dorsal foot wound.
- The incision is placed between the tibialis anterior medially and extensor hallucis longus and the extensor digitorum longus laterally (FIG 6B).
- Anterior tibial artery and peroneal nerve usually course through the groove between them.
- Dissect between these tendons and retract them to expose the supramalleolar segment of anterior tibial artery.

Exposure of the Dorsal Pedal Artery

- The dorsal pedal artery (or "dorsalis pedis" in Latin) is the extension of the anterior tibial artery as it passes beneath the extensor retinaculum. It can serve as a suitable distal bypass target, especially in patients with diabetes.
- The artery is best exposed beyond the inferior extensor retinaculum. Place an incision between the 1st and 2nd metatarsal shafts and distal to the extensor retinaculum (FIG 6B).
- The dorsalis pedis artery resides in the groove between the 1st and 2nd metatarsal heads, usually just lateral to the extensor hallucis longus tendon, which is readily identified by dorsiflexion of the great toe, and medial to extensor hallucis brevis.
- Carry down dissection through subcutaneous tissue and longitudinally divide the fascia to expose and control the artery.

PEARLS AND PITFALLS

- Preoperative ultrasound duplex mapping aids the selection and placement of the incision. Dissection can be guided by palpation of the underlying arterial pulse. In most cases, because distal pulses are frequently absent or difficult to palpate, use of an intraoperative Doppler probe will aid the localization and dissection of vessel. Nonetheless, knowledge of appropriate anatomic landmarks will greatly facilitate careful and expeditious exposure. In all circumstances, dissection should be directly targeted on and around the artery. This guidance is similar in many ways to the orthopedic axiom to "stay on the bone" during dissection—keeping exposure centered on the target artery minimizes venous bleeding and damage to surrounding structures. Placement of an encircling silastic vessel loop will aid in further mobilization.
- In the exposures of the thigh arteries, the sartorius muscle serves as an important landmark for the exposure of the common, superficial, and profunda femoral arteries.
- In the setting of reoperation, alternative surgical exposures allow operation in a virgin field that is unscarred by previous operation.

COMPLICATIONS

- Bleeding complication: Aim to achieve satisfactory hemostasis for surgical bleeding prior to skin closure. Full anticoagulation from heparin can be reversed with protamine to reduce the risk of postoperative bleeding.
- Vessel injury: Vascular clamps or silastic loops can lift atherosclerotic plaques and create dissection and arterial injury in the presence of arterial calcification. The vascular clamp should be placed at a relatively soft, disease-free segment. Occasionally, this requires lateral positioning of a clamp to provide anterior/posterior rather than lateral compression of a vessel. In the CFA, the accumulation of significant posterior plaque often mandates modification of "atraumatic" clamp placement. In the tibial vessels, care should be taken to obtain control in the least traumatic fashion possible to limit compression of inelastic runoff vessels and the potential for clamp injury and restenosis. Often, alternative devices such as "flow arresters" or intraarterial no. 2 embolectomy catheters attached to stopcocks may provide sufficient control to maintain a hemostatic field during completion of the distal anastomosis without exerting undue force on the target artery. In any extent, pressure is reduced to begin with in distal tibial arteries, so the amount of force exerted to obtain control should be modified accordingly. As previously mentioned, strategic use of proximal thigh tourniquets and Esmarch bandage, deployed following creation of the proximal anastomosis and graft tunneling, may also be useful in limiting bleeding and the risk of clamp injury and dissection in diseased tibial vessels.
- Distal embolization: Most frequently, periprocedural embolization is due to fragmentation of atherosclerotic plaque fragments or thrombus during dissection or clamping. Full systemic anticoagulation with intravenous (IV) heparin prior to clamping the vessel and intraoperative monitoring of active coagulation time (ACT) will minimize the risk of graft or native vessel thrombosis. Prior to closure of arteriotomy and clamp release, all involved arteries must be meticulously and repeatedly flushed and back-bled to remove residual thrombus or loosen plaque fragments. Attention to this portion of the procedure, as well as to the precise course of graft tunneling, will optimize outcome and eliminate the need for reanticoagulation, embolectomy, and revision at the end of an often long procedure.
- Nerve injury: Nerves and vessels are often intimately associated. Nerve injury can be caused by dissection, a poorly placed retractor, injudicious spreading and clamp placement, and thermal energy from the electrocautery. These injuries can be reduced by knowledge of appropriate anatomic landmarks, accurate incision placement, and meticulous sharp dissection directly down to and immediately around the intended artery. Importantly, excessively deep placement of self-retaining retractors in an extended common or deep femoral artery exposure can cause traction injuries to motor branches of the femoral nerve, significantly limiting the ability of patients to stand or bear weight for weeks following the procedure. In general, to avoid nerve injury, retractors should be placed in the most superficial plane possible to obtain sufficient exposure of target vessels. In all circumstances, retractors should be removed immediately as soon as they are no longer needed or if attention is turned to alternative sites or other portions of the procedure that do not require continuous exposure.
- Lymphatic leakage: Lymphatic vessels usually course close to the arteries and veins. Avoid transection of lymph nodes. If necessary, cauterize the divided end of lymphatics. Visible lymphatic vessels should be suture ligated. Careful dissection respecting tissue planes allows layered closure to eliminate dead space and lymphatic accumulation, formation of seroma, or hematoma. When lymph nodes are injured, extra time should be taken to control, ligate, and divide afferent and efferent vessels and remove the node completely.

POSTOPERATIVE CARE

- Following bypass, patients should be maintained on a comprehensive medical regimen to optimize their cardiopulmonary status. Lower extremity bypass operations are often performed on patients with diabetes and debilitating symptoms of claudication or CLI. Postoperative care should also aim to optimize nutritional status, functional status, and control of blood sugar level.
- Most surgeons routinely employ routine antiplatelet and selective anticoagulation therapy to improve graft patency in lower extremity bypass patients. The Dutch Bypass Oral Anticoagulants or Aspirin (BOA) trial suggested that oral anticoagulation improved vein graft patency compared with aspirin, whereas aspirin improved prosthetic graft patency compared with anticoagulation. The antiplatelet and/or anticoagulation regimen must be tailored to individual patient with lower extremity bypass considering their risk for graft failure and risk of bleeding. We routinely

administer aspirin to bypass patients and reserve warfarin for high-risk situations (redo bypass, marginal or alternative vein conduits, spliced vein grafts, poor outflow, prior graft thrombosis) due to the increased bleeding risk associated with anticoagulation.

- Wound care: Considerable efforts on wound care are required to achieve wound healing after lower extremity revascularization in patients with CLI with tissue loss. Meticulous nursing care and early ambulation are also crucial to prevent decubitus ulcer in the lower extremities and the sacrum, creating new wounds in patients with lower extremity ischemia.

OUTCOMES

- Outcomes of revascularization should be reported and interpreted through the reporting standards created and updated by the Society for Vascular Surgery.
- In general, autogenous vein conduits are superior to all others for infrainguinal bypass, even for the AK popliteal insertion site, where vein has proven superior to polytetrafluoroethylene (PTFE) beyond 2 to 3 years. Ipsilateral and contralateral greater saphenous vein (GSV) conduits exhibit patency rates superior to alternative veins such as small saphenous vein, arm vein, and spliced veins. Vein graft primary patency rates for femoral BK popliteal bypasses are approximately 70% to 75% at 5 years, and assisted primary patency can be improved even further by a duplex vein graft surveillance protocol. Infrapopliteal vein graft primary patency rates range from 60% to 70% at 5 years. Multiple randomized trials have shown no benefit of reversed versus in situ vein configurations. PTFE grafts have acceptable short- and intermediate-term patency rates only in the AK popliteal position and therefore should only be used in limb salvage situations if autologous vein is truly unavailable. When PTFE must be used, an adjunctive venous Miller cuff or Taylor patch may improve results. The primary factors influencing graft patency are indication, conduit type, and conduit quality. Poor runoff adversely impacts prosthetic graft patency.
- The reader is further referred to standard textbook sources such as Cronenwett et al.'s *Rutherford's Vascular Surgery*, 7th edition, Chapter 109 for a more detailed discussion of the expected outcomes after surgical revascularization for infrainguinal disease.

Percutaneous Femoral–Popliteal Reconstruction Techniques: Reentry Devices

Danielle E. Cafasso *Peter A. Schneider*

DEFINITION

- Reentry devices facilitate true lumen reentry after subintimal recanalization for endovascular treatment of complex lesion morphologies and occlusions in the femoral–popliteal segment.
- Subintimal recanalization and reconstruction of the femoral and popliteal arteries have diminished reliance upon femoral–popliteal bypass. Reentry into the true lumen can be challenging and is often the rate-limiting factor for the success of this procedure. Improved wires and support catheters, and also reentry devices, have been developed for crossing chronic total occlusions (CTOs).
- Tools for managing CTOs are listed in Table 1. CTO support catheters may be used to support the guidewire that is being used to cross the occlusion. These typically have lubricious surface and a stiff tip. Distal access may be used to recanalize infrainguinal occlusions from a retrograde direction. Reentry catheters may be used to reenter the true lumen. CTO crossing catheters are not discussed in the chapter. These are relatively new and use either mechanized or hand power to manipulate through an occlusion in hopes of remaining in the true lumen.
- Planning and performing subintimal recanalization and reentry into the true lumen of the femoral and popliteal arteries are described herein.

Table 1: Tools for Managing Chronic Total Occlusions in the Lower Extremity

Tool for Managing CTO	Purpose	Examples
CTO support catheters	Support during wire crossing	CXI™ (Cook Medical) Quick-Cross™ (Spectranetics) TrailBlazer (Covidien) Gopher (Vascular Solutions)
Distal access	Access for bidirectional approach	Retrograde puncture of SFA–popliteal Tibial–pedal
Reentry catheters	Enter true lumen from subintimal space	Outback™ (Cordis) Pioneer™ (Medtronic) Enteer (Covidien) OffRoad (Boston Scientific)
CTO crossing devices	True lumen crossing	Crosser (Bard) Frontrunner (Cordis) Laser (Spectranetics) TruePath (Boston Scientific) Wildcat (Avinger) Viance (Covidien)

CTO, chronic total occlusion; SFA, superficial femoral artery.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with clinical symptoms and signs of lower extremity ischemia may benefit from subintimal recanalization and the use of reentry techniques in the course of their clinical care.
- Patients present with claudication, rest pain, nonhealing ischemic ulcers, or gangrene. The history and physical examination is consistent with these lower extremity presentations and is described elsewhere in this atlas.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Patients who might benefit from subintimal recanalization and reentry typically have complex lesion morphology, such as arterial occlusion, that may be managed by creating a new channel outside of the potential space offered by the subintimal area. Imaging studies that define the anatomy and lesion morphology are useful prior to revascularization. This may include duplex scanning, magnetic resonance angiography, or computerized tomographic angiography. We usually perform duplex mapping prior to any lower extremity intervention. Long lesions, occlusions, and complex lesions are typically identifiable with preoperative imaging.
- Patients with lower extremity ischemia should have objective physiologic confirmation of the degree to which perfusion is diminished. This may be accomplished by ankle–brachial indices or toe pressures.

SURGICAL MANAGEMENT

Preoperative Planning

- Preoperative planning includes identifying the best access site for arterial entry. Subintimal recanalization of the femoral–popliteal segment may be performed using an up and over approach, from the contralateral common femoral artery, or using an antegrade approach from the ipsilateral common femoral artery. A reentry catheter may be used through either of these access choices. Preoperative noninvasive imaging is very helpful in making this plan for approach.
- The location of lesion helps determine access site and approach. Many patients with superficial femoral artery (SFA) and/or popliteal artery disease are treated with an up and over approach. If the patient has inflow iliac artery disease or has an SFA lesion that begins near the origin of the SFA, an up and over approach is warranted. Reentry devices require placement of a 6-Fr sheath. If an up and over approach is anticipated, the aortic bifurcation should also be assessed to make sure that the reentry device can be passed.
- Patients with extensive disease below the knee and without iliac or proximal SFA disease and who are not obese can be treated using an antegrade approach.

RECANALIZATION STRATEGY

- In managing complex lesions of the femoral and popliteal arteries, it is quite common to attempt to recanalize the true lumen. Stenosis can almost always be crossed transluminally using a wire supported by a catheter. A steerable, hydrophilic, low-profile wire is best. Long lesions, especially if occluded, may not be possible to cross in the true lumen. In this case, subintimal recanalization and reentry is the best option.
- Strategy is based on selection of a reentry site where the artery has an acceptable lumen, collaterals can be preserved, calcification is avoided, and potential bypass sites remain intact. Staying in the true lumen when possible offers the shortest reconstruction and preservation of most collaterals. When subintimal passage is required, reenter the true lumen as close to the distal reconstitution as possible. The most common method of subintimal recanalization is using a loop of hydrophilic wire to dissect the subintimal space and the loop can also be used to reenter the true lumen.
- There is typically a large incoming collateral feeding the reconstituted segment. If the reentry site is calcified, the success rate for loop passage is lower and use of a reentry catheter is more likely to be indicated.
- If there is a substantial plaque at the intended reentry site, consider a site more distal than the initial reconstitution site. If there is another lesion distal to but near the reentry site, this can pose a challenge for passing the guidewire distally after it has popped into the true lumen.
- The operator must decide in this case whether it would be appropriate to reenter distal to all the lesions, given that it might negatively affect bypass options. If the reentry fails and the patient needs a bypass, target sites for distal anastomosis should be anticipated, although failed reentry usually does not result in thrombosis of that segment.

TREATMENT PLATFORM

Sheath Placement

- Place sheath tip close to the origin of the occlusion. Contrast administered through sheath fills the distal reconstitution site through collaterals. For an SFA occlusion, the tip of the sheath is usually positioned near the femoral bifurcation and the distal artery is visualized with contrast flowing through profunda collaterals. Use a sheath that is one size larger than that used for angioplasty and stenting, usually 7 Fr. This permits contrast administration even if a reentry device is being positioned (FIG 1).

Entering the Subintimal Space

- Place an angled tip catheter pointing toward the artery wall at the origin of the occlusion. Point it opposite the location where the largest runoff collateral is located. Advance a Glidewire™ into the wall. Push it and the tip will catch and a loop will form (FIG 2).

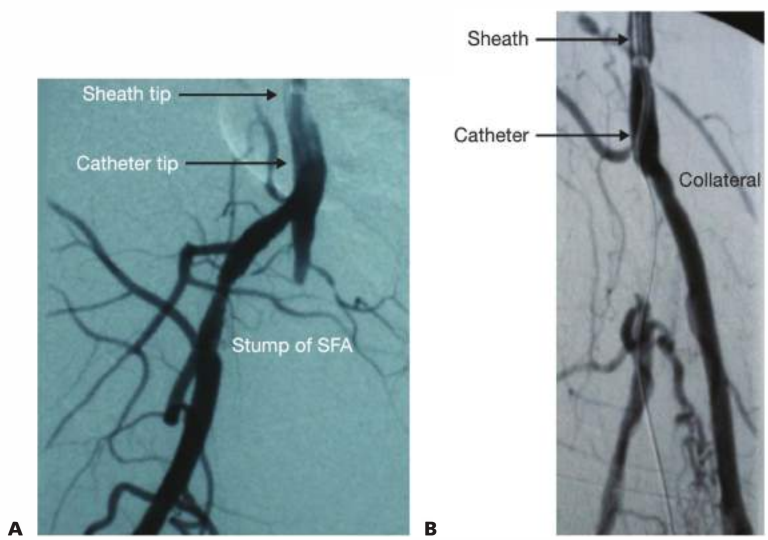

FIG 1 ● Sheath placement. **A.** There is a stump of proximal SFA that is patent. The sheath was placed up and over the aortic bifurcation. The tip of the sheath is in the common femoral artery and can be recognized by a radiopaque tip. The catheter is used to direct the guidewire into the blind sac of the occluded proximal SFA. **B.** This arteriogram shows a short popliteal artery occlusion. The tip of the sheath is placed directly into the proximal popliteal artery to support the recanalization. There is a large perigenicular collateral that originates from the popliteal artery at the location where the artery occludes. Typically, the subintimal space is entered by directing the catheter tip and the guidewire to the arterial wall on the side opposite the origin of the large collateral.

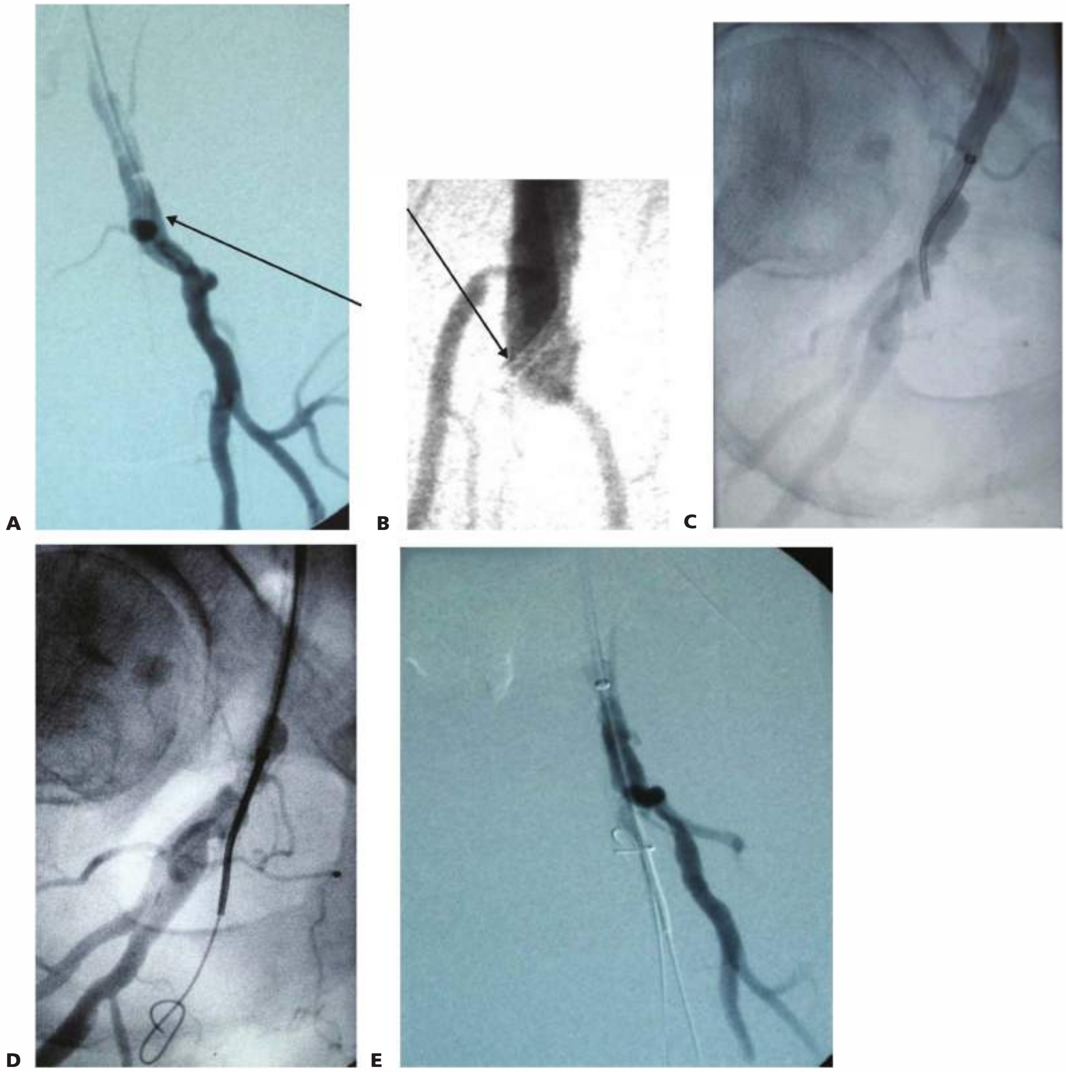

FIG 2 ● Enter the subintimal space. **A.** After sheath tip placement near the origin of the occlusion and where the administered contrast will opacify the location where the artery reconstitutes. An angled tip catheter is used *(arrow)* to direct the wire toward the superficial femoral artery origin. **B.** In the popliteal artery, the catheter is pointed to the interface between the artery and the occlusion on the side opposite the largest exiting collateral *(arrow)*. **C.** The tip of the catheter is pointed against the artery wall at the location where the occlusion starts. **D.** The hydrophilic guidewire is pushed into the wall until the tip of the wire catches and a loop forms. The loop usually forms at the transition zone along the wire between the soft, floppy tip of the hydrophilic wire and the stiffer shaft of the wire. **E.** After the wire loop is embedded within the occlusion, the supporting catheter is advanced.

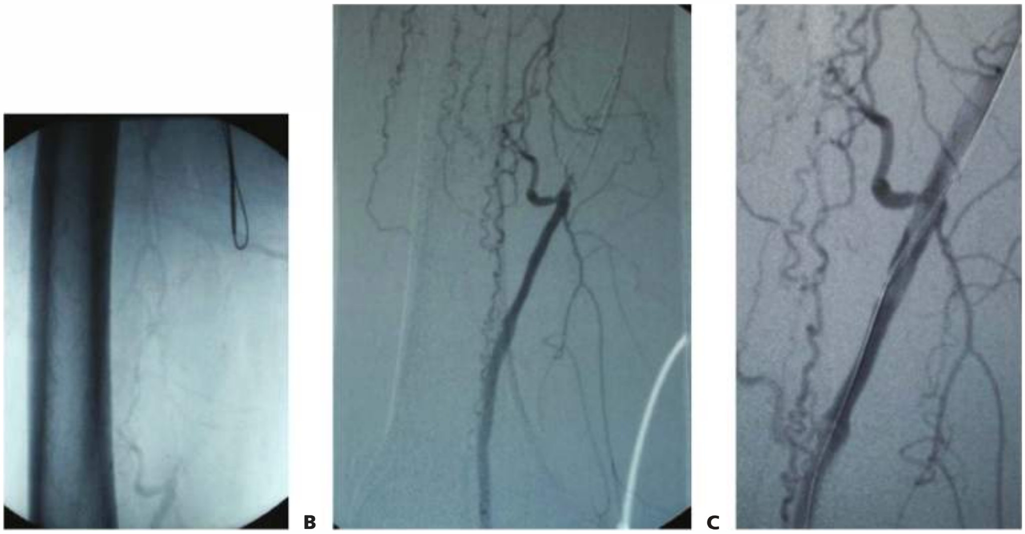
LOOP MANAGEMENT

Loop Advancement

- Visualization, loop management, and assessment of the reentry site are the maneuvers that enhance success. The looped hydrophilic wire is advanced past the lesion (FIG 3). The loop is kept narrow and is optimal if less than the diameter of the artery lumen, and this is done by closely following the loop with a supporting catheter. Because the loop is in the subintimal space, keeping the loop narrow keeps the subintimal space tight. This helps to direct the wire in a straighter trajectory toward its target and also makes the knuckle of the wire loop a more effective tool for piercing tissue to get into the true lumen.
- The standard Glidewire™ (Terumo) has a directional tip with a soft shaft. If subintimal passage is being performed past a heavily calcified lesion, the artery wall may be more adherent to the calcified segment, making



A B C

FIG 3 ● Loop advancement. **A.** After entering the subintimal space, the loop is advanced with the support of the catheter. The loop works best when it is maintained in a narrow configuration. This is enhanced by closely following the loop with the supporting catheter. If the loop encounters a heavily calcified segment, it tends to widen or to spiral around the calcific segment. **B.** The loop is advanced to the arterial segment where the true lumen is reconstituted. Quite commonly, the loop of wire will pass into the true lumen. The location where the artery reconstitutes is visualized by administering contrast into the sheath. **C.** After the loop passes into the true lumen, advance the catheter into the true lumen. Always confirm location in the true lumen before starting reconstruction. This is usually done by removing the wire and administering contrast into the catheter. The guidewire of choice for use during treatment can then be placed.

wire passage alone more difficult. Catheter support is required, and sometimes a low-profile balloon must be used to create space in the subintimal plane. Typically, a standard Glidewire™ is used, but when passing a very calcified lesion, a stiff Glidewire™ should be considered. A nylon catheter, 4 or 5 Fr, with an angled tip and a hydrophilic coating is best.

- A recent development is the availability of CTO support catheters, such as the Quick-Cross™ (Spectranetics) or the CXI™ (Cook Medical) offering more support and low profile. The loop usually seeks the weakest point in the tissue and breaks across the membrane from subintimal potential space to true lumen more than 70% of the time in our experience. Orthogonal views are helpful in assessing the trajectory of the loop and whether it is progressing toward the reentry site.
- Even if the reentry site is calcified, a wire loop or a stiff wire with catheter support may reenter the true lumen and it is worth an attempt. If this approach is unsuccessful, select a reentry catheter as the next step. This saves time and the reentry site is best for success before too much manipulation has taken place.

REENTRY DEVICE

Reentry Device Placement

- The subintimal wire is exchanged for a stiff 0.014-in guidewire.
- The reentry device is advanced.
    - If the proximal part of the subintimal space is too tight to allow passage of a 6-Fr reentry catheter (approximately 2 mm), a long, low-caliber balloon may be used to slightly enlarge the subintimal space. Do not dilate the area intended for reentry. If the subintimal space at the reentry site is enlarged, it prevents the reentry needle from having adequate support to puncture the true lumen.

Reentry into True Lumen

- After the catheter is in place, a needle in the tip of the catheter is advanced into the true lumen.
- A 0.014-in guidewire is advanced from the reentry catheter into the true lumen.
    - The direction of the needle is oriented using fluoroscopy.
    - Orthogonal views are obtained to locate the juxtaposition of the true and false lumens.
    - The image intensifier is positioned so that the catheter and an acceptable target vessel segment are viewed side-by-side.
- Rotate the catheter until the "L" shape appears at the tip.

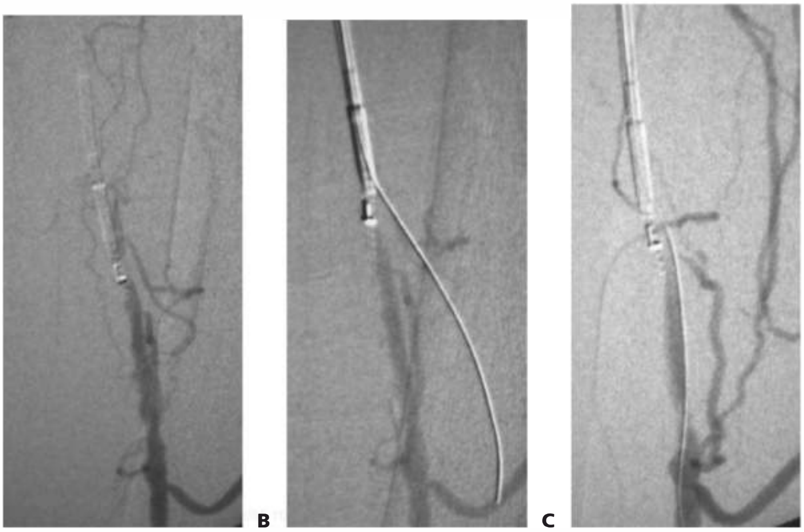


FIG 4 ● Use of a reentry catheter. **A.** If the wire loop does not pass into the true lumen, consider a reentry device. In this example, the Outback™ (Cordis) device is used. This is a 6-Fr catheter that is advanced in the subintimal space, along the same course where the channel was created by the catheter and guidewire. The reentry catheter is oriented side-by-side with the true lumen. The catheter is rotated so that the "L" shape at the tip of the reentry catheter is pointing toward the true lumen. **B.** The needle is advanced. In this case, the tip of the needle had passed beyond the true lumen and the wire is outside the artery. **C.** The needle is passed again, this time not quite so deeply, and the wire passes into the true lumen. After each throw of the needle, if it appears to be going in the correct direction into the true lumen, the wire is passed to explore and see if the tip progresses into the correct location in the true lumen.

- Advance the needle into the true lumen
  - Multiple needle passes may be required. The risk of a needle pass is low.
  - The needle may only require a partial advancement to get into the true lumen. A full advancement may go through the true lumen and into the wall on the opposite side.
  - Multiple small adjustments are often required before the true lumen is reentered, especially if the reentry site is diseased.
- The needle throw is oriented with intravascular ultrasound (IVUS) when using the Pioneer™ catheter (Medtronic). The needle is at 12 o'clock position on the IVUS image and the catheter is rotated to face the true lumen. Using color ultrasound, the true and false lumens can be distinguished and the wire passed into true lumen.
- After passing the wire, the needle is retracted and the reentry catheter is removed over the wire.
- Some commercially available reentry catheters are listed in Table 1. Reentry catheters may be guided by fluoroscopy or IVUS, and reentry is achieved by passage of a needle, stiff wire tip, or drill. Orthogonal views are obtained to locate the juxtaposition of the true and false lumens and the image intensifier is positioned so that the catheter and an acceptable target vessel segment are viewed side-by-side (FIG 4).

ALTERNATIVE REENTRY OPTIONS

Reentry Device Cannot Be Used

- Use a catheter with a stiff tip to bluntly push on the reentry site or use low-profile balloon angioplasty to break up the tissue membrane in hopes of achieving a fenestration as shown by active blood return.
- This approach is sometimes successful but it enlarges and occasionally perforates the subintimal space at the reentry site and will render the reentry catheters less efficacious because they rely on a tight subintimal space to provide leverage for the needle passage into the true lumen.
- Another option is to consider a straight 0.035-in Glidewire™ or a straight 0.014 in, or 0.018 in CTO wire and push on the location desired for reentry and see if it can be drilled into place.

Retrograde Approach

- Retrograde puncture can be performed on a distal artery, such as a tibial or pedal artery. Retrograde passage of a wire is often possible, even when antegrade passage

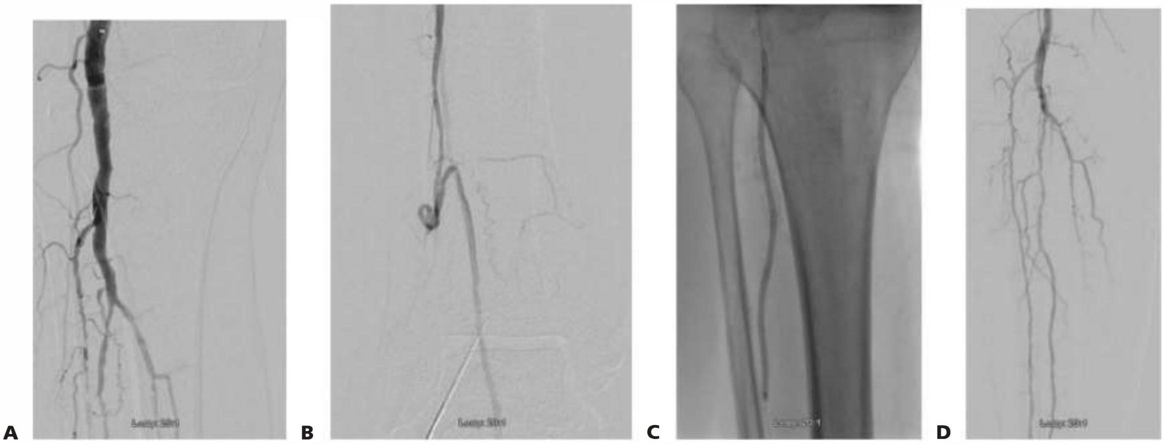

FIG 5 ● Retrograde puncture using pedal access. **A.** This patient has a pedal gangrene in an angiosome that is perfused by the anterior tibial artery. Revascularization of the anterior tibial artery using a traditional antegrade approach was not successful. **B.** A roadmap of the distal anterior tibial artery was performed. The arterial access needle is advanced into the distal anterior tibial artery under roadmapping. **C.** After retrograde access, the guidewire is passed into the antegrade sheath. The angioplasty balloon is then introduced through the antegrade sheath. **D.** After angioplasty, the anterior tibial artery is patent.

across the same lesion was not. This is especially the case for occlusions of the popliteal and proximal tibial level where there are collaterals that an antegrade wire tends to follow blindly along and where reentry devices are not as applicable.

- Contrast is administered through the proximal access to obtain a roadmap of the distal puncture site or ultrasound used to guide the access.
- A 4-cm 21-gauge micropuncture needle is used.
- A V18 wire (Boston Scientific) is introduced.
  - Sheath placement is avoided if possible to keep the arteriotomy small.
  - If the retrograde wire cannot break into the true lumen, a coronary balloon catheter is passed over it.
- A balloon introduced from the antegrade direction and the balloon introduced retrograde are juxtaposed and inflated and are usually able to split the dissection flap to open the true lumen (FIG 5).

PEARLS AND PITFALLS

Staying in true lumen	■ Shortest reconstruction ■ Preservation of most collaterals ■ May increase risk of embolization at time of recanalization
Subintimal passage	■ Intraluminal contents are excluded. ■ The subintimal space often can be converted to a smooth, large diameter conduit. Usually, the entry and reentry sites require extra angioplasty or mechanical support from implants.
Optimal reentry site	■ Minimal calcifications ■ Healthy true lumen ■ Shortest subintimal channel
Collaterals	■ Reenter as close to distal reconstitution as possible ■ Typically large incoming collateral feeding reconstituted segment ■ Subintimal space (flow channel)—no collaterals and can fail suddenly
Reentry catheters more likely	■ Calcified reentry site ■ Worse disease morphology

POSTOPERATIVE CARE

- Postoperative care involves standard care after endovascular procedures. True lumen recanalizations have collaterals, whereas subintimal passages do not. The subintimal recanalization should be monitored with duplex because they may fail suddenly in a manner similar to a bypass. We typically perform duplex surveillance every 6 months.

OUTCOMES

- Loop reentry using standard technique is successful in about 70% to 80% of cases.[1,2]
- Patients that failed loop reentry were treated with reentry catheters and approximately 80% of these were successful.[2]
- Reentry success was 90% successful in a study using the Outback™ (Cordis) reentry catheter for all-comers.[3]

COMPLICATIONS

- Complications are similar to other endovascular procedures.
- Access site complications are the most common and include bleeding, hematoma, pseudoaneurysm, and arteriovenous fistulae.
- Embolism to the runoff may be slightly more common in this patient population because it involves treatment of the most complex infrainguinal lesions.
- Perforation may also occur with greater frequency because angioplasty and manipulation in the subintimal space are key maneuvers in this procedure. However, when perforation occurs, it is only rarely clinically significant.

Percutaneous Femoral–Popliteal Reconstruction Techniques: Antegrade Approaches

F. Gallardo Pedrajas *Peter A. Schneider*

DEFINITION

- Overview: Femoral–popliteal revascularization, for indications of limb salvage or claudication, is performed using open, endovascular, or hybrid approaches. Advanced open surgical techniques are detailed elsewhere. Guidewire-catheter combinations are particularly effective and widely used to cross femoral–popliteal stenoses or occlusions. Once across, reconstructions are performed with any combination of angioplasty, stenting, stent grafting, or atherectomy.
- Basic procedural goals: Improve functional status, quality of life, and, in the setting of ischemic tissue loss, augment wound healing and limb preservation.
- Challenges influencing long-term clinical success: (1) superficial femoral and popliteal artery movement during activities of daily living, including flexion, compression, torsion, and stretching; (2) compromised runoff; (3) the generally diffuse nature of femoral–popliteal disease, requiring angioplasty of long segments of diseased and stiffened artery; (4) complex pathology, including ostial lesions, luminal thrombus accumulation, and mural calcification.
- Indications for intervention:
  - Rutherford class 1, 2, and 3 ischemia—exercise therapy and medical management are pursued as primary intervention.[1]
  - Rutherford class 4, 5, and 6 ischemia—rest pain, ischemic ulcer, and gangrene warrant revascularization as initial therapy.
- Technical approach: Utilization patterns are trending toward percutaneous-first approaches to management of Inter-Societal Consensus for the Management of Peripheral Arterial Disease (TASC II) type A, B, and C lesions.[2] Full consideration of current indications for open versus percutaneous interventions is beyond the scope of this text; reference should be made to most recent TASC updates.[3]

PATIENT HISTORY AND PHYSICAL FINDINGS

- History includes a detailed description of ischemic symptoms pertaining to claudication, rest pain, or tissue loss. The progression of symptoms and timeframe are helpful in determining the urgency of therapy.
- The presence and severity of cardiovascular disease risk factors should be assessed and managed to ensure optimal perioperative and long-term clinical results, including tobacco use, diabetes, hypertension, hyperlipidemia, renal dysfunction, and sedentary lifestyle.
- Previous vascular or endovascular surgery procedures should be reviewed in detail, including obtaining operative notes, prior imaging and surveillance studies, and prior physiologic testing results whenever possible.
- For claudicants, the potential presence and contribution of nonvascular causes of leg pain with exercise should be considered; for example, neurologic claudication secondary to lumbar radiculopathy and other degenerative spine diseases.[4]
- Physical examination should document peripheral pulses at all levels, both lower extremities, including the strength and quality of femoral pulses and skin integrity at potential access sites.
- The severity and extent of ischemia, degree of existing tissue damage, and presence of infection are documented prior to initiating intervention.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Physiologic vascular testing provides objective determination of the location and severity of disease, assists in procedural planning, and provides documentation of baseline conditions.
  - Ankle–brachial index (ABI): ratio of the continuous wave Doppler–determined blood pressure in the anterior or posterior tibial arteries (whichever is higher) to the blood pressure in the brachial artery (>0.9 = normal; 0.5 to 0.9 = usually consistent with mild to severe claudication; <0.5 = present in patients with very short distance claudication, rest pain, or tissue loss)
  - Toe pressures: The ABI may be artifactually elevated in diabetic patients with calcified tibial arteries. Toe pressures may provide more reliable assessment of pedal and forefoot perfusion when the ABI is greater than 1.2. Hallux pressure less than 50 mmHg may predict delayed or inadequate wound resolution, 50 to 80 mmHg is indeterminant, and greater than 80 mmHg is generally sufficient to promote healing.
  - Duplex arterial imaging: Direct insonation provides insight into the location and severity of disease. The ratio of the peak systolic velocities (PSV) obtained from the most compromised location divided by PSV from the most adjacent, proximal noninvolved segment provides additional guidance regarding the severity of disease; greater than or equal to 2.5:1 usually identifies a stenosis greater than 50% (**FIG 1**).
- Computed tomographic arteriography (CTA): CTA has assumed an increasing role in guiding peripheral vascular intervention, particularly in regard to choosing appropriate devices and optimal interventional approach (e.g., ipsilateral antegrade vs. contralateral retrograde). This additional guidance, however, comes at the cost of substantially more iodinated contrast and radiation exposure than that provided by catheter-directed, intraarterial contrast arteriography, augmented by direct ultrasonic visualization and physiologic testing (**FIG 2**).

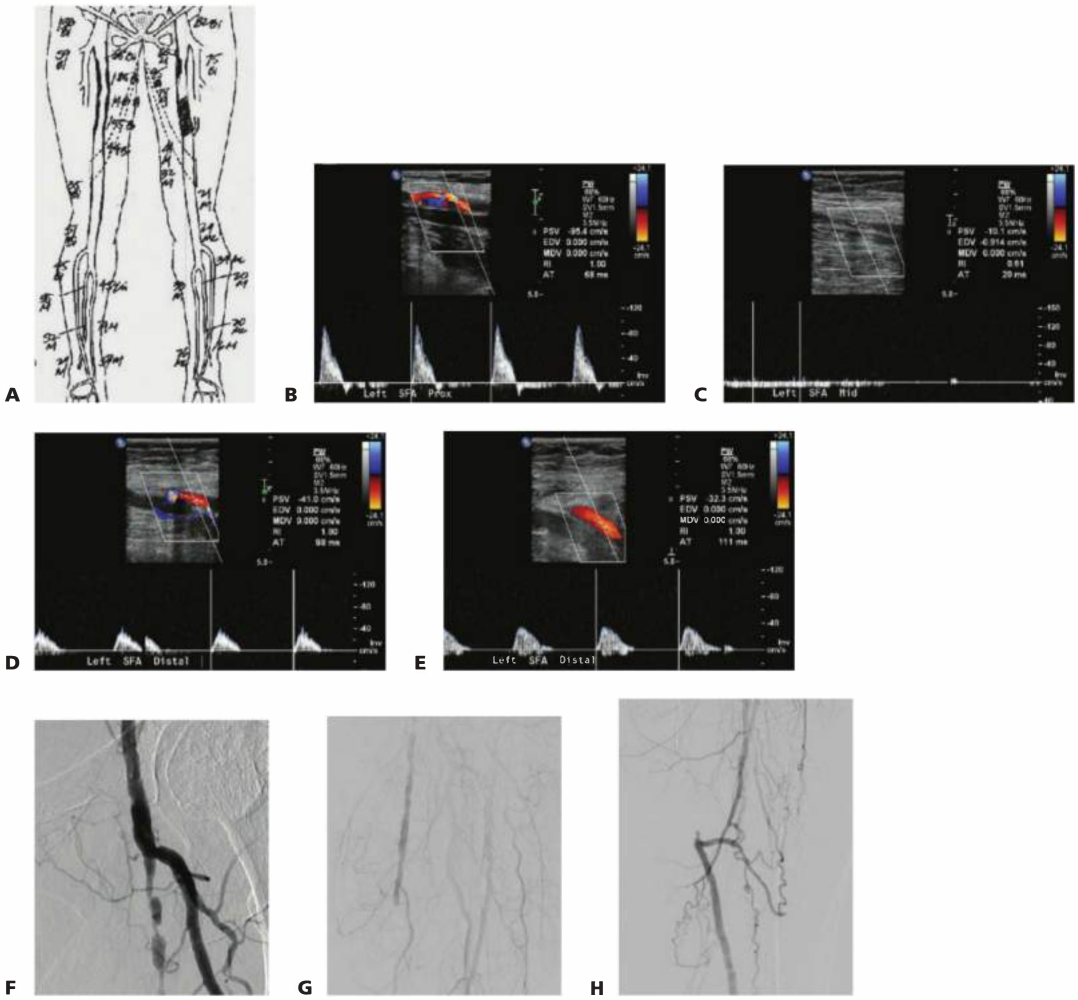

FIG 1 ● Duplex evaluation of lower extremity arteries. **A.** Duplex mapping was performed on a patient with very severe left lower extremity claudication. There is a left SFA occlusion with reconstitution of the distal SFA. **B.** Duplex image of proximal left SFA shows some plaque formation and a peak velocity of 95 cm per second. **C.** This duplex image demonstrates no flow in the occluded segment of the SFA. **D.** The left distal SFA duplex image shows the point of reconstitution of the artery with a patent distal artery and low velocity flow. **E.** The more distal SFA is a healthier artery with a reasonable lumen, but it has a low peak velocity of 32 cm per second. **F.** The arteriogram performed on the left lower extremity of this patient at the time of intervention showed a patent but diseased proximal SFA. The CFA and profunda femoris artery do not have significant occlusive disease. **G.** There is a mid-SFA occlusion as demonstrated by duplex evaluation. **H.** There is reconstitution of the left distal SFA as indicated by duplex mapping.

- Magnetic resonance arteriography (MRA): MRA may also assist preoperative planning. Although MRA does not expose patients to ionizing radiation, artifactual overestimation of disease severity is common in low flow conditions. Also, gadolinium contrast administration is contraindicated in patients with a glomerular filtration rate of less than 30 mL per minute due to risk of contrast-associated glomerulosclerosis (**FIG 3**).

SURGICAL MANAGEMENT

- Overview—Success in percutaneous management of femoral–popliteal occlusive disease has catalyzed a reciprocal decline in the use of open bypass for definitive revascularization. Key features of percutaneous management include detailed preoperative planning, choice of access site and closure techniques, and familiarity and facility with a wide range of complementary intraluminal wire-guided devices.[4]

Preoperative Planning

- The operative plan includes access site selection, planned method of crossing, and options for arterial reconstruction.
- Endovascular inventory: An essential element of endovascular success is a robust and redundant device inventory. In contrast to open reconstruction techniques, where similar instruments will suffice for all lower extremity bypass configurations, regardless of routing, a unique and task-specific

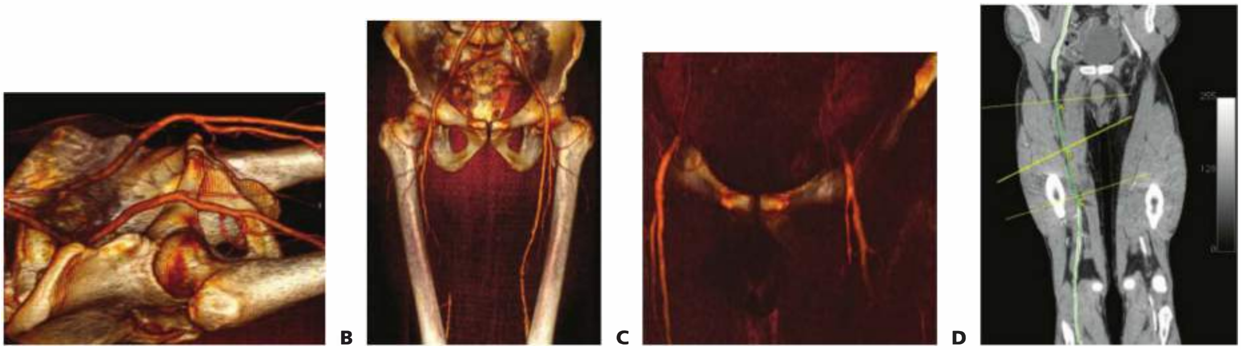

FIG 2 ● CT angiography for infrainguinal occlusive disease. Volume rendering technique. Preoperative study of puncture zones in the CFA in a patient with a long right SFA occlusion. **A.** Evaluation of iliac artery inflow. **B.** Long right SFA occlusion with reconstitution of the above-the-knee popliteal artery. **C.** CT evaluation of the CFAs and femoral bifurcations prior to access. **D.** Centerline measurements performed to measure diameters and plan for stent graft placement in the right SFA.

repertoire is required for almost every endovascular approach. Procedural success requires that the necessary devices, including guidewires, sheaths, catheters, angioplasty balloons, stents, reentry devices, stent grafts, and atherectomy catheters are identified and available before intervention is attempted.

- Appropriate radiation protection must be available for all individuals involved in interventional procedures. All team members must conscientiously wear a radiation dosimeter, submitted monthly for aggregate exposure documentation. Leadership ensures that all team members adhere to basic radiation safety tenants, including limiting the length and intensity of exposure to the minimum required for precision imaging and intervention (the "as low as reasonably achievable" [ALARA] principle). Safety principles, including distance from the radiation source, appropriate shielding and optimal table height, and source-image intensifier distance, must be understood and applied during every procedure.

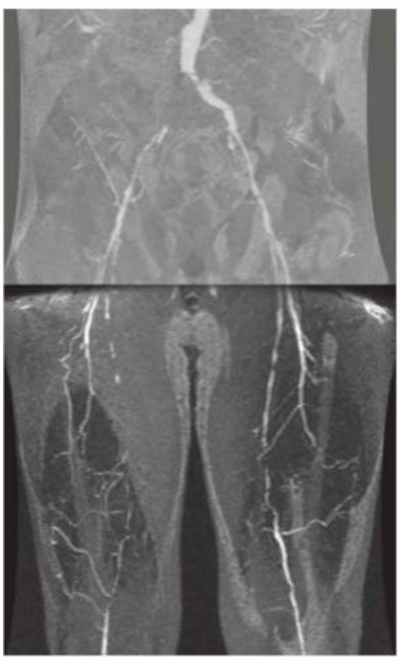

FIG 3 ● Magnetic resonance angiography as preoperative assessment of lesion location and severity. This patient has extensive iliac and femoral artery occlusive disease. Both femoral artery puncture sites are compromised. There are long lesions in both superficial femoral arteries.

- Antibiotic prophylaxis is administered prior to the initiation of the procedure, whenever permanent implants are considered.
- Percutaneous procedures are performed under local anesthesia with appropriate sedation. Care should be taken to avoid oversedation to ensure that patients can cooperate with instructions and imaging requirements during the procedure. When hybrid open endovascular procedures are contemplated, general anesthesia may facilitate more rapid and accurate device deployment, with reciprocally less radiation exposure for the patient, cath lab team, and operator.
- An important initial consideration is the approach and optimal puncture site. The common femoral artery (CFA) is the most frequent access site. The approach is typically either up and over the aortic bifurcation from the contralateral femoral artery or ipsilateral antegrade femoral puncture. The transbrachial, transthoracic approach may also provide optimal antegrade access under certain circumstances.

Positioning

- Surgeon position should provide forehand access, whenever possible (**FIG 4**).
- Retrograde femoral puncture: This is the most common type of access for all endovascular procedures, including femoral–popliteal revascularization (**FIG 5**). The needle is placed in the CFA and the guidewire is advanced retrograde into the iliac artery.
- The femoral area is examined prior to puncture of the artery. The inguinal ligament extends from the anterior superior iliac spine to the pubic tubercle. The best puncture

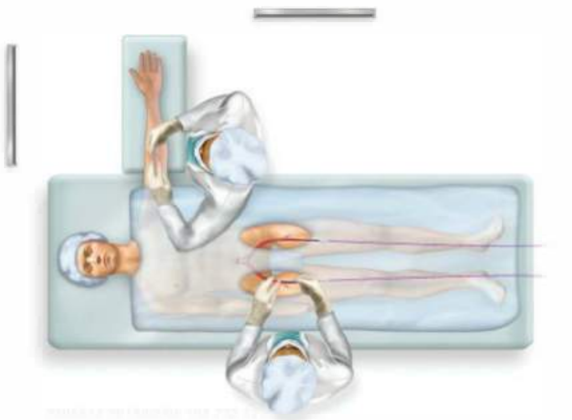

FIG 4 ● Patient positioning. The operator works forehand when possible. The right-handed operator stands on the patient's right side for a retrograde femoral puncture of either groin. The right-handed operator stands at the inferior aspect of the left arm when performing a left brachial puncture. The monitors are placed so that they can be comfortably observed by the operator.

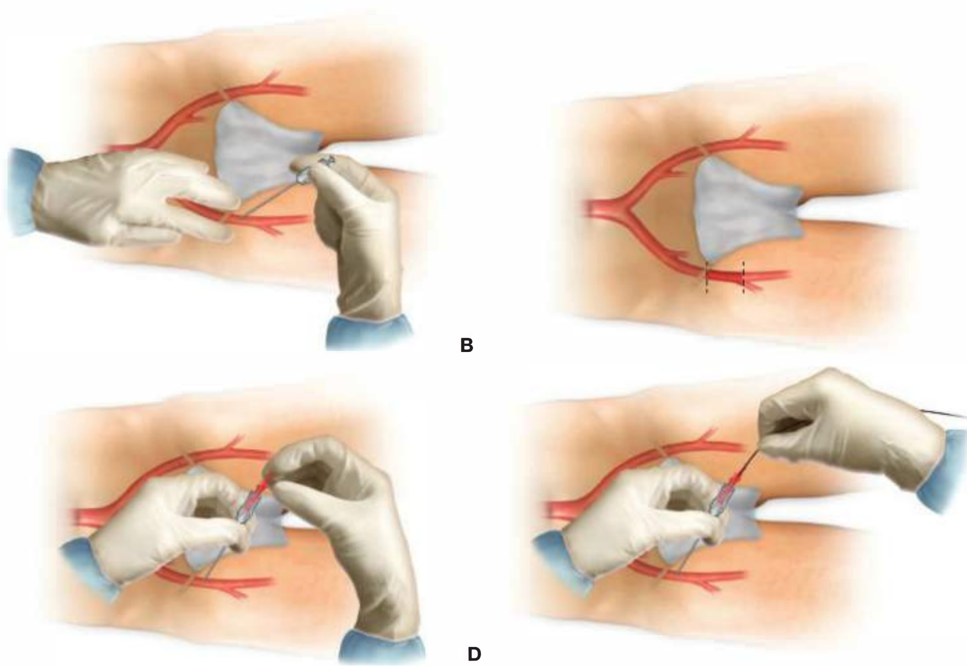
site is inferior to the inguinal ligament and at least a centimeter superior to the femoral bifurcation. Ultrasound provides useful guidance for arterial puncture (**FIG 6**). Following needle insertion, spot fluoroscopy from an ipsilateral oblique angle is obtained to confirm position. If arterial insertion is determined to be proximal to the femoral head, the access attempt is aborted before larger devices are inserted to minimize the risk of retroperitoneal hematoma formation due to inadequate compression or control following the procedure. Common femoral access also enables closure devices to be employed with confidence when necessary.

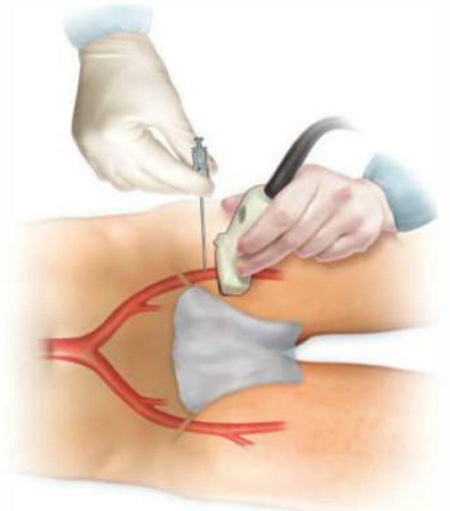
- Closure devices: recommended for retrograde femoral access site management following insertion of greater than or equal to 6-French (Fr) sheaths. Sheath puncture less than 6 Fr is best managed by compression for 10 to 15 minutes, with or without adjuncts such as a thrombin-impregnated dressing (e.g., D-stat® patch).
- When pulses are not palpable at the desired access site, ultrasound or fluoroscopic guidance (assisted by mural femoral artery calcification) may provide valuable assistance. Under these circumstances, bilateral femoral access and ipsilateral iliac intervention may be required for procedural success. Ideally, this eventuality is anticipated based on the results of preprocedural examination and physiologic testing. Fortunately, the pulseless femoral artery is often palpable based on mural calcification alone. Patience and spot fluoroscopic images to confirm needle and artery position following failed needle passes often ensures ultimate success.
- Secondary puncture of the postoperative groin presents special challenges. Whenever possible, scar tissue and anastomoses should be avoided. Access in native artery is preferable to prosthetic or autogenous grafts. Considerable force may be required for needle and micropuncture set access; consideration should be given to using "stiff" 0.018-in wires and



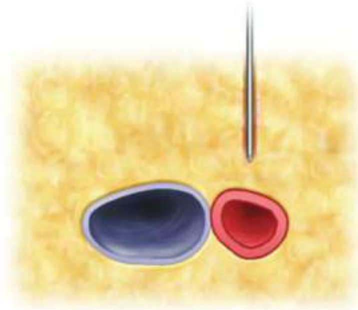
A B C D

FIG 5 ● Retrograde femoral puncture. **A.** The anatomic relationships are evaluated. The left hand may be used to help guide the needle. **B.** The access needle is placed in the CFA inferior to the inguinal ligament and superior to the femoral bifurcation. **C.** The needle is advanced into the CFA until arterial blood return is apparent. **D.** In the image a prolongation of the guide inside the retrograde femoral should be included, in order to understand that with this approach and these needle angulation the guide should never go to the SFA, or profunda artery.

A



B



C

FIG 6 ● Ultrasound-guided puncture. **A.** In this case, the operator is evaluating the left CFA using the ultrasound probe with a longitudinal orientation. The monitor is placed in a location where the operator can visualize the arterial puncture real time. **B.** In the drawing, the operator is preparing for an antegrade femoral puncture with ultrasound guidance. **C.** In this rendering of an ultrasound image that is seen during common femoral arterial puncture, the common femoral vein is typically much larger in diameter, lies side-by-side to the artery, and the vein is typically easily compressible. The entry needle can be visualized as it enters the artery to ensure the correct location of the puncture.

micropuncture sets specifically manufactured to facilitate difficult groin access.

- Antegrade femoral puncture: The femoral pulse and inguinal ligament are carefully marked (**FIG 7**). Needle placement is directed proximal to the femoral artery bifurcation under real-time ultrasound guidance.
- Guidewire placement into the superficial femoral artery (SFA) requires patience and practice. Ultrasound imaging in a longitudinal view may facilitate SFA wire intubation. When using a micropuncture set with a "steerable" 0.018-in wire (e.g., one with a slight curve placed at the tip), fluoroscopic control may also be employed. If repeated attempts result in deep femoral artery placement, the micropuncture set should be exchanged for an 11 cm 4- or 5-Fr sheath over a standard multipurpose (e.g., Bentsen) wire. Once safe antegrade deep femoral access is obtained, the 5-Fr sheath may be gradually withdrawn with sequential fluoroscopic contrast "puffs" of 1 mL or less performed until the femoral bifurcation is imaged (but while the sheath tip is still in the CFA). At this juncture, roadmapping or last-image-hold digital subtraction angiography from an ipsilateral oblique angle is performed to outline femoral bifurcation anatomy, after which a steerable hydrophilic guidewire and, ultimately, the 5-Fr sheath is directed under fluoroscopic imaging into the SFA.
- Antegrade femoral access should be avoided in the obese, in patients with a short CFA, or in patients with extreme proximal or orificial SFA disease. Although antegrade access improves "pushability" across total occlusions and enables usage of a wider inventory of guidewire-catheter combinations, there is no option for inflow disease management using this approach. Also, the safety of current generation closure device placement is uncertain in antegrade approaches and should be avoided whenever possible.
- Brachial puncture and transaortic sheath placement may provide an alternative option for "antegrade" femoral access. Upper extremity arteries are smaller, less forgiving, more prone to spasm, and less predictably managed with compression following access. Notoriously, small amounts of arterial extravasation may catalyze debilitating and permanent neurapraxia, even when brachial access is obtained well distal to the axillary fossa. Debilitating nerve injury from "axillary" sheath hematomas may occur at any location proximal to the antecubitum. In our practice, we minimize this risk by defaulting to surgical exposure and direct arterial puncture with suture closure for essentially all brachial artery access procedures. Exposure is easily obtained with local anesthetic in most patients.
- The longer guidewires and catheters required to access the femoral and popliteal arteries are also less responsive to surgeon manipulation from a brachial approach and also limit the available inventory of appropriate devices for femoral or popliteal intervention.
- When brachial access is required, the level of access is determined by the diameter of the largest sheath required

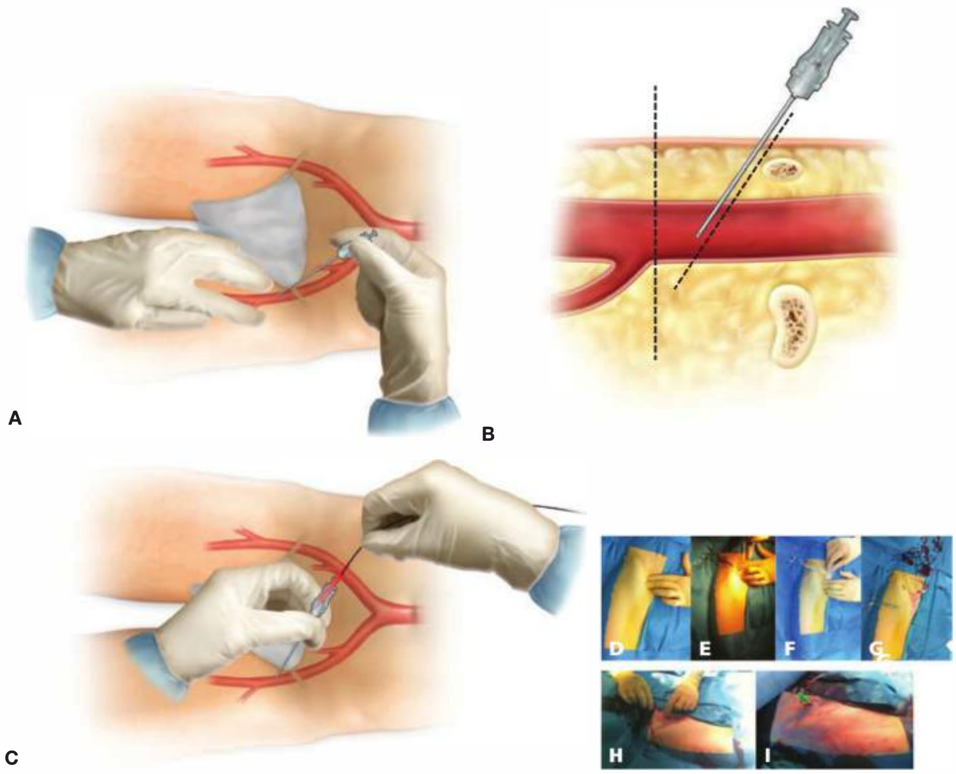


FIG 7 ● Antegrade puncture. **A.** The needle punctures the skin at the level of the inguinal ligament or just superior to that level. The angle of trajectory of the needle will permit the artery puncture to be proximal to the femoral bifurcation. **B.** The further proximal to the femoral bifurcation the artery puncture is located, the easier it is to steer the wire into the SFA. The best location for needle placement is inferior to the inguinal ligament but well proximal to the femoral bifurcation. **C.** The needle enters the CFA and when arterial return is achieved, the floppy-tip guidewire is advanced into the artery. **D.** The artery and the anatomic boundaries are palpated. **E.** A clamp is used to assist with fluoroscopic identification of the desired puncture location. **F.** The needle is placed. **G.** Arterial return is achieved. **H.** A guidewire is placed. **I.** A sheath is advanced.

to complete the procedure. For 6- or 7-Fr sheaths, the segment immediately proximal to the antecubital fossa is sufficient. For larger sheaths, access should be obtained in the distal axillary artery, proximal to the bifurcation of the deep brachial artery. The left arm should be used whenever possible to minimize risk for embolic iatrogenic stroke. During micropuncture access, even under direct vision, back-bleeding may not be pulsatile due to the smaller caliber of the brachial artery. Sheaths should be managed with frequent flushing with 100 units/mL heparin, as well as systemic anticoagulation once definitive interventional sheaths (6 to 7 Fr, 55 to 90 cm from the arm) are positioned in the target artery, or whenever sheaths appear to be occlusive. Intraarterial nitroglycerine injection may reduce arterial vasospasm to the distal extremity when necessary.

- Percutaneous femoral–popliteal revascularization techniques include balloon angioplasty alone, or self-expanding stent graft implantation as an adjunct to angioplasty. These techniques require placement of interventional-grade sheaths, braided when required to cross the aortic arch or bifurcation to prevent kinking as well as sufficient length to reach the treatment site without limiting device selection. Sheath access also permits serial angiographic imaging to guide device positioning, deployment, and confirm procedural success.

SHEATH PLACEMENT

- Ensure that the appropriate sheath is selected and that alternatives are available should plans or needs change.
- Decide on optimal sheath positioning. Usually, placement immediately adjacent to the target lesion maximizes the ability to cross the lesion, control the procedure, and minimize contrast usage. In many circumstances, it may not be possible or practical to advance the sheath past

the femoral bifurcation when approaching from the contralateral femoral artery.

Up and Over Approach

- Crossing the aortic bifurcation (**FIG 8**): Through a contralateral retrograde puncture, an infrarenal aortogram is performed to evaluate aortic bifurcation anatomy and location. Usually located at the level of the iliac crest, vascular calcifications may outline the bifurcation and guide positioning. The aortic bifurcation must be free of occlusive or aneurysmal disease to ensure safe sheath passage. Occasionally, iliac artery lesions must be treated prior to femoral intervention to ensure optimal outcome.

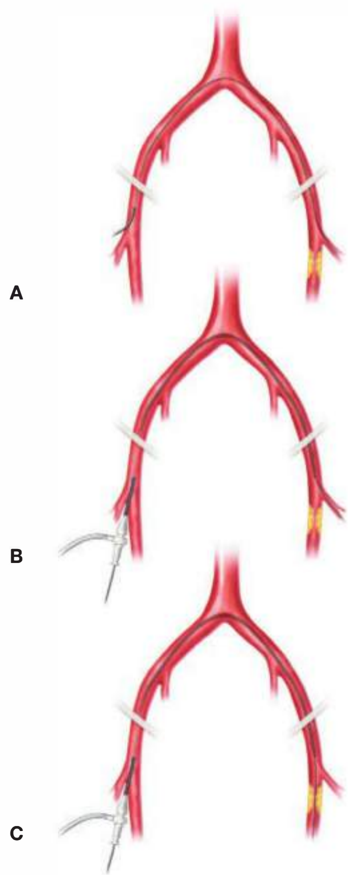

FIG 8 ● Sheath access. **A.** An exchange guidewire is placed over the aortic bifurcation. The tip of the guidewire is placed in a large, safe branch. In this example, the profunda femoris artery is used to anchor the wire. **B.** The sheath is advanced over the stiff guidewire. The advancement of the sheath is observed under fluoroscopic control to ensure that it is being passed safely. **C.** After sheath placement over the aortic bifurcation, the stiff wire is removed and the directional wire is advanced across the lesion in preparation for treatment.

- Selective catheterization of the aortic bifurcation is performed, followed by antegrade catheterization of the contralateral iliac artery system, either with the flush or pigtail catheter used for the aortogram or an exchange catheter advanced at least to the femoral bifurcation.
- The sheath tip is placed somewhere between mid-iliac artery and the mid- to distal SFA, depending on lesion location and interventional intention. A 6-Fr sheath may be adequate for this purpose, but 7 Fr may be required for many devices (read the package insert). The angioplasty catheter length for proximal SFA lesions is 75 to 80 cm; for more distal lesions, 90 to 110 cm.
- Access to the deep femoral artery may be required to safely advance the "up and over" sheath over a stiff exchange wire (e.g., Rosen®). After flushing and dilator placement, ensure that the sheath sidearm stopcock is turned to the "off" position. The skin incision may need to be enlarged to facilitate placement. Consider serial dilator exchanges when upsizing a sheath by two or more French sizes. Occasionally, depending on the angle of the aortic bifurcation, sheath placement may be facilitated by passage over a stiff, exchange length hydrophilic wire. When using hydrophilic wires for this purpose, care should always be taken to keep the tip of the wire in the image screen field to prevent inadvertent arterial puncture and extravasation from wire injury. Similarly, when confronted by extreme tortuosity in the iliac arterial system, interval advancement of the sheath into the internal iliac artery may be required to gain access to the contralateral iliac artery with a second or "buddy" wire, following which, standard catheter and guidewire techniques may be used to advance the sheath to its ultimate desired location.
- Regardless of procedure or access approach, it is always advisable to keep the wire tip in the imaging field whenever sheaths are exchanged or advanced—arterial perforation and extravasation may limit procedural options, or the ability to initiate systemic anticoagulation, and may increase compartment pressures to the point of requiring surgical release if not recognized and managed promptly.

Ipsilateral Approach

- See prior recommendations for securing access (Table 1). Obesity and excessive abdominal pannus may significantly limit the use of this approach. Before initiating treatment, obtain angiographic documentation of existing ipsilateral anatomy, including infrapopliteal runoff.
- Shorter guidewires and devices improve the efficiency of the ipsilateral antegrade approach.
- If balloon angioplasty alone is planned, 4- or 5-Fr sheath can be used to treat ipsilateral SFA lesions. More complex reconstructions require 6 Fr and occasionally 7-Fr sheaths.

Table 1: Approach: Up and Over or Ipsilateral Antegrade

Approach	Antegrade	Up and Over	Brachial
Puncture	More challenging	Simple retrograde femoral	Retrograde brachial
Catheterization	Proximal femoral puncture and selective catheters	Challenging with tortuous arteries, diseased bifurcation Easy to catheterize SFA	Challenging, long distance, diseased aorta
Catheter control	Excellent	Fair	Fair
Catheter inventory	Minimal	More supplies, long catheters Up and over sheaths	Specific material, long sheaths, catheters
Indications	Infrapopliteal, femoropopliteal disease	Proximal SFA disease	Proximal SFA, femoropopliteal disease
Limitations	Obesity, CFA disease, proximal SFA disease	Contralateral disease, bifurcation disease	Aortic disease, infrapopliteal disease

SFA, superficial femoral artery; CFA, common femoral artery.

CROSSING OCCLUSIVE LESIONS

- Guidewire-catheter skills form the basis of all endovascular procedures. Successful guidewire positioning requires familiarity with a range of devices and guidewire-catheter pairings. The guidewire required for crossing the lesion could not be adequate for working or deploying a stent or a stent graft. Familiarity with and access to a wide selection of wires (depending on length, diameter, tip pressure, and hydrophilic qualities) is essential for success (**FIG 9**).
- Guidewire features to be considered:
  - Length: Must be adequate to cover the cumulative distance, both inside and outside the patient, to perform the procedure and support the catheter. Guidewire lengths vary from 145 to 300 cm. For an ipsilateral antegrade approach, 145- to 180-cm guidewires are adequate, but for contralateral or brachial access, 260- to 300-cm lengths are necessary. As a general rule of thumb, guidewire length must be at least twice that of the coaxial device to be positioned over the wire.
  - Diameter: Most femoral–popliteal procedures are performed with 0.035-in guidewires, but smaller caliber angioplasty is generally performed with 0.018-in or 0.014-in guidewires.
  - Stiffness: An inner steel core confers different magnitudes of stiffness on the shaft of the wire. A stiffer wire may help to cross a calcified lesion, but it is

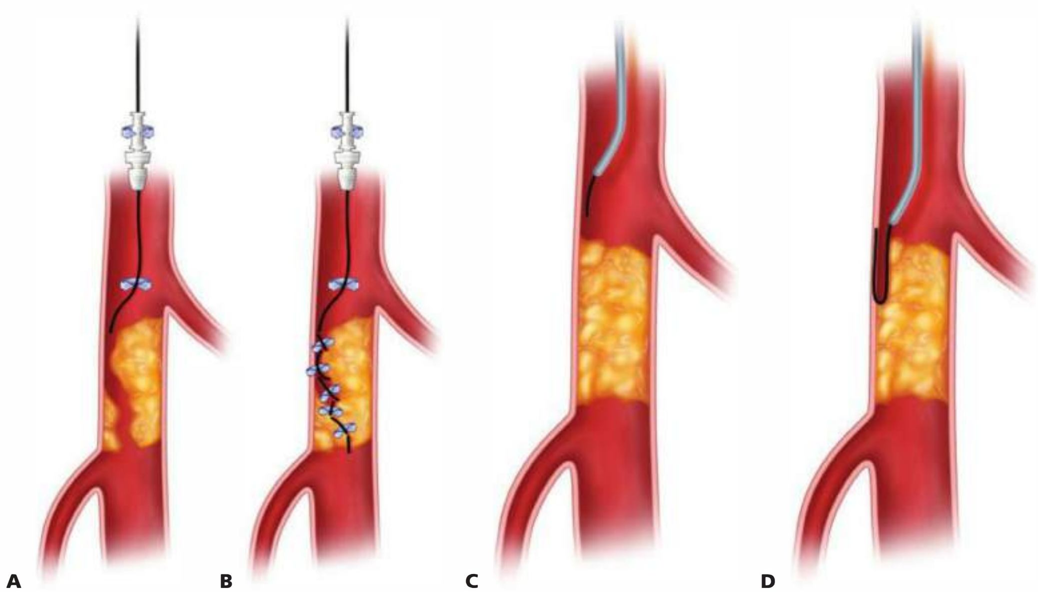

FIG 9 ● Crossing the lesion. **A.** In this case, a critical stenosis is crossed. The image intensifier is angulated to get the best view of the pathway through the lesion. **B.** Typically, a hydrophilic wire with a directional tip is used and the wire tip is steered through the lesion. **C.** In this case, an occlusion is crossed using subintimal technique. The guidewire is advanced and is supported by a catheter with an angled tip. **D.** The guidewire is pointed toward the arterial wall at the beginning of the lesion and is pointed away from the collateral that fills the segment and is near the location where the lesion begins. The wire is pushed until an elbow forms and enters the subintimal space. *(continued)*

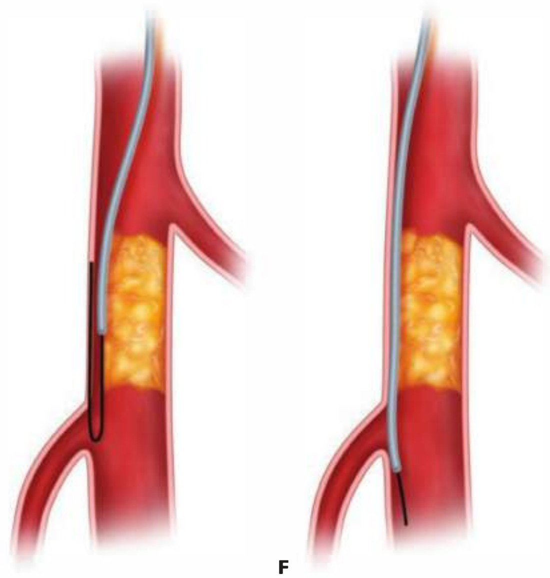

FIG 9 ● *(continued)* **E.** The loop is advanced. The loop is maintained in a narrow configuration by supporting it closely with the catheter. **F.** After the loop pops into the patent distal segment, the catheter is advanced. The wire is removed and contrast is administered to confirm the location of the catheter tip in the true lumen.

also easier to injure the vessels. In wires specifically designed to cross femoral–popliteal lesions, tip pressure may also vary across wires with similar stiffness along the majority of their length.
  - Coating: Hydrophilic guidewires may reduce the coefficient of friction. Typically, they are passed in conjunction with purpose-specific crossing catheters.
- Crossing catheters support guidewire passage and, depending on design, confer varying degrees of support and directionality. After the guidewire is used to cross the lesion, the catheter may be advanced so that the choice working wire may be placed. Crossing catheter technology has advanced considerably in the last 5 to 10 years. Options abound for torsionality (braided or unbraided), tip taper, tip shape, length, and diameter. Examples include the Quick-Cross® and CTX® catheter families. Some experience is required to learn how to use these catheters optimally in most situations.

BALLOON ANGIOPLASTY

- The angioplasty process enlarges the lumen by compressing and rupturing the plaque, as well as stretching and, in some cases, damaging the media and adventitia (**FIG 10**).
- Heparin is typically administered, 50 to 100 units/kg following sheath placement and prior to intervention.
- The balloon length and diameter are typically selected to treat the entire lesion, with minimal proximal or distal overlap, to restore original diameter as determined by proximal or distal measurement. The balloon catheter is positioned over the guidewire and inflated to nominal pressure to achieve the specified diameter. Occasionally, higher pressures may be required to reduce lesion "waisting."
- Inflate slowly. Balloon inflation is maintained for 2 minutes.
- Deflate slowly, and ensure full deflation fluoroscopically before withdrawal.
- The balloon angioplasty catheter may be used repeatedly during the same procedure; however, its capacity to recover the predeployment diameter following deflation degrades with sequential use.
- Balloon diameters range from 4 to 7 mm for the SFA and 3 to 6 mm in the popliteal artery.
- Conventional angioplasty is limited somewhat by target artery dissection. Not all dissections need further treatment. In general, only flow-limiting dissections as judged by sequential contrast injections through the interventional sheath need additional treatment. Dissections may be managed by prolonged periods of inflation followed by gradual deflation to "tack" the plaque up to the arterial wall. Persistent flow obstruction following angioplasty is the most common indication for subsequent secondary stenting.

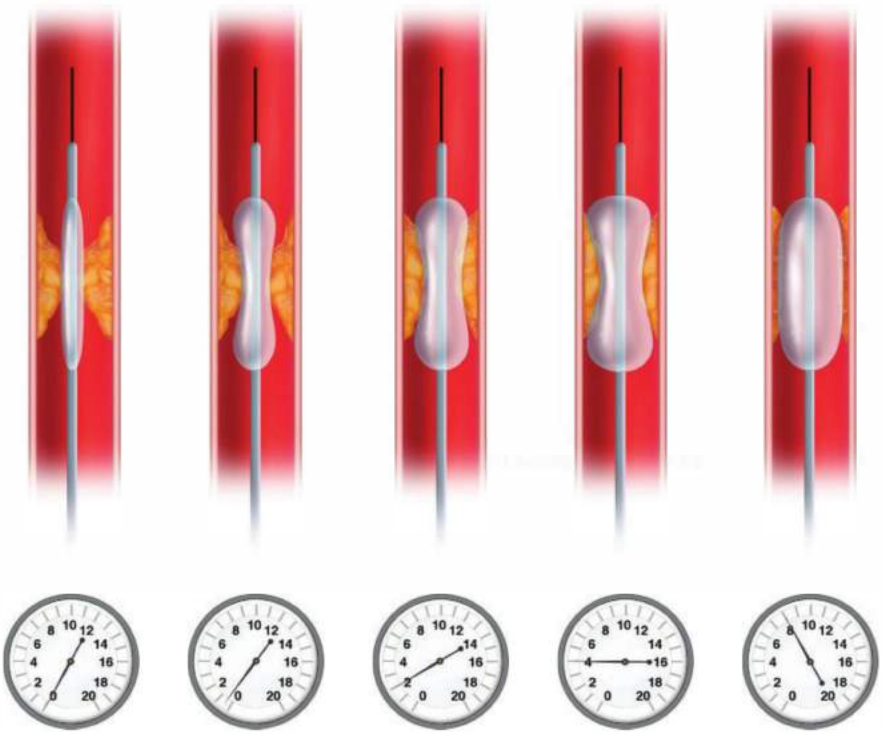

FIG 10 ● Balloon angioplasty. **A.** The balloon catheter is advanced over the guidewire and into the lesion. If possible, an angioplasty balloon is selected that is able to treat the whole lesion length with a single inflation. **B.** The balloon is inflated and this is observed using fluoroscopy. At very low pressure, the balloon will inflate freely in the locations where there is minimal or no impingement of the lesion on the balloon. **C.** Usually with 2 atm of pressure, the waist on the balloon becomes apparent and the lesion begins to yield to the outward force exerted by the balloon. **D.** The balloon is inflated gradually. This helps to avoid delivering more pressure to the artery than is required. This also allows the lesion to gradually give way. At higher pressure, the waist becomes smaller. **E.** Pressure in the balloon is gradually increased until the balloon reaches its full diameter. The balloon is typically inflated for 2 to 3 minutes in situations where the operator is hoping to use angioplasty as stand-alone therapy.

STENTS

- Although all vascular-compatible, size-appropriate, self-expanding (nitinol) stents may be deployed in the superficial femoral or popliteal arteries as clinically indicated, select devices have obtained specific indications for this application from the U.S. Food and Drug Administration. The operator is encouraged to familiarize himself or herself with this designation and to use application-approved devices whenever appropriate to ensure optimal outcome.
- Material and characteristics of peripheral stents have evolved in recent years. Self-expanding nitinol stents are most appropriate for SFA and popliteal applications. The ideal stent should have the ability to adapt to the vessel with a precise deployment and without kinking, collapsing, or fracturing as well as limit long-term arterial injury and restenosis. More recently, drug-eluting stents have been developed and are approved for use in the United States to limit chronic restenosis of the stent arterial segment following deployment. The potential clinical benefits derived from these devices are offset to a significant degree by their substantial increase in cost over "bare metal" stents.
- Femoral–popliteal stents may be placed routinely or selectively. Selective stent placement may be considered for significant postangioplasty dissection, long lesions (>15 cm), residual stenosis postangioplasty, pressure gradient (>10 mmHg) after angioplasty, recurrent stenosis, occlusion, or to prevent or limit postangioplasty embolization of plaque.
- Localization: A stent is typically deployed to span the distance between relatively healthy artery proximal and distal to the target lesion. "Healthy" is a relative term in this sense, and care should be taken to limit stent coverage to the minimal distance required to achieve an optimal result. Long lesions in the SFA are the most commonly stented segment, but be aware that stents in the distal superficial femoral and popliteal arteries may be damaged by stress from knee flexion (**FIG 11**). Excessive

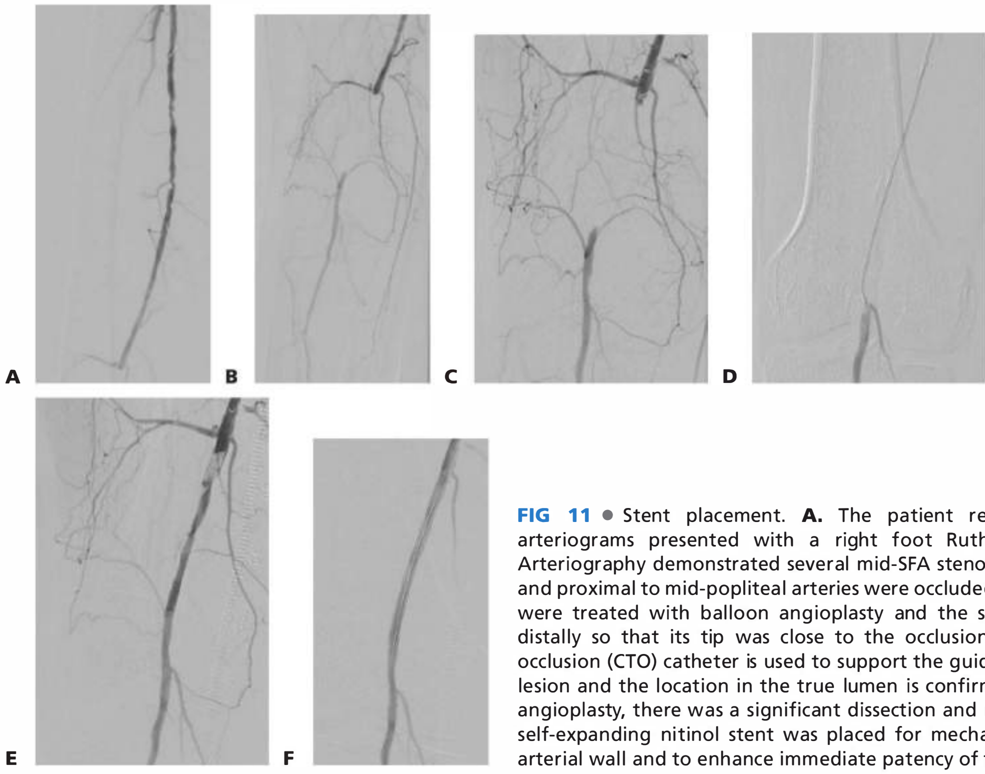

FIG 11 ● Stent placement. **A.** The patient represented by these arteriograms presented with a right foot Rutherford 5 gangrene. Arteriography demonstrated several mid-SFA stenoses. **B.** The distal SFA and proximal to mid-popliteal arteries were occluded. **C.** The SFA stenoses were treated with balloon angioplasty and the sheath was advanced distally so that its tip was close to the occlusion. **D.** A chronic total occlusion (CTO) catheter is used to support the guidewire in crossing the lesion and the location in the true lumen is confirmed. **E.** After balloon angioplasty, there was a significant dissection and residual stenosis. **F.** A self-expanding nitinol stent was placed for mechanical support of the arterial wall and to enhance immediate patency of the reconstruction.

stent coverage may accelerate long-term restenosis and luminal compromise, regardless of the degree of initial success or the type or size of deployed stent.

- Sheath size: Most stents for infrainguinal deployment require a 6- or 7-Fr sheath. Refer to the individual instructions for use for each individual device.
- Deployment: Most infrainguinal nitinol stents are deployed using a pin and pull maneuver that retracts the cover from the constrained stent and the underlying mandrel. A ratcheting mechanism may also be integrated into the deployment process. Typically, these may be removed for basic pin/pull deployment if the ratchet becomes jammed or disabled. After deployment, completion angioplasty is performed to bring the stent to profile.
- Complications of stent deployment:
  - Acute: arterial dissection, occlusion, rupture, stent migration or embolization, embolization of atherosclerotic material, thrombosis
  - Chronic: intimal hyperplasia, recurrent stenosis, infection, stent damage, thrombosis

STENT GRAFTS

- Nitinol-based, flexible stent grafts may be deployed over long and calcified SFA lesions as an alternative to bare metal or drug-eluting stents. As a general rule of thumb, the longer and more complex the target lesion(s) and length of required coverage, the more suitable the indication for covered stent placement.
- Stent grafting may require exchange of a 0.035-in wire system for smaller guidewires (e.g., 0.025 in or 0.018 in); the operator is again cautioned to refer to the instructions for use for each device considered for placement. Stent grafts must be deployed over the specific guidewire adequate for the stent graft. Sheath upsizing may also be required, depending on the diameter selected. Choosing a larger sheath at the outset will minimize the need for awkward or inefficient sheath exchange after the procedure is well underway. Aggressive predilatation is also often necessary in order to create sufficient space for bulkier covered stent to pass the lesion prior to deployment. Similar to bare metal stents, covered stent deployment is usually followed by completion angioplasty to bring the covered lumen to profile (**FIG 12**).
- Relative advantages of stent grafting, compared to bare metal stents, include the ability to create an entirely new lining for a disease arterial segment. This coverage obviates the possibility of in-stent stenosis within the graft. However, experience has shown that unlike surgically placed prosthetic bypass grafts, covered stents in the superficial femoral and popliteal arteries tend to incite restenosis at the proximal end. Thus, placement usually requires coverage up to the origin of the SFA. Any uncovered artery in this region is likely to develop critical restenosis. Disadvantages include the necessary coverage

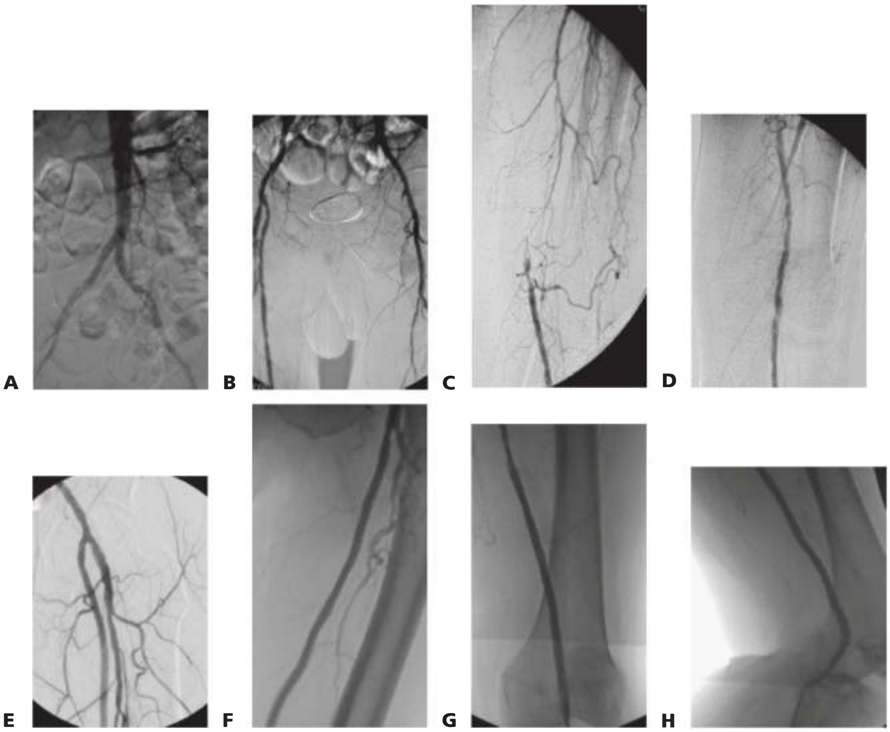

FIG 12 ● Stent graft. **A.** This patient has a long SFA occlusion that was relined with Viabahn® stent graft. An aortoiliac arteriogram was performed using contralateral access. **B.** The left SFA is occluded. There is a patent proximal stump of SFA. **C.** The point of reconstitution is the above-the-knee popliteal artery. **D.** The proximal popliteal artery, extending to the knee, is diffusely diseased. **E,F.** After recanalization and aggressive balloon angioplasty, the artery is reconstructed with Viabahn® stent graft placement. **G,H.** The distal end of the graft is fully dilated and without flow limitation in the straight leg and bent knee positions.

of all collateral vessels encompassed in the covered segment, as well as the increased risk for graft infection inherent in fabric-covered metal stents. Also, although some stent grafts are heparin-bonded, the thrombogenicity of covered stents varies directly with the length of segment covered, such that complete SFA coverage from the origin to the adductor canal necessitates long-term oral anticoagulation therapy in patients treated in our practice. Anticoagulation in this circumstance is designed to limit thrombus extension following future graft occlusion rather than increasing long-term graft patency. Anticoagulation does not typically extend prosthetic graft patency in the lower extremity, regardless of open or endovascular placement.

PEARLS AND PITFALLS

Indications	A complete vascular history is essential to accurately confirm the diagnosis. Objective evidence of ischemia is required to justify intervention and to provide a baseline for future comparison.
Artery puncture	The puncture is planned prior to the procedure. Access site issues are the most common type of complication. A well-performed access will set the procedure up for success.
Specific material	In planning the procedure, check to make sure that all the necessary inventory is available prior to the procedure.
Crossing the lesion	Do not force the wire across the lesion.
Closure	Closure devices can simplify the procedure and allow for more patient comfort and earlier discharge, but accurate CFA access should be confirmed, typically at the outset of the procedure, before therapeutic sheaths are placed.
Follow-up	The patient is evaluated after the procedure at 1 week and 1 month and then 6-month intervals after that. We typically obtain some assessment of perfusion (ABI). Duplex mapping may also be performed for surveillance.

POSTOPERATIVE CARE

- The patient should remain at bedrest for at least 6 hours after the procedure. After use of a closure device, usually 2 hours of bedrest is required.
- Puncture site management: Obtaining hemostasis is made safer and simpler when the arteriotomy site is carefully managed during the procedure. Ensure the patient is comfortable prior to removing the sheath.
- Holding pressure: After ipsilateral antegrade puncture, use two hands to hold pressure, one is placed proximal to the inguinal ligament to apply pressure over distal external iliac artery to decrease the pressure flowing through the puncture. The other hand applies pressure over the area of arterial puncture just distal to the inguinal ligament. There are no approved closure devices for antegrade puncture. Following a retrograde puncture, digital pressure is held at the location of arteriotomy, proximal to the skin puncture site.
- Closure devices: Closure devices are used whenever possible to reduce risk of access site complications and limit patient immobility following the procedure. Newer generations of closure devices are easier to use and are considered a good option for closing the arteriotomy in puncture procedures for 6 Fr and larger.
- The patient should be encouraged to
  - Avoid smoking
  - Walk daily
  - Follow best medical treatment
  - Follow-up with the vascular clinic

OUTCOMES

- Patients with peripheral artery disease (PAD) and critical limb ischemia (CLI) have a shorter life expectancy than the general population. The most effective method of revascularization that returns patients to their premorbid functional state in the shortest period of time, with the least amount of surgical risk, is considered ideal. In this regard, most centers have adopted a percutaneous-first approach to lower extremity revascularization, when intervention is indicated.[5] This rubric reserves open surgical reconstruction for patients who fail percutaneous intervention. More recently, controversy has arisen as to how many unsuccessful secondary interventions constitute "failure."
- Successful percutaneous revascularization is considered equivalent to traditional standard management strategy—that is, bypass surgery—in providing freedom from major and minor amputation, in patients with severe limb ischemia, up to 2 years following revascularization. To date, the Bypass versus Angioplasty in Severe Ischemia of the Leg (BASIL) trial remains the only randomized prospective trial comparing the success of open surgical bypass versus endovascular therapy for CLI. When life expectancy extends beyond 2 years, bypass patency is superior.[6]
- Although percutaneous transluminal angioplasty (PTA) provides superior limb salvage rate and assisted patency rates than prosthetic bypass, care should be taken to avoid outcomes that limit future bypass options (e.g., injury or occlusion of significant infrageniculate arteries that could serve as future bypass targets). Modern surgical practice should incorporate a full range of postprocedural outcomes, beyond arterial patency alone, in the assessment of procedural success. As such, consideration to postoperative ambulatory status, potential for independent living, wound care requirements, and pain management is essential and comparable to the impact on graft patency on long-term patient satisfaction and quality of life.[7]
- A comparison of self-expandable stents versus femoral–popliteal above-the-knee bypass had been published by Kedora et al., reporting similar limb salvage, with comparable primary (73.5% vs. 74.2%) and secondary patency rates (83.9% vs. 83.7%) at 1 year with both techniques.[8]
- Others studies reported that despite the reduced primary patency, limb salvage rates remain comparable to surgical bypass and range from 74% at 5 years to 84.7% at 8 years.[9]
- Lower limb revascularization of diabetic patients affected by intermittent claudication, in addition to improved walking performance, is associated with a reduction in the incidence of future major cardiovascular events when accompanied by increased physical exercise and improved glucose management and weight control.[10]

FIG 13 ● Complications. Hematoma is the more common access site complication and most common complication of endovascular procedures.

COMPLICATIONS

- Artery puncture: hematoma, occlusion, dissection, pseudoaneurysm, arteriovenous fistula (**FIG 13**)
- Failure of recanalization: intimal dissection, branch occlusion, thrombosis, embolization, vessel rupture, remote hemorrhage
- Stent/stent graft complications: stent embolization, stent will not expand lesion, stent kink, stent thrombosis
- Infection

Chapter 31 Maximizing Vein Conduit for Autogenous Bypass

Gregory J. Landry

DEFINITION

- Autogenous conduit is preferred for all lower extremity bypasses when available. The greater saphenous vein (GSV) is the most frequently used conduit. Other options for native conduit include the short saphenous vein, arm vein (basilic, cephalic, brachial), and femoral vein.

DIFFERENTIAL DIAGNOSIS

- The majority of patients for whom autogenous vein bypass is necessary will have atherosclerotic peripheral vascular disease.
- Other conditions for which autogenous vein bypass may be necessary include aneurysms (e.g., femoral, popliteal), trauma, and vasculitis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A history of cardiovascular risk factors should be elicited in all patients undergoing lower extremity bypass, including smoking history and history of cardiac and cerebrovascular disease and history of diabetes, chronic kidney disease, hyperlipidemia, and chronic obstructive pulmonary disease.
- Upper and lower extremity pulse exam should be performed. Because atherosclerosis is a systemic disorder, the following pulses should be assessed bilaterally: carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial. Both the presence and strength of pulses should be recorded.
- If lower extremity pulses are absent, which is usually the case in patients undergoing surgery for peripheral vascular disease, ankle–brachial indices should be measured. The highest ankle pressure is divided by the highest brachial pressure.
- Lower extremities should be evaluated for the presence of ulcerations or gangrene.
- A history of prior vein use or removal should be elicited. Veins may have previously been used for prior lower extremity or coronary artery bypass. Patients with varicose veins may have undergone prior vein stripping or ablation. Patients with chronic kidney disease may have had prior upper extremity arteriovenous fistula placement. In dialysis-dependent patients, upper extremity veins should be used judiciously as they may be necessary for future arteriovenous access.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- All patients considered for lower extremity bypass should undergo arteriography to define the proximal (inflow) and distal (outflow) targets.
  - Digital subtraction angiography remains the gold standard and provides the greatest anatomic detail for operative planning.
  - Alternative imaging modalities include computed tomography (CT) and magnetic resonance (MR) angiography or duplex ultrasonography.
- Duplex ultrasonography should be used for preoperative vein mapping to identify suitable autogenous conduit (**FIG 1**). If the patient has good-quality GSV, no further vein mapping is typically necessary. If the GSV is of poor quality or absent, small saphenous vein and arm vein should be mapped (**FIG 2**).
  - Ideal conduit diameter is 3.5 mm or greater.
  - Vein should be easily compressible. Thick-walled or noncompressible vein indicates prior superficial venous thrombosis and vein is likely not suitable for bypass.
  - Mapping should ideally immediately precede surgery with vein course marked with an indelible marker on the skin. This allows precise placement of incisions, which avoids the creation of skin and tissue flaps that might impede wound healing.

SURGICAL MANAGEMENT

- Preoperative planning
  - If not previously marked or if marks have faded, it is useful to remark the intended venous conduit with ultrasound guidance prior to surgery (**FIGS 3 and 4**).
  - Open foot lesions or gangrene should be covered with sterile adhesive to prevent contamination of sterile incisions.
  - Prophylactic intravenous antibiotics should be administered to reduce risk of perioperative infection.

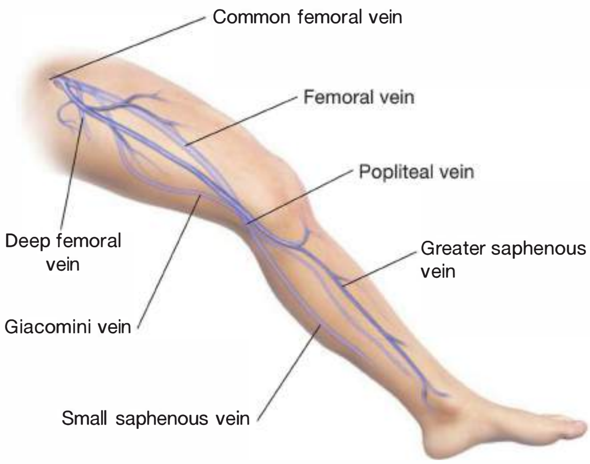

FIG 1 ● Lower extremity venous anatomy.

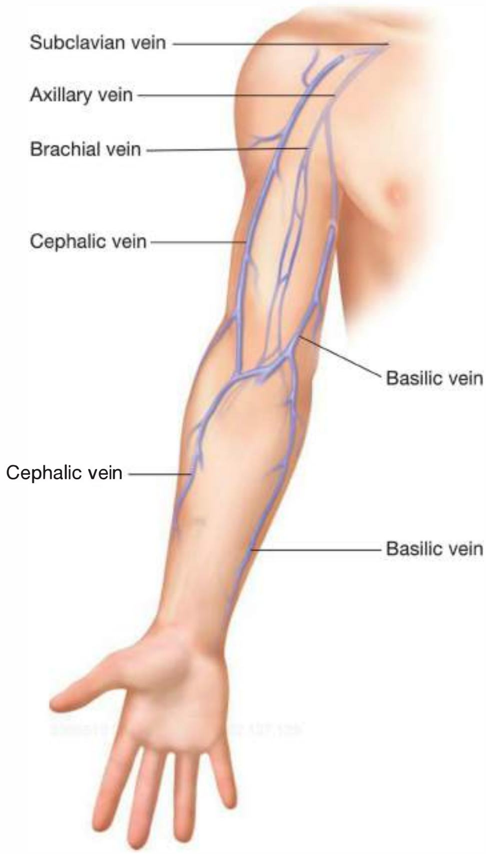

FIG 2 ● Upper extremity venous anatomy.

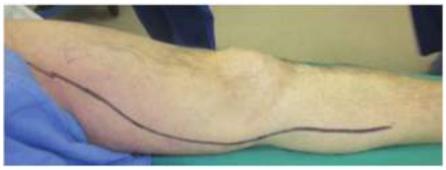

FIG 3 ● Lower extremity vein mapping with marking of GSV.

- If arm vein is to be harvested, it is important to avoid blood draws or intravenous lines in the intended arm(s). If veins from both arms are necessary, central venous access may be necessary.
- Positioning
  - The majority of the procedures are performed with the patient supine. If small saphenous vein is the intended conduit, it is often easier to perform this part of the procedure with the patient prone and then to reprepare and drape with the patient supine.
  - If arm vein is to be harvested, the arms should be abducted and placed on arm boards.

FIG 4 ● Upper extremity vein mapping with marking of the cephalic and basilic veins.

- Open vein harvest: GSV
  - A longitudinal incision is made directly over the marked vein. Either a single incision or multiple skip incisions can be used, with some evidence of fewer wound infections with the latter approach (FIG 5).
  - The necessary length of vein is unroofed. Using blunt and sharp dissection with Metzenbaum scissors, the vein is freed from surrounding structures. Side branches are ligated and divided with silk ligatures and hemoclips.
  - The GSV is divided proximally at the saphenofemoral junction (FIG 6), distally according to the length of vein needed.
  - It is helpful distally to identify a branch point in the vein that can subsequently be used for the proximal anastomosis if the graft is placed in reversed configuration (FIG 7A,B).
- Open vein harvest: small saphenous vein
  - The same technique is used as for the GSV, except typically with the patient prone.
  - Proximally, the vein is typically divided at the saphenopopliteal junction. Some patients will have continuation of the small saphenous vein in the thigh (Giacomini vein) which allows harvesting additional length of vein in the thigh.

FIG 5 ● Open GSV harvest through skip incisions. The vein is encircled with silastic vessel loops.

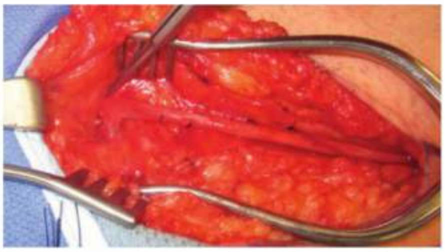

FIG 6 ● GSV mobilized proximally to saphenofemoral junction. Side branches ligated with silk ligatures.

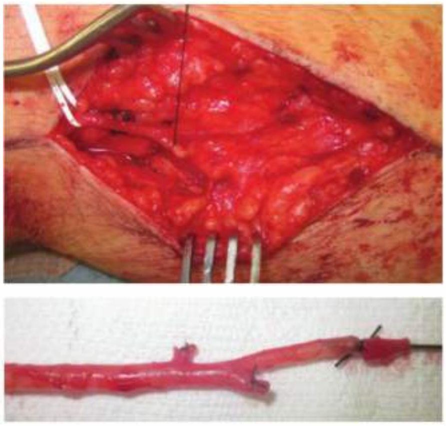

A

B

FIG 7 ● **A,B.** Distal GSV divided at branch point to provide starting spot for proximal anastomosis of reversed vein graft.

- Open vein harvest: arm vein
  - Both the cephalic and basilic veins can be harvested through longitudinal arm incisions. The same technique is used as for leg vein; however, care must be taken as the arm veins tend to be more thin walled and fragile than leg vein.
  - The cephalic vein can frequently be harvested as a single conduit from the wrist to the deltopectoral groove (**FIG 8A–C**). A single segment is frequently adequate for a femoral–popliteal or femoral to proximal tibial bypass.
  - The basilic vein tends to be larger in diameter than the cephalic vein, although often, only a short segment in the upper arm is available. The basilic vein is well suited for use as an extension graft when revision of a previously placed bypass is necessary. When used as a new bypass, a composite graft composed of two or more vein segments is frequently necessary.
  - The basilic vein often has large branches that communicate medially with the brachial vein. These branches are often broad based and are better ligated with a running monofilament suture than simple ligation.
  - The median antebrachial cutaneous nerve frequently interdigitates with the basilic vein. With meticulous dissection, this nerve can be preserved (**FIG 9**).
  - Brachial vein is intimately associated with both the brachial artery and median nerve. This vein can also be harvested as conduit, but great care needs to be taken to avoid injury to adjacent structures (**FIG 10**).
- Open harvest: femoral vein
  - Although typically used for larger vessel reconstruction, femoral vein can be used for autogenous lower extremity bypass if necessary.
  - Proximal femoral vein is harvested medial to Sartorius muscle. Vein is adjacent to superficial femoral artery. Vein can be harvested proximally up to the profunda femoral vein.
  - Distally, the femoral vein is easier to harvest with the Sartorius muscle reflected posteriorly. The vein can easily be harvested as far as the adductor canal.
  - If a longer segment is needed, the vein can be further harvested caudal to the adductor tendon into the popliteal fossa.
- Endoscopic harvest: GSV
  - Endoscopic harvest works best for veins within the saphenous fascial envelope (**FIG 11A**). It is technically more difficult in cases where the vein leaves this fascial envelope and is situated more

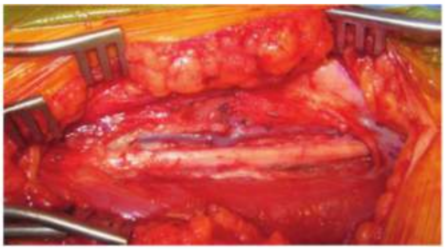

FIG 10 ● Brachial vein harvest with vein adjacent to median nerve. Brachial artery deep to nerve.

superficially or in the subcutaneous fatty tissue (**FIG 11B**).

- Available harvesting systems are described in Table 1.
- A 2-cm incision is made at the level of the knee and the GSV dissected free at this site and encircled with a silastic vessel loop (**FIG 12**).
- The vein is dissected from the knee to the saphenofemoral junction using a conical dissecting tip (**FIG 13**). CO_2 insufflation is performed through an inflatable trocar.
- The vein is held in place with the C-ring or V-lock mechanism and side branches are divided with bipolar electrocautery or harmonic scissors depending on the manufacturer (**FIG 14**).
- Harvesting can also be performed in the calf; however, this is more technically challenging due to multiple geniculate venous branches, subcutaneous position of vein, and close approximation with saphenous nerve.
- If an incision in the groin is going to be made for the proximal anastomosis of the graft, the incision can be made at this point to complete the proximal harvest. If an incision is not going to be made in the groin, a stab incision is made in the groin and the vein grasped under direct vision with a tonsil clamp.

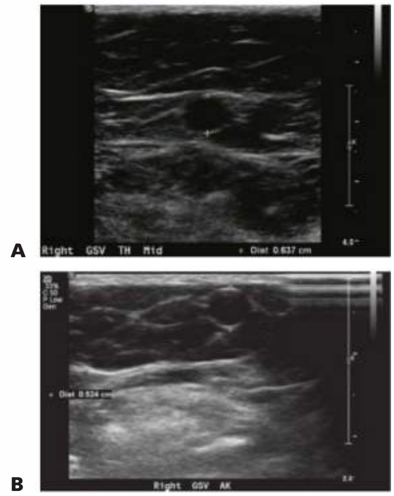

FIG 11 ● **A.** GSV (marked by *cursors*) within the saphenous fascial envelope suitable for endoscopic vein harvest. **B.** Subcutaneous GSV outside of saphenous fascial envelope, less suitable for endoscopic harvest.

FIG 12 ● A 2-cm incision at the level of the knee through which GSV (encircled with silastic loop) dissected for endoscopic harvest.

FIG 13 ● Conical dissecting tool mounted on camera used to isolate GSV. Operator standing opposite screen depicting endoscopic image.

Table 1: Endoscopic Vein Harvesting Systems

Manufacturer	Device	Dissecting Tool	Vein Securing	Side Branch Ligation
Maquet	Vasoview	Conical tip	C-ring	Bipolar ligating forceps
Maquet	Vasoview Hemopro	Conical tip	C-ring	Thermostatic cut and seal
Terumo	VirtuoSaph	Conical tip	V-lock	Bipolar cut and coagulation

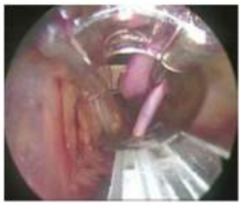

FIG 14 ● GSV held in plastic cradle while side branch ligated and divided with bipolar electrocautery.

The vein is then pulled through the incision and ligated and divided with silk ligatures.

- After proximal division, the vein can be pulled out of the tunnel through the knee incision.
- A below-knee incision can be made to harvest the distal vein if this incision is already intended for the distal anastomotic site.

- Back-table vein preparation
  - Harvested veins are prepared on a back table (**FIG 15**). Veins are distended with the surgeon's solution of choice. The author prefers using chilled, heparinized autologous blood, although heparinized saline is also sufficient.
  - Any side branches not ligated during the initial harvest are ligated with silk ligatures or, if too small or short, with 7-0 polypropylene suture.
  - For endoscopically harvested veins, because the side branches are not ligated during the initial harvest, they are ligated at a back table with silk ligatures or 7-0 polypropylene suture after vein removal.

FIG 15 ● Back-table preparation of harvested vein.

- Composite graft creation
  - A venovenostomy can be performed with two (or more) venous segments to create a single conduit of adequate length. The vein of larger diameter should be placed proximally. The veins are spatulated and sewn end-to-end with running 7-0 polypropylene suture (**FIG 16A–E**). Additional vein segments can be added as necessary with the same technique to create a conduit of adequate length.
- Graft tunneling
  - Grafts are best tunneled using a hollow tube tunneler, such as a Scanlan tunneler, in order to avoid unnecessary tension on the vein as it is pulled through the subcutaneous tissue. This is particularly important in a composite graft where suture line disruption can potentially occur.
  - Tunneling performed after the proximal anastomosis allows the graft to be passed under pressure,

FIG 17 ● Anatomic tunnel through popliteal fossa for femoral to below-knee popliteal artery bypass.

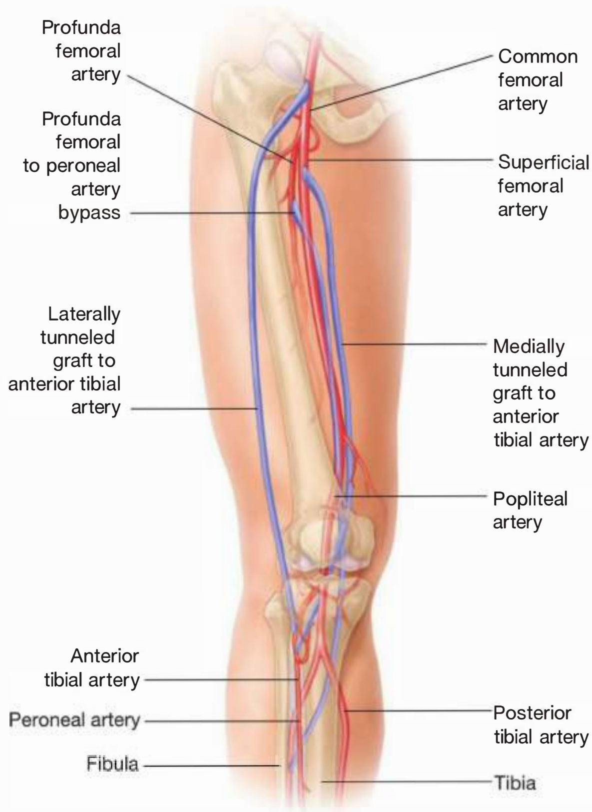

FIG 18 ● Diagram depicting tunneling options for tibial grafts.

which lessens the likelihood of twisting or kinking during tunneling.

- In a first-time bypass, tunneling anatomically through the popliteal fossa for below-knee targets provides the most direct route to maximize vein length (**FIG 17**). In redo procedures in which previous grafts were tunneled through the popliteal fossa, a subcutaneously tunneled graft may be necessary.
- Two options exist for grafts tunneled to the anterior tibial artery. For grafts based on the common femoral artery, a lateral, subcutaneously tunneled graft is the most straightforward. For grafts based further distally on the superficial femoral or profunda femoral arteries, an anatomic tunnel through the popliteal fossa and interosseous membrane is more direct and maximizes vein length. The interosseous membrane should be directly visualized and a cruciate incision made to prevent graft stricture. Grafts to the posterior tibial or peroneal artery are tunneled either through the popliteal fossa or medially and subcutaneously (**FIG 18**).

- Choice of proximal anastomotic site
  - The choice of proximal anastomotic site depends on the anatomy and vein length and quality.
    - If adequate vein length is present, an anastomosis to the common femoral artery is generally preferred.
    - If vein length is insufficient, the graft can be based on either the superficial or profunda femoral artery. For patients with atherosclerotic lower extremity arterial occlusive disease, the profunda femoral artery is more likely to be better preserved than the superficial femoral artery, which is more likely to be affected by atherosclerosis (**FIG 19A,B**).
    - In the presence of common femoral or proximal profunda femoral artery stenosis, a common and/or profunda femoral endarterectomy with placement of a vein or prosthetic patch (Linton patch) can provide adequate inflow for the graft, with the proximal anastomosis to the distal end of the patch (**FIG 20**).
    - In patients with patent superficial femoral arteries and more distal tibial artery disease, as is often seen in patients with diabetes, grafts may be based on either the above- or below-knee popliteal artery.
    - For patients requiring tibial or pedal bypasses with insufficient vein length, the superficial femoral artery can be treated with angioplasty with or without stenting to provide inflow for a graft based on the above- or below-knee popliteal artery. This is ideally performed either in a hybrid operating room (OR) suite or in a standard OR with C-arm fluoroscopy.
- Choice of distal anastomotic site
  - In general, the shortest bypass configuration that provides adequate distal flow is chosen.
    - If direct runoff to the foot can be achieved through a bypass to the popliteal artery, this is preferred.
    - If the popliteal artery is occluded and a tibial artery serves as the distal target, a direct angiosome revascularization should be chosen if possible in cases of foot ulcers or ischemia. For rest pain or claudication, the dominant tibial vessel should be chosen.
- Proximal anastomosis
  - Proximal and distal arterial control is obtained with atraumatic vascular clamps, silastic loops, or Fogarty catheters as needed and per surgeon's choice.

Note tunneling device in subsartorial position.

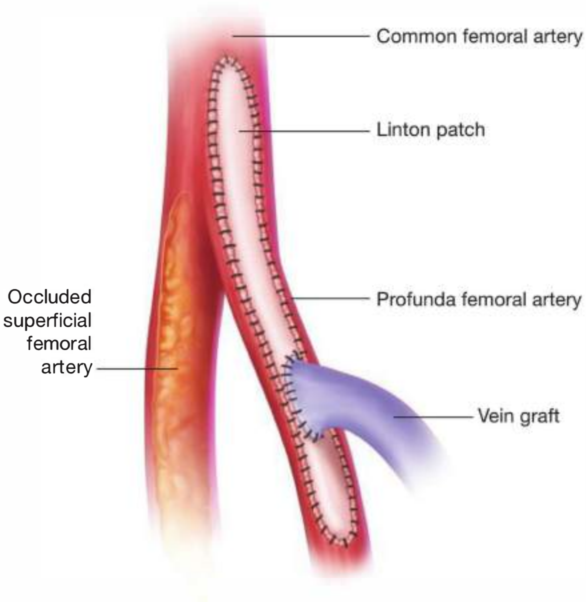

FIG 20 ● Diagram of Linton patch on common and profunda femoral arteries from which proximal anastomosis of bypass is based.

    - The anastomotic arteriotomy is made with a no. 11 scalpel and extended with Potts scissors. The arteriotomy length should be about 1.5 to 2 times the diameter of the vein.
    - The proximal anastomosis is ideally performed using a vein branch as the heel in order to avoid heel stricture (FIG 21). The vein is spatulated through the heel (FIG 22A–C).
    - The anastomosis is performed with running polypropylene rule. As a rule of thumb, suture diameter is 4-0 in the iliac artery, 5-0 femoral, 6-0 popliteal, and 7-0 tibial (FIG 23).
- Distal anastomosis
    - This is performed in similar fashion to the proximal anastomosis, although spatulation through a side branch is generally not possible and less necessary as for the proximal anastomosis, because the graft toe geometry is more important for patency than the heel geometry in the outflow (FIG 24).
- Intraoperative assessment
    - Augmentation of Doppler signals at the ankle with the graft open compared to the graft occluded generally indicates graft patency with improved arterial perfusion. Intraoperative duplex or arteriography should also be considered to rule out technical problems with the graft.

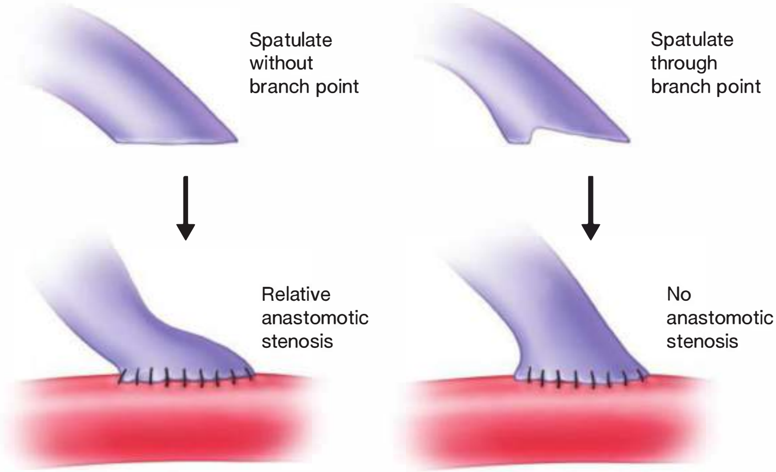

FIG 21 ● The vein is spatulated through a branch point to avoid a stricture at the heel of the proximal anastomosis, which can occur if a side branch is not used.

PEARLS AND PITFALLS

Open vein harvest	■ Preoperative vein mapping is important to localize the site of the incision to avoid tissue flaps that can lead to poor wound healing. ■ Vein branches should not be ligated flush with the vein as "dimpling" can occur when the vein is distended. It is good to ligate the vein branch at least 1 mm away from the vein to allow proper vein expansion (**FIG 25**). ■ Arm veins tend to be more fragile than leg veins, requiring gentler handling during harvest.
Endoscopic vein harvest	■ Avoid harvesting veins that are subcutaneous or not enclosed within a fascial envelope as these are technically more difficult to harvest and therefore more prone to injury.
Vein preparation	■ Avoid overdistending the vein during preparation. A good technique is to inject a small amount of fluid into the vein and then manually distending the vein in segments rather than trying to inflate the vein with the syringe.
Graft tunneling	■ Passing the graft while distended reduces the risk of twisting or kinking. ■ Using a sterile marking pen, a line can be drawn on the anterior surface of the vein to help orient the graft distally and prevent twisting.
Anastomotic placement	■ Severely diseased vessels tend to delaminate when handled. Great care must be taken to include all layers in the anastomosis to prevent dissection. ■ In severely calcified vessels, vessel loops may not provide adequate control and vascular clamps may cause a crush injury. In these cases, Fogarty balloons may be needed for arterial control.

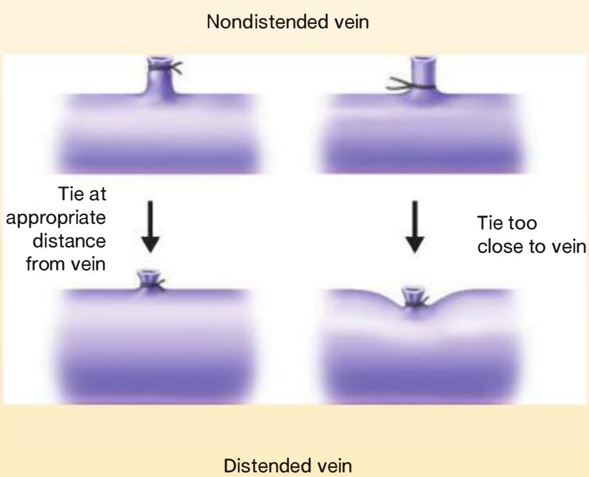

FIG 25 ● "Dimpling" can occur with graft distention if side branch tie is too close to vein.

POSTOPERATIVE CARE

- Patients should be monitored postoperatively in either an intensive care unit or a surgical ward. Hourly vascular checks should be performed with continuous wave Doppler.
- Early ambulation, generally on the first postoperative day, is encouraged, particularly in patients with claudication or rest pain. Patients with ulcers or gangrene may require a longer period of non–weight bearing if lesions are on a weight-bearing surface.

OUTCOMES

- Anticipated 3-year primary patency rates for reversed saphenous vein grafts are 70% to 80% for femoral–popliteal and 60% to 75% for femoral–tibial. Comparable patency rates for arm vein bypasses are 60% to 70% and 50% to 60%, respectively, and for prosthetic grafts, 45% to 65% and 20% to 30%, respectively. Anticipated 5-year limb salvage in patients with critical limb ischemia is 80% to 90%, with 5-year survival in 40% to 70%.[1–5]
- Reversed and in situ vein grafts have been shown to have comparable patency rates in multiple studies.[6]
- Ambulatory function and independent living status is preserved in the majority of patients who undergo successful revascularization.
- Quality of life measures are improved in the majority of patients who undergo successful revascularization.[7]
- Up to 20% of patients will develop vein graft stenoses requiring either open or endovascular revision during follow-up.
- Data on patency rates of open versus endoscopically harvested vein grafts are mixed, making definitive recommendations on the preferred approach difficult.

COMPLICATIONS

- Wound infection
- Seroma
- Hematoma
- Graft occlusion
- Myocardial infarction

Chapter **32**

Tibial Interventions: Tibial-Specific Angioplasty Considerations and Retrograde Approaches

Georges E. Al Khoury   Rabih A. Chaer

DEFINITION

- Endovascular tibial intervention is a minimally invasive, endoluminal revascularization of the infrapopliteal vessels. It is an accepted treatment of critical limb ischemia (CLI) in patients with tibial occlusive disease. It is usually performed from a transfemoral access (antegrade approach) and, in selected cases, from transpedal or tibial access (retrograde approach).
- Therapeutic interventions performed in tibial arteries include balloon angioplasty, drug-eluting balloon angioplasty, stenting, and atherectomy.
- Procedures are most commonly performed under local anesthesia with moderate conscious sedation in a fixed-imaging hybrid operating room or in the interventional angiography suite. Portable imaging systems may also provide sufficient resolution for precise, image-guided intervention depending on circumstances.

FIG 1 ● **A.** Patient with tibial occlusive disease and ischemic right first toe ulceration. Rutherford class 5. **B.** Patient with severe multilevel occlusive disease with gangrene of the left first toe and ulcerations on the dorsum of the foot. Rutherford class 6.

DIFFERENTIAL DIAGNOSIS

- Neuropathic pain is commonly described as burning sensation, stabbing, or aching pain that is commonly accompanied by numbness or hypoesthesia. Diabetic neuropathy is probably most common and is frequently nocturnal as well. The symptom complex of diabetic neuropathy may be confused with ischemic rest pain or metatarsalgia, given the similar dermatomal distribution and overlapping risk factors.
- Venous ulcers are associated with skin pigmentation, induration from chronic venous hypertension, and inflammation. They develop primarily in the perimalleolar region of the ankle and usually do not involve the forefoot.
- Musculoskeletal pain resulting from mechanical etiology, stress fracture, arthritis, and plantar fasciitis
- Soft tissue infection and malperforans ulcers in diabetic patients with advanced sensory neuropathy and/or Charcot deformity of the foot
- Chronic, nondiabetic peripheral neuropathies such as dorsal foot paresthesias and dysesthesias following long saphenous vein harvest

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with infrainguinal occlusive disease present with symptoms of claudication (Rutherford ischemia classification categories 1, 2, and 3), ischemic rest pain, or tissue loss (Rutherford categories 4, 5, and 6). When the atherosclerotic disease is limited to the infrapopliteal arterial segments, pain is mainly located in the forefoot. Advanced arterial insufficiency can also lead to ischemic ulceration, gangrenous changes, and nonhealing wounds. This constellation of symptoms represents CLI and typically occurs when the ankle pressure is less than 50 mmHg, the ankle–brachial index (ABI) is less than 0.4, and the great toe pressure is less than 30 mmHg (**FIG 1A,B**).
- CLI with tissue loss often occurs in the setting of multilevel arterial occlusive disease. In the case of isolated diabetic tibial occlusive disease, femoral, and frequently popliteal, pulses remain palpable. In either circumstance, limb-threatening ischemia may ensue. In the latter circumstance, multilevel approaches to complete revascularization, either staged or simultaneous, should be pursued.
- Neurovascular exam, with particular focus on the wound location and the extent of tissue loss, should be evaluated and documented. Probably, the most deterministic variable is the extent of tissue loss—Wagner wound classification, the presence and severity of osteomyelitis, exposure or involvement of the calcaneus bone, residual intact skin on either the dorsal or plantar foot. These conditions all impact decision making and clinical outcome.
- Patient functional capacity also plays an important role in the therapeutic strategy. Options and outcome goals vary substantially between ambulatory and nonambulatory patients.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Pulse volume recordings (PVRs) (**FIG 2**)
- Duplex (**FIG 3**)

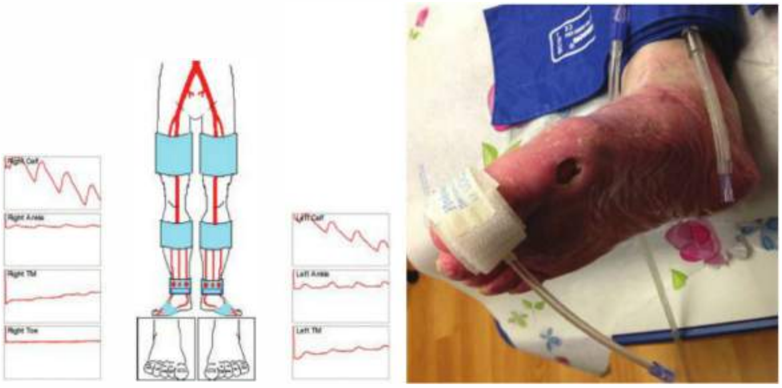

FIG 2 ● PVR on a patient with severe right tibial occlusive disease and nonhealing toe ulcer. The tracings are pulsatile at the calf level consistent with adequate femoropopliteal flow; however, the waveforms are flat, distally suggestive of tibial occlusive disease.

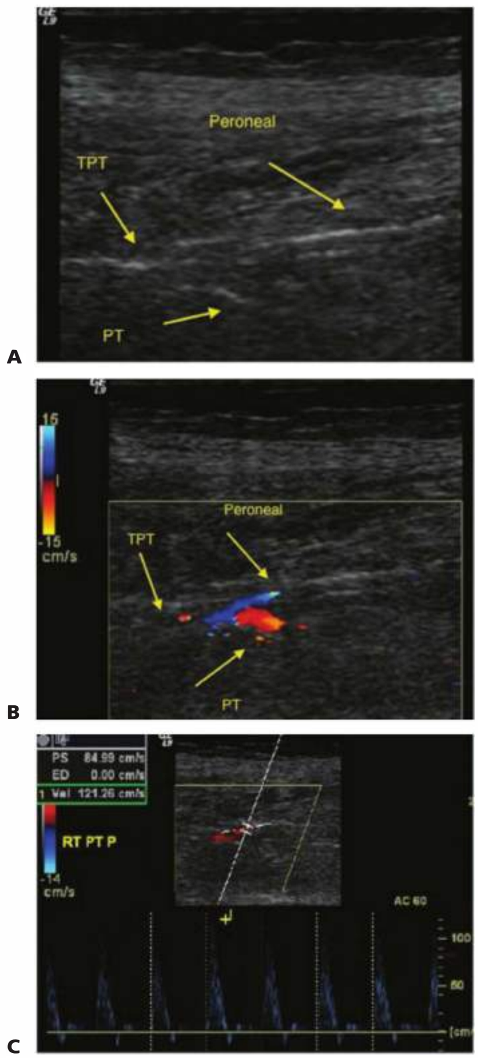

FIG 3 ● **A.** Duplex B-mode image shows the calcified tibioperoneal trunk bifurcation into the posterior tibial artery and peroneal artery. **B.** Duplex of the tibioperoneal trunk bifurcation shows flow into the posterior tibial artery. **C.** Duplex of the proximal posterior tibial artery shows normal triphasic Doppler waveform.

- Computed tomography (CT) and magnetic resonance (MR) angiograms can be obtained; however, their diagnostic use in planning tibial interventions is frequently limited by the imprecision of bolus timing with distal extremity cross-sectional imaging techniques, heavy medial calcification frequently present in target arteries, and the diminutive size of reconstituted target arteries, which may be present in the peri- and inframalleolar regions.
- Catheter-directed, intraarterial angiography remains the gold standard imaging study for tibial occlusive disease for both diagnostic and therapeutic purposes (**FIG 4**).

SURGICAL MANAGEMENT

- Technical skills, careful planning, and knowledge of the relevant arterial anatomy determine tibial revascularization strategies for limb salvage. Current controversies include the potential value of restoring patency in more than one tibial vessel to optimize blood flow and maximize the chances of

FIG 4 ● Selective left leg angiogram shows patent popliteal artery, patent tibioperoneal trunk, complete occlusion of the anterior tibial artery, and complete occlusion of the peroneal artery.

wound healing. Proponents of this approach reference the "angiosome" concept of the foot or the idea that specific skin regions derive primary perfusion from end-arterioles arising primarily from either the dorsal pedal or posterior tibial arteries as they cross the ankle. This practice is pursued in marked contradistinction to the open surgical imperative to restore in-line flow to the foot in the single largest, most continuous crural artery. The many advantages of endovascular reconstruction techniques in tibial reconstruction include restoring partial flow in multiple target arteries as compared to a single artery following surgical bypass, as well as opportunities to repeat procedures with relatively simple outpatient interventions as needed, to maintain patency and skin integrity. Treatment decisions regarding revascularization strategy in individual circumstances should be guided by patient-specific anatomic considerations, arterial runoff into the foot, patient habitus and ambulatory status as well as patency and feasibility considerations related to either open or endovascular options.

- Currently available endovascular technology facilitates successful treatment of complex occlusive lesions at and below the malleolar level. Technical limitations remain, however, highlighted by risks of arterial perforation (**FIG 5**), difficulty in true lumen reentry in complete occlusions (**FIG 6**), procedure-related distal arterial embolization, and limited pedal vessel outflow in certain circumstance.
- The retrograde or SAFARI (SubintimAl Flossing with Antegrade-Retrograde Intervention) tibial intervention technique may improve technical results in challenging lesions, particularly those resistant to ipsilateral antegrade access, including flush occlusions at the origin of the target artery or with large collateral arteries adjacent to the occluded origin. In nearly every circumstance, even chronic and recalcitrant occlusions may be crossed more easily from the retrograde rather than antegrade approach; this is true regardless of the chronicity of the lesion in question, degree of calcification, or length of occlusion.

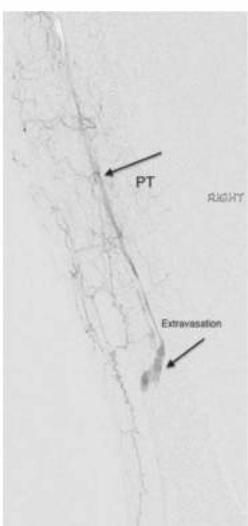

FIG 5 ● Angiogram shows extravasation from distal posterior tibial artery in an attempt to cross a total occlusion with a catheter and wire.

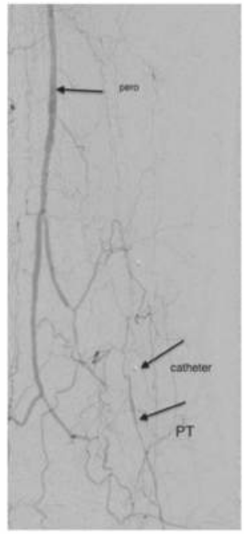

FIG 6 ● Angiogram from sheath shows the catheter in the subintimal plane after recanalization of posterior tibial (PT) with reconstitution of distal PT away from the catheter.

Preoperative Planning

- Preoperative vein mapping prior to the diagnostic angiogram is helpful in handicapping potential surgical alternatives and determining the extent to which interventional alternatives to be pursued.
- Patients should be medically optimized prior to their procedure: Preventive strategies are advised to reduce the risk of kidney injury in patients at risk for contrast nephropathy; smoking cessation is encouraged as well as antiplatelet and statin therapy.
- Tibial interventions can entail significant radiation exposure. Protective shields, lead glasses, and judicious use of fluoroscopy are recommended to protect all participants in the procedure. Ultrasound-guided access can minimize radiation exposure, particularly for pedal access; needle extenders allow the operator to puncture remotely and minimize hand exposure.
- Micropuncture and pedal access kits are essential access tools.
- Sheaths: 5 and 6 Fr, braided, 90 cm or 110 cm from contralateral femoral access; 45- to 55-cm sheath from the ipsilateral transfemoral access
- Wires: 300-cm, 0.014-in or 0.018-in wires; 260-cm, 0.035-in floppy Glidewire™
- Catheters: 150- to 170-cm catheters and balloons
- Medications: heparin (or other anticoagulant), clopidogrel, nitroglycerin, papaverine, alteplase, and calcium channel blockers. Consider preprocedural perioperative antibiotics prior to procedures potentially requiring prosthetic implants.

Positioning

- The patient is placed supine on the angiographic table with both groins prepped and draped. Consider preparing the foot and the leg in anticipation for retrograde approach if needed. Stockinette can be placed over the involved foot and the leg is covered with the angiographic drape (**FIG 7**).

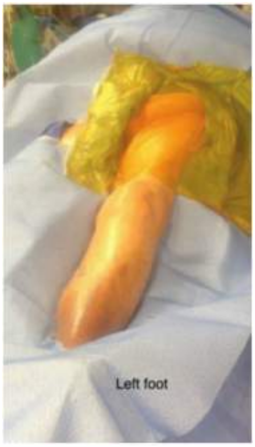

FIG 7 ● Patient is placed in the supine position on the angiographic table; the groins and lower extremity are prepped and draped in anticipation of antegrade and retrograde approaches.

ANTEGRADE TIBIAL REVASCULARIZATION

First Step: Femoral Access and Anticoagulation

- Contralateral femoral access with standard up and over technique is our routine approach for diagnostic arteriograms and most tibial interventions.
- Antegrade femoral approach has distinct advantages for tibial or pedal interventions, especially in the setting of a hostile and narrow aortic bifurcation or occluded or severely diseased contralateral iliofemoral system. Antegrade access generally provides easier pushability and reduced radiation to the patient and procedural team.
- Ultrasound-guided access may minimize risk for access site complications.
- Diagnostic arteriogram to image the inflow is performed.
- A 5- or 6-Fr sheath is advanced over a stiff wire to the popliteal artery, positioned as close as possible to the tibial trifurcation. (Sheath: 90 to 110 cm from the contralateral femoral access and 45 to 55 cm from the ipsilateral femoral access) (**FIG 8**).
- Sheath tip positioning close to the target vessel maximizes pushability across total occlusions. Also, improved visualization of tibial vessels is achieved with reduced contrast volumes.
- Anticoagulation is established using unfractionated heparin or other alternatives to achieve an activated clotting time (ACT) of more than 250 seconds.

FIG 8 ● After obtaining femoral access, the sheath is advanced to the popliteal artery for the intervention. It allows better visualization of the tibial vessels and facilitates the pushability and the ability to cross total occlusions.

Second Step: Selective Angiogram

- Imaging of the tibial outflow is obtained from sheath injections or through diagnostic catheters (5- to 10-mL power or hand injection). To reduce contrast load, contrast may be diluted 50% for all but the most distal arterial beds.
- Anteroposterior or ipsilateral anterior oblique projections are obtained to visualize the popliteal "trifurcation" and separate the tibia and fibula. True lateral oblique projections are obtained to visualize pedal outflow.
- Arteriographic images must be carefully examined to optimize outcome; multiple projections may be required to sufficiently opacify tibial and pedal vascular anatomy, especially distal to extended or serial occlusions. Delayed views (prolonged digital subtraction angiography [DSA] time) may improve opacification of patent tibial or pedal vessels distal to occluded segments (**FIG 9**). Withdrawing the sheath to the femoral bifurcation may uncover reconstitution of distal tibial artery segments through extended deep femoral artery collateral pathways.

Third Step: Crossing the Occlusion

- Angled catheters and guidewires are typically used to select the respective tibial arteries.
- The catheter/guidewire combination is advanced into the target tibial artery proximal to the occlusion or stenosis.
- Anatomy is confirmed with magnified arteriographic views.

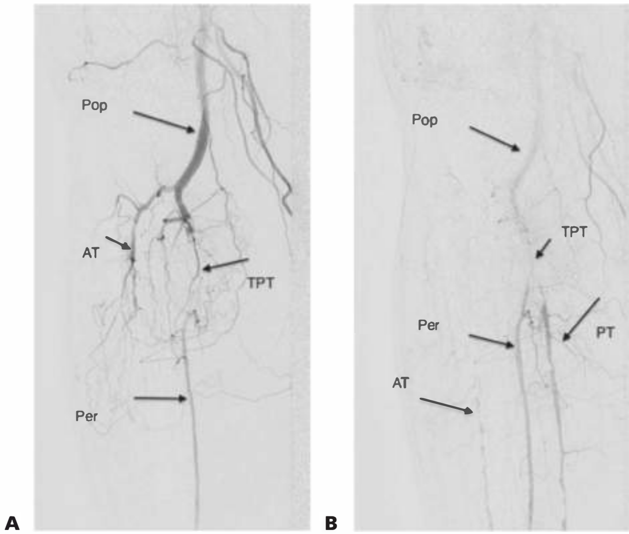

FIG 9 ● **A.** Diagnostic angiogram from the popliteal sheath demonstrates patent right popliteal artery, occluded anterior tibial artery, and occluded distal tibioperoneal trunk with reconstitution of peroneal artery. The posterior tibial artery appears to be occluded. **B.** Angiogram with delayed DSA time identifies a patent diseased posterior tibial artery distal to the occluded tibioperoneal trunk and patent peroneal artery.

- "Road mapping" may improve guidance across occlusions. The wire leads through the occlusion, followed by the crossing catheter (e.g., Quick-Cross™ or Cook CXI™, 0.014 in or 0.018 in) (**FIG 10**).
- Transluminal passage is preferred to subintimal access, because reentry into the true lumen may be unpredictable and challenging.
- Soft-tipped hydrophilic guidewires are used to negotiate and traverse tibial stenosis with the support of crossing catheters under magnified road map guidance.
- Heavier weighted tip, chronic total occlusions (CTO) guidewires (either 0.014-in or 0.018-in platforms) are designed to provide improved performance and penetration across total occlusions.
- For longer occlusions, leading with a 2-mm percutaneous transluminal angioplasty (PTA) balloon as an alternative to low-profile crossing catheters (e.g., Quick-Cross™ or CXI™) can improve access by extending or reestablishing the recanalization plane during transit.

Fourth Step: Reentry into the True Lumen

- Reenter into the true lumen under road map guidance (**FIG 11**).
- Advance the catheter over the wire into the true lumen beyond the target lesion and remove the wire.
- Aspirate to check for back-bleeding and subsequently perform a selective angiogram through the catheter to confirm the proper intraluminal position (**FIG 12**).

FIG 10 ● Recanalization of occluded PT. Under road map guidance, the PT was selected, and using a wire and support catheter, the occlusion was crossed.

FIG 11 ● Angiogram from catheter in PT during recanalization of occluded PT.

FIG 12 ● Angiogram from catheter in the plantar artery to confirm the proper intraluminal position after recanalization of PT.

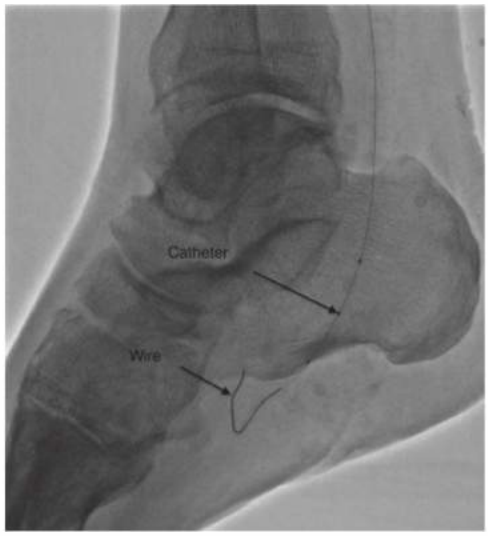

FIG 13 ● Placement of wire into the plantar artery prior to angioplasty of the occluded PT.

- Advance a stiff wire with long, soft tip into the target vessel as distal as possible (**FIG 13**).
- Remove the catheter carefully under fluoroscopic guidance while maintaining wire access into the distal patent artery.
- Reentry devices can be used to select the true lumen from a dissection plane. Alternatively, if failure to reenter the true lumen persists despite the use of reentry devices or balloon angioplasty to disrupt the dissection membrane, access into the distal true lumen can be reattempted in a staged future setting.

Fifth Step: Treatment with Balloon Angioplasty

- The proximal and distal ends of the lesion are demarcated by a repeat contrast injection through the sheath. The use of radiopaque adhesive rulers applied on the affected leg may help with measurement and device selection.
- Deliver the appropriate size balloon (typically 2 to 3.5 mm in diameter) to the target lesion and perform the balloon angioplasty for 2- to 3-minute inflation time (**FIG 14**).

A B

FIG 14 ● **A.** Balloon angioplasty of distal PT with 2-mm balloon for 2-minute inflation time. **B.** Balloon angioplasty of PT with 3-mm balloon for 2-minute inflation time.

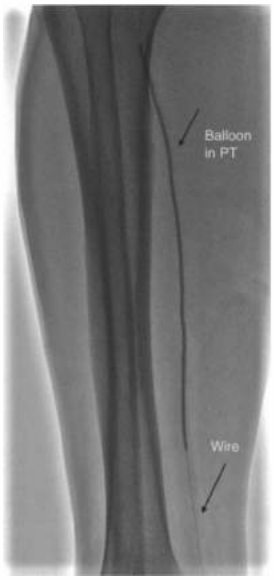

FIG 15 ● Angioplasty of PT with long balloon.

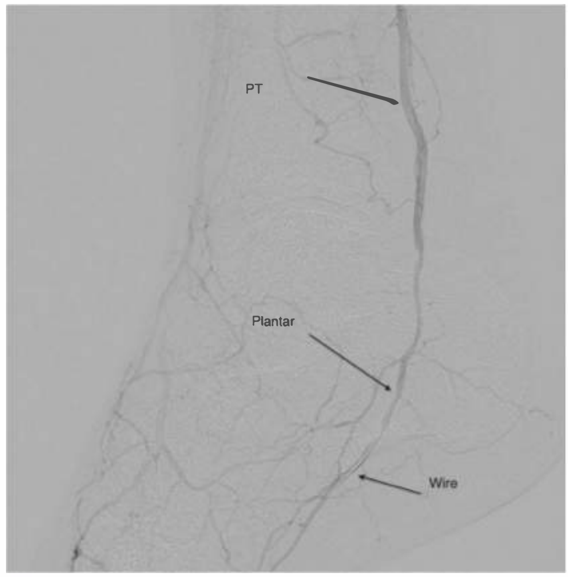

FIG 16 ● Angiogram from sheath postrecanalization and angioplasty of PT shows good flow without any flow-limiting dissection.

- Single inflation using a long balloon decreases the procedural time and reduces the risk of postangioplasty dissection requiring reintervention (FIG 15). Tapered balloons can help treat lesions across vessels of variable size.
- Heparin flush, continuous or intermittent, through the sheath is recommended during balloon inflation and throughout the procedure.
- Selective injection of intraarterial nitroglycerin through the sheath will minimize the effects of spasm at or distal to the intervention.

Sixth Step: Angiogram Post–Balloon Angioplasty

- The treatment balloon is retracted back over the wire to the popliteal artery level.
- The completion arteriogram is performed from a sheath injection to assess the angioplasty outcome and pedal runoff (FIG 16).
- Recoil or dissections are treated with sustained reinflation of the balloon for 3 to 5 minutes or by upsizing the balloon, followed by more gradual deflation.
- Flow-limiting dissections in the proximal tibioperoneal trunk and proximal tibial arteries may be resolved with stent placement when necessary.
- Distal embolization can be managed by aspiration through the existing catheter or aspiration with a purpose-specific catheter such as the Export™.
- Other modalities may be useful in restoring patency, such as atherectomy devices and can be used as stand-alone therapy or as adjuncts to balloon angioplasty.
- The routine use of tibial stenting is not advocated at this stage. Although there is some evidence to suggest that drug-eluting stents may result in improved durability, these are subject to cost restrictions, regulatory approvals, and availability depending on the country of practice.

Seventh Step: Reconstruction of Another Tibial Vessel

- The ultimate goal is to reestablish direct, in-line arterial flow to the ischemic part of the foot. A secondary goal is to optimize flow by reconstructing more than one occluded tibial artery, when possible.
- The wire is redirected into another tibial vessel and recanalization is performed as described earlier (FIG 17).
- When the peroneal artery is the sole outflow vessel, revascularization to the level of the peroneal collaterals at ankle is needed.
- Ostial lesions at the bifurcation of anterior tibial artery and tibioperoneal trunk can be treated with kissing balloon technique to prevent plaque shifting.

Eighth Step: Completion Angiogram and Hemostasis

- If the completion angiography is satisfactory (FIG 18), the sheath is pulled back to the common femoral artery and injection from that level is recommended to rule out any complications in the femoropopliteal segment related to sheath position.
- The sheath is removed and hemostasis is obtained at the access site either by using closure device or manual compression without heparin reversal unless necessary.

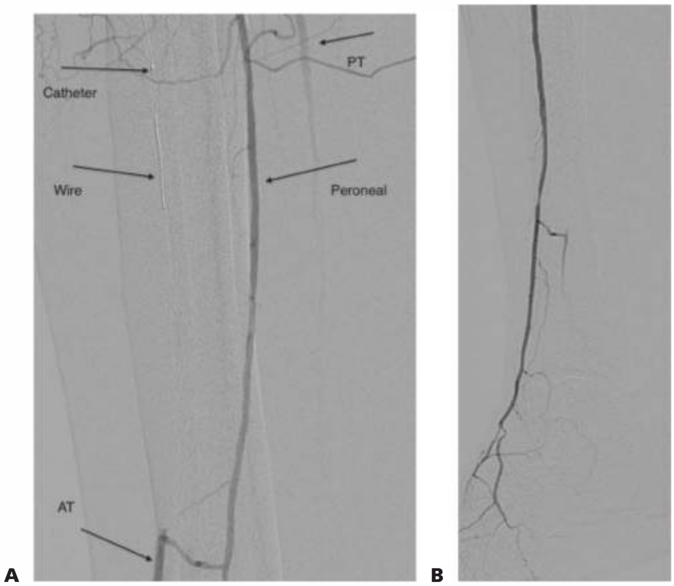

FIG 17 ● **A.** Angiogram from the sheath at the time of recanalization of anterior tibial (AT) artery with a wire and catheter. The peroneal artery is patent and reconstitutes a distal anterior tibial artery. **B.** Angiogram from the sheath postangioplasty of the AT with 3-mm balloon, shows patent AT without any dissection or flow-limiting stenosis.

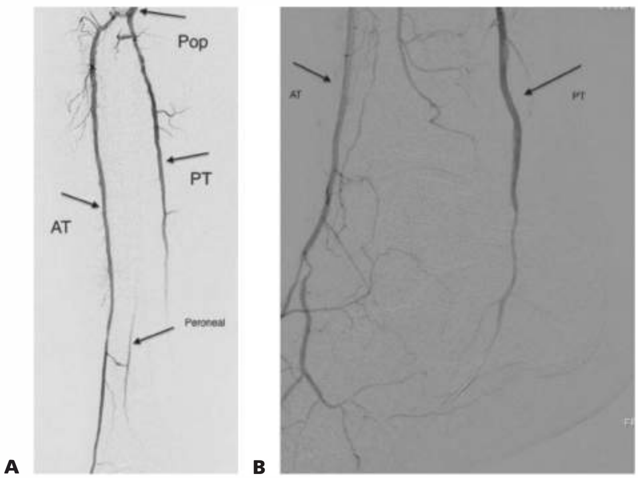

FIG 18 ● **A.** Completion angiogram from the sheath postrecanalization of occluded AT and PT shows patent vessels with good flow mainly in the AT without any significant dissection. The peroneal artery reconstituted in a retrograde fashion from the AT. **B.** Patent distal AT and PT runoff into the foot.

RETROGRADE TIBIAL RECANALIZATION

First Step: Retrograde Access

- Antegrade access is obtained first as described earlier. This is used for initial imaging and delivery of treatment devices.
- Retrograde tibial arterial access is performed under ultrasound or fluoroscopic guidance using a micropuncture 21-gauge needle; a 300-cm, 0.018-in or 0.014-in wire; and balloon or support catheter. An introducer dilator, although potentially useful, is not essential.
- Sedation should be managed to minimize movement when road mapping is used to identify target arteries.
- Local anesthesia is infiltrated at the intended puncture site.
- Access to the posterior tibial artery is obtained in the region of the medial malleolus. Dorsiflexion and/or eversion of the foot may facilitate access.
- Access to the anterior tibial artery is obtained on the dorsum of the foot or the distal aspect of the leg anteriorly, where the target artery may be larger. Dorsalis pedis access is facilitated by plantar flexion of the foot.
- The peroneal artery should be approached laterally through the interosseous membrane.
- More proximal access to the posterior or anterior tibial arteries may be obtained with road map guidance when necessary.
- Inadvertent venous puncture may occur during attempts at retrograde access, and when it does, consider leaving

FIG 19 ● Retrograde approach: access to PT under ultrasound (US) guidance.

the wire in place to help guide further attempts at arterial access.

- Ultrasound-assisted retrograde access, as an adjunct to road map guidance alone, may help to define the three-dimensional orientation of the needle in relation to the target artery (FIG 19).
- Image quality is optimized by incorporating a sufficient delay following contrast injection to maximize opacification of the target artery. Selective use of intraarterial vasodilators through the antegrade may reduce the severity of access-related vasospasm, when present, distally.
- The C-arm is adjusted to best align the needle to the target vessel, typically using an ipsilateral oblique projection.
- Surgical exposure may become necessary to ensure adequate access for retrograde tibial reconstruction. Retrograde access may also be obtained concomitant with planned transmetatarsal amputation by identifying and cannulating the open end of transected distal dorsal pedal artery.

Second Step: Retrograde Angiogram

- Once good back-bleeding is achieved, the wire is advanced under fluoroscopic guidance (FIG 20), followed by an appropriately sized support catheter, balloon, or the inner dilator of the 4-Fr microsheath.
- In most cases, retrograde sheaths are generally *not* deployed to minimize trauma to the puncture site and distal target artery (FIG 21). When sheaths are required, use of a radial access sheath will facilitate atraumatic access.
- Intraluminal position is confirmed by retrograde angiography through the catheter or dilator (FIG 22).

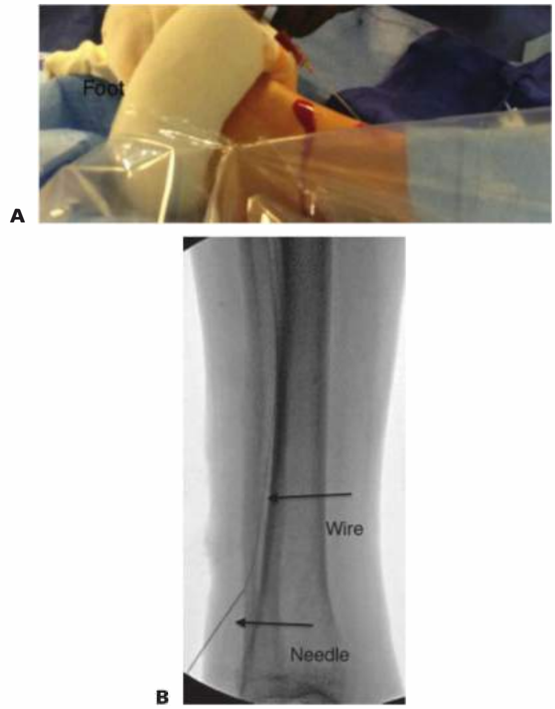

FIG 20 ● **A.** Retrograde access to AT with adequate arterial back-bleeding from the micropuncture needle. **B.** Needle in AT and wire advanced proximally under fluoroscopic guidance.

Third Step: Recanalization of Tibial Occlusion

- Antegrade sheath arteriography is used to delineate the extent of the target lesion.
- The occlusion is crossed using 0.018-in or 0.014-in wires, supported by a crossing catheter or low-profile angioplasty balloon (FIG 23).
- The wire and crossing catheter combination is advanced from distal to proximal and into the popliteal artery if possible. The wire is removed.
- Following aspiration to confirm luminal position, a selective arteriogram is performed from the retrograde catheter.

FIG 21 ● Retrograde access: wire and inner dilator of the microsheath.

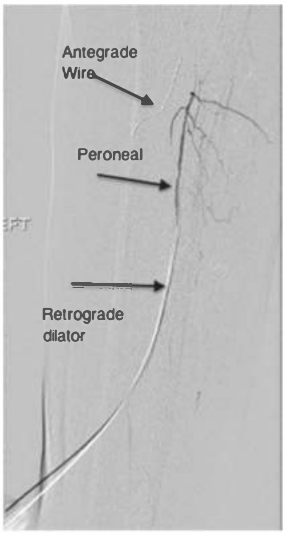

FIG 22 ● Retrograde access of the peroneal artery angiogram from the introducer confirms the intraluminal position.

Fourth Step: Exteriorization of the Wire from the Femoral Access Site

- Next, an attempt is made to advance the guidewire into the antegrade sheath.
- When this proves difficult on its own, a snare is deployed through the antegrade sheath to capture and externalize the distal retrograde wire (**FIG 24**).
- Following successful externalization of the retrograde wire, "wire access" is available from both ends.
- A crossing catheter is then advanced from the antegrade access site over the wire to the patent tibial vessel distal to the occlusion.
- Distal intraluminal position is confirmed with arteriography through the crossing catheter.
- Next, the through and through wire is removed from the antegrade sheath, leaving the crossing catheter across the lesion. The wire is exchanged for a 300-cm working wire, advanced distally through the antegrade crossing catheter.
- The retrograde access catheter or micropuncture 4-Fr access dilator is subsequently removed from the distal target artery. Hemostasis is obtained and maintained by manual pressure at the access site (**FIG 25**), the application of a blood pressure cuff across the site

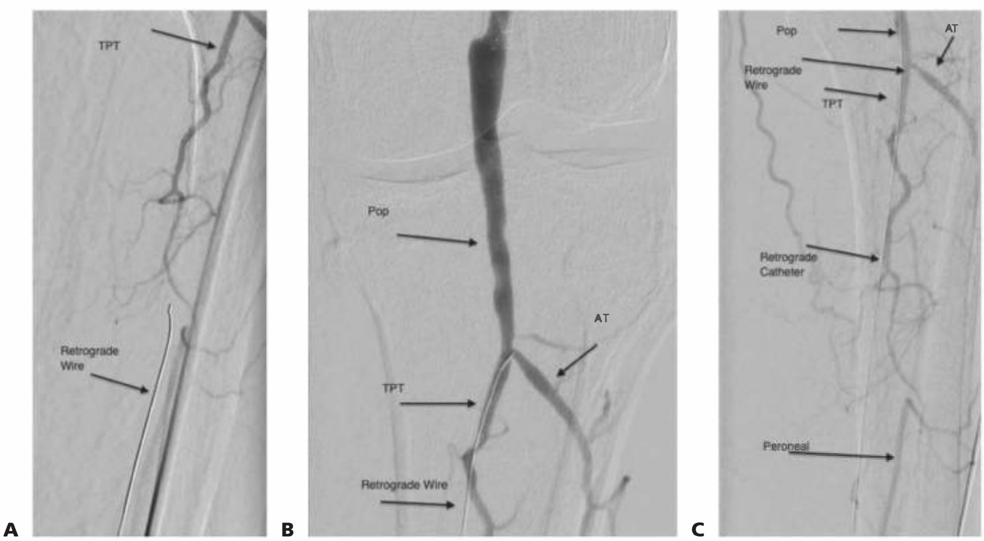

FIG 23 ● **A.** Angiogram from antegrade sheath. Wire crossing the occluded PT. **B.** Angiogram confirming entry of the wire into the tibioperoneal trunk (TPT). **C.** Angiogram shows the retrograde wire and catheter across the occlusion into the popliteal artery proximally.

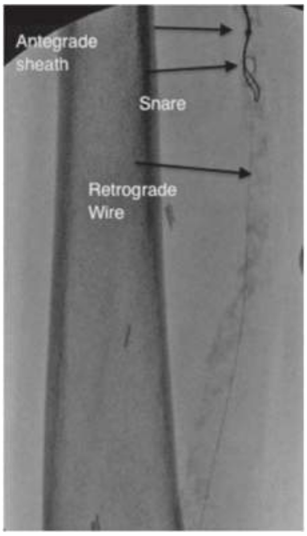

FIG 24 ● Snaring the retrograde wire into the proximal sheath.

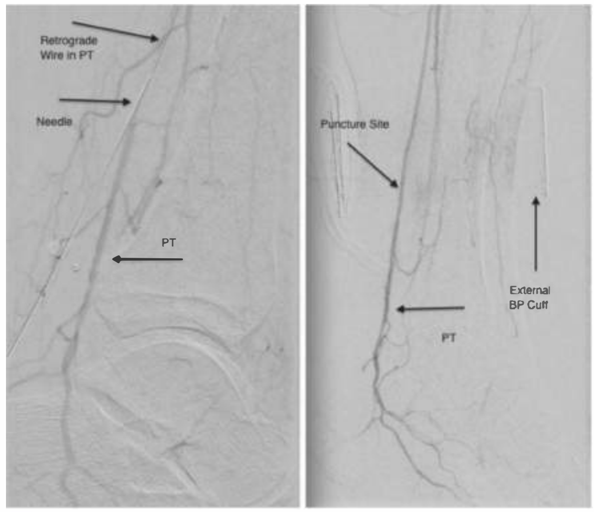

FIG 26 ● Angiogram of PT access site with blood pressure cuff used for hemostasis (image on the right of the screen).

(FIG 26), or a radial compression device (Dstat™ Radial Hemostat Band).

- Removing all devices from the retrograde access site as quickly as possible reduces instrumentation time and potential for arterial injury and distal thrombosis.
- Inflating a balloon advanced from the antegrade access sheath across the retrograde access site (FIG 27) may affect hemostasis but can also increase traumatic injury and access site bleeding and is thankfully rarely needed.

Fifth Step: Treatment with Balloon Angioplasty

- The intervention is then performed in the standard fashion from the antegrade approach (FIG 28).

Antegrade-Retrograde Approach

- If the retrograde wire is not able to cross the lesion and regain access to the true lumen, an antegrade-retrograde approach may be used to create adjacent subintimal planes in opposing directions (FIG 29).
- The dissection flap separating the adjacent subintimal spaces may be disrupted by simultaneous inflation in both directions.
- This allows visualization and recanalization of true lumen from either or both directions. The two PTA balloons selected for this maneuver should be sized appropriately to minimize risk for target arterial rupture.

FIG 25 ● Hemostasis with manual compression postretrograde PT access.

FIG 27 ● Angiogram shows extravasation from retrograde peroneal access site postrecanalization of TPT.

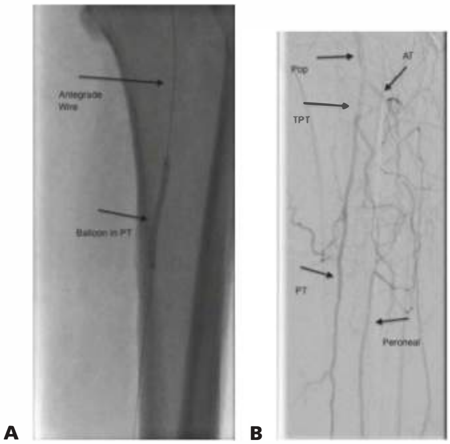

FIG 28 ● **A.** Balloon angioplasty of the occluded PT post-retrograde recanalization and exteriorization of the wire from the antegrade sheath. **B.** Completion angiogram shows good flow into the PT without any dissection.

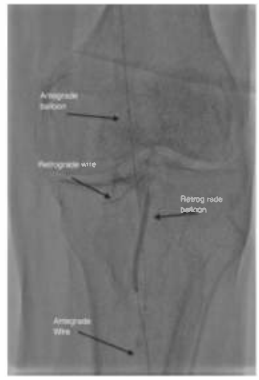

FIG 29 ● Retrograde/antegrade PTA to disrupt the membrane between two subintimal planes.

PEARLS AND PITFALLS

Goals for percutaneous tibial revascularization	■ Achieve direct in-line flow to the ischemic foot and, when possible, optimize pedal perfusion by recanalizing more than one occluded tibial artery.
Contralateral or antegrade femoral access	■ Choice based on inflow anatomy and target lesion. Advancement of the antegrade sheath tip into the popliteal artery is key for successful tibial revascularization.
Ultrasound-guided access	■ Can help access the anterior wall of the vessel in a relatively disease-free spot and minimize access site complications. It is recommended in antegrade femoral access and retrograde pedal access.
Retrograde approach	■ Should not be regarded as the first option for tibial interventions. It is selectively considered after failed attempts at antegrade access and in the setting of flush occlusions of the antegrade artery with large, adjacent collaterals.
Sheathless retrograde technique	■ Is preferred to minimize tibial artery access complications such as dissection and thrombosis. Recanalization is achieved with a wire and support catheter. Hemostasis with manual compression is usually sufficient.
Crossing total occlusions	■ The intraluminal plane is attempted first with a stiff wire and crossing catheter. The proper catheter position should be confirmed with a selective arteriography prior to definitive angioplasty.
Balloon-assisted recanalization	■ Inflation of a 2-mm balloon may assist with the recanalization of long calcified occlusions.
Kissing balloon technique	■ Is sometimes needed to treat the ostial lesions at the origin of the anterior tibial or posterior tibial artery, depending on the amount of plaque in the adjacent peroneal artery or tibioperoneal trunk.
Anticoagulation	■ Maintain an ACT of greater than 250 seconds throughout the intervention. Continuous or intermittent flushing of the popliteal sheath with heparinized solution is recommended.
Vasodilators	■ Are used from the antegrade sheath and at the pedal access site to prevent vasospasm and to allow better visualization of tibial vessels distal to the occlusion

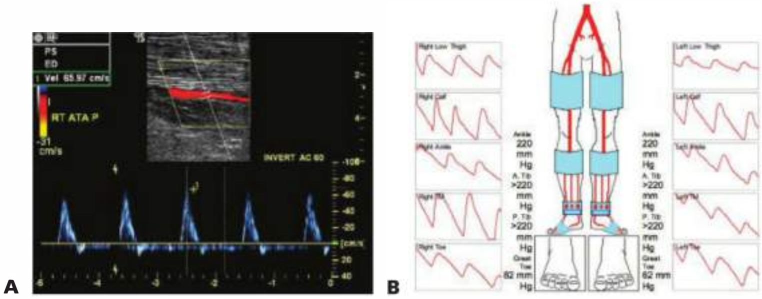

FIG 30 ● **A.** Duplex of the anterior tibial artery postrecanalization and angioplasty shows patent vessel with relatively normal Doppler flow. **B.** Follow-up PVRs postrecanalization and angioplasty of the right anterior tibial artery and right posterior tibial artery demonstrates normal PVR waveforms in the foot with adequate toe pressure.

POSTOPERATIVE CARE

- Following the procedure, the patient is observed in the recovery unit with serial postarterial intervention, neurovascular exams, and intravenous and oral hydration.
- A clopidogrel loading dose (usually 300 mg) is administered when the patient is not already on dual antiplatelet therapy. Dual antiplatelet therapy is recommended for at least 3 months; longer when stents are used.
- Clinical follow-up is obtained 2 to 4 weeks after the procedure is performed, including vascular lab studies (usually PVRs, segmental pressures, and Duplex arterial insonation) (**FIG 30**).
- Close follow-up is essential to ensure optimal symptom resolution and limb salvage.

OUTCOMES

- Tibial balloon angioplasty carries a relatively low primary patency rate but can greatly augment long-term limb salvage rates. The minimally invasive nature of the procedure is especially advantageous in high medical risk patients. One year primary patency rates in experienced hands range from 30% to 40%; secondary patency rates approach 60%, with ultimate limb salvage greater than 70%.[1,2]
- Use of a drug-eluting balloon may improve patency rates.
- Primary stenting does not appear to offer any advantage over tibial angioplasty alone.[3] There may be some patency advantage associated with drug eluting, as compared to bare metal stents.[4] Stenting under all circumstances should be considered as a "bail-out," used to improve suboptimal results of angioplasty alone.[5]
- Patients with significant tissue loss and gangrene should be followed very closely after successful tibial angioplasty. Lesional restenosis rates trend higher in patients at increased risk for limb loss.[6]
- Multilevel interventions, when necessary, are associated with improved limb salvage rate and wound healing compared to isolated tibial interventions.[2]
- Postangioplasty arterial restenosis may portend less clinical significance once healing is achieved in the distal limb or forefoot. The temporary increase in blood flow following angioplasty is often sufficient to heal small ulcerations.[7]
- There is some evidence of improved patency with drug-eluting stents and drug-eluting balloons.[4,8]

COMPLICATIONS

- Access site complications (hematoma, bleeding, pseudoaneurysm) are more common with the ipsilateral antegrade femoral approach.
- Contrast-induced nephropathy can be avoided by sufficient preoperative, intraoperative, and postoperative hydration as well as judicious use of contrast at all times.
- Vessel thrombosis can be avoided by maintaining a therapeutic anticoagulation level throughout the procedure. The use of nitroglycerin can help prevent vasospasm and a low-flow state. Dual antiplatelet therapy is recommended to avoid early postprocedural target artery thrombosis.
- Outflow embolization may be successfully treated with aspiration embolectomy or alteplase if needed.
- Retrograde access site bleeding, dissection, and vessel thrombosis are described after the retrograde pedal access. Using ultrasound-guided access, sheathless technique and the use of local vasodilators may minimize the risk of retrograde access site complications.
- Compartment syndrome may develop either from reperfusion injury following successful intervention or, more commonly, perforation of tibial arteries in the deep compartments of the leg.
- Limb loss may result from failed intervention, iatrogenic vessel thrombosis, distal arterial occlusion following embolization, and compartment syndrome.

Chapter **33**

Perimalleolar Bypass and Hybrid Techniques

Geetha Jeyabalan Rabih A. Chaer

DEFINITION

- Perimalleolar bypasses are defined by the anatomic location of the distal target outflow vessel. Perimalleolar bypasses refer to any bypass in which the distal target vessel of revascularization is the posterior tibialis, anterior tibialis, or peroneal arteries at the level of the ankle. The pedal vessels (dorsalis pedis, posterior tibialis, lateral or medial plantar artery) are also target vessels in some patients with very distal disease.
- These bypasses are performed in patients with advanced critical limb ischemia (CLI), which includes tissue loss, or ischemic rest pain for which there is not a durable or feasible endovascular option. With the advent of advanced endovascular techniques, the indications for perimalleolar or tibial bypasses are evolving. The inflow vessel and conduit chosen are tailored to individual patients and their anatomic limitations.

DIFFERENTIAL DIAGNOSIS

- The three major etiologies of lower extremity ulceration include ischemic, neuropathic, and venous stasis disease. Although all of these can have poor perfusion as a primary contributing factor, the diagnostic workup and management may be slightly different. Arterial ulcerations typically have a punched-out dry appearance and usually occur on the distal forefoot and toes, whereas neuropathic ulcerations often occur on pressure points and are associated with calluses. Venous stasis ulcerations are typically located on the medial or lateral malleolus and have associated skin changes and brawny induration in addition to serous drainage.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with CLI typically present with ischemic rest pain and/or tissue loss or forefoot gangrene. Most of these patients have significant comorbid conditions such as diabetes mellitus, coronary artery disease, hyperlipidemia, and hypertension that will be important for risk stratification and in deciding between different revascularization modalities. Additionally, managing and optimizing these risk factors are keys to successful outcomes following lower extremity revascularization, regardless of the technique used. As such, optimizing lipid profile, glycemic control, smoking cessation; minimizing renal dysfunction; and managing hypercoagulable states are all essential components to the perioperative medical management, in addition to managing any concomitant coronary disease. The majority of patients are already followed by a team of physicians for their comorbidities (primary care physician, cardiologist, endocrinologist, nephrologist), whereas the surgical team is evaluating the peripheral vascular disease. It is imperative that these consultants remain actively involved in the perioperative period for both the short-term and long-term success of limb salvage and overall survival. The age of the patient, functional status, and comorbidities guide the vascular surgeon's decision making in terms of the type of revascularization offered to the patient.
- Most patients presenting as outpatients will have a history of symptoms of disabling claudication, rest pain, or tissue loss. Taking a careful history noting duration of symptoms, level of pain/claudication, areas of tissue loss, and history of traumatic neuropathic ulceration will guide the workup. Young patients, younger than 60 years of age, or patients with multiple arterial/venous thromboses should undergo a thrombophilia evaluation. Physical examination should include a thorough peripheral vascular examination, including assessment of the potential presence of a palpable aortic aneurysm on abdominal exam. The quality and symmetry of pulses and/or handheld Doppler signals between both legs at the femoral, popliteal, and pedal levels assist in determining the anatomic level of disease. Wound documentation, when present, should note location, depth, presence of infection, bone exposure, and extent of soft tissue defects. Neuropathic deformities of the foot should also be taken into careful consideration for offloading purposes. If there is gross purulence or systemic signs of infection, a debridement of the affected area is required prior to revascularization, even if the area is malperfused, for source sepsis control.
- The location and appearance of ulcerations will often assist in differentiating ischemic, neuropathic, or decubitus wounds. Location of the ischemic wound is important in determining which target vessel will be chosen for revascularization. If the history and physical examination suggest peripheral vascular disease as the primary diagnosis, then noninvasive vascular testing is the next step in determining need for revascularization and level of disease.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- After a thorough history and physical examination, the diagnostic workup of patients with ischemic ulcerations, rest pain, or significant claudication involves noninvasive vascular testing. This involves calculation of ankle–brachial indices and pulsed volume recordings in addition to duplex imaging of the extremity. An ankle–brachial index (ABI) of less than 0.4 is typically seen in patients with CLI (**FIG 1**). Toe pressures of less than 40 mmHg suggest inadequate perfusion for wound healing. In cases of severely calcified vessels, it is important to obtain associated pulsed volume recordings and toe pressures because ABIs can be falsely elevated due to vessel incompressibility. Transcutaneous oxygen tension ($TcPO_2$) measurement can also be used to determine the severity of ischemia and probability of wound healing.

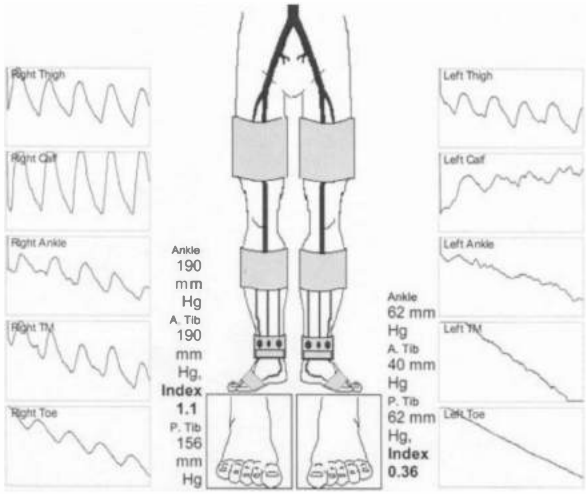

FIG 1 ● Severely reduced ABI and flattened distal pulsed volume recordings (PVRs).

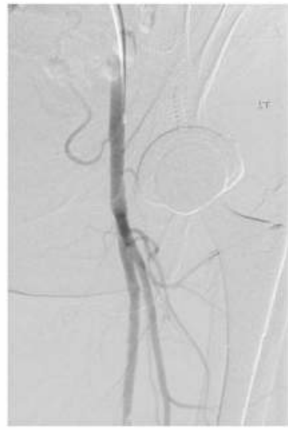

FIG 2 ● Digital subtraction angiography with catheter placed in the common femoral artery to fill collaterals from the profunda to more distal target vessels.

- Once the history, physical examination, and noninvasive testing are complete, the surgeon must determine the next step in imaging, which may be both diagnostic and therapeutic. The patient's functional status, cardiac risk profile, and other comorbidities (ambulatory status, etc.) will all play an important role in determining whether any revascularization attempt is even feasible. If femoral pulses are not palpable on physical examination and noninvasive testing is also suggestive of inflow disease, computed tomography arteriography (CTA) may be instrumental in evaluating the extent of aortoiliac disease, taking into account renal function and risk of contrast-induced nephrotoxicity. Alternatively, aortography obtained from contralateral femoral access or upper extremity arterial access may suffice. General management approaches to aortoiliac versus infrainguinal disease are discussed elsewhere in this book.
- Once the clinical determination is made that the level of disease is infrainguinal, digital subtraction angiography is an excellent diagnostic test and provides access for therapeutic intervention as well. This chapter focuses on patients with multilevel infrainguinal disease who, presumably, have either failed endovascular revascularization, prior open bypass, or who have no endovascular options for revascularization. Therefore, the primary goal of diagnostic angiography is to assess the caliber and quality of inflow vessels and bypass targets.
- The contralateral femoral artery is accessed and an aortogram with oblique pelvic views is obtained to rule out the presence of inflow disease that may need treatment prior to evaluating the infrainguinal segment. An ipsilateral oblique magnified projection will be helpful in determining if there is any significant common femoral or profunda femoris stenosis, which is especially important if these vessels are to be chosen as the source of inflow for an open bypass (**FIG 2**).
- Deciding on which type of intervention to perform, endovascular versus open, and how aggressive to be about either approach is determined by multiple considerations as outlined earlier and elsewhere in this section. Patients requiring open bypass typically have multilevel disease. As such, it is critically important to image the runoff with the catheter placed proximal to the profunda origin, as the distal runoff will likely be filling from profunda collaterals that are communicating with geniculate collaterals. With common femoral or profunda disease, the catheter will need to be placed in the common iliac artery to evaluate internal iliac collaterals that are in communication with the profunda and more distal collaterals. Performing magnified, time-delayed digital subtraction angiography will assist in revealing which tibial vessels are patent and filling through collateral networks. It is also essential to identify the primary named crural artery that is in continuity to the foot that will perfuse the tissue affected by ischemic ulceration (**FIG 3**).
- Using full-strength contrast, magnified projections of the foot will help delineate which pedal vessels are patent, which fill the tarsal and plantar branches, and confirm the status of the plantar arch. Occasionally, there are situations in which no suitable target (e.g., "named" artery) is identifiable and

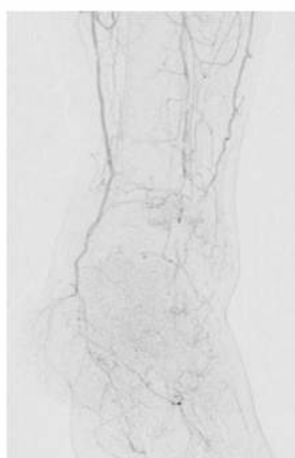

FIG 3 ● Magnified oblique projection of the foot demonstrating a patent plantar arch and digital vessels.

exploration of a tibial vessel at the time of operative intervention may be required. This exercise is fraught with risk, however, especially in the setting of a desperately ischemic foot, and should rarely be undertaken without conclusive pre- or intraoperative arteriography. Duplex ultrasonography may assist in further defining quality, caliber, and patency of tibial vessels in these situations. Choosing a patent posterior tibialis or anterior tibialis artery in direct continuity with the pedal arteries is preferred over a peroneal artery as a distal target when the former is available, especially in cases of forefoot wounds; however, peroneal arteries are perfectly suitable and serviceable in this situation in the absence of other alternatives.

- The decision to proceed with open perimalleolar bypass is made in the context of the patient's overall clinical functional status, cardiopulmonary and renal comorbidities, presence of autogenous saphenous vein conduit, and options for endovascular revascularization. Preoperative autogenous conduit assessment is best performed by detailed ultrasonographic imaging along the length of the vein. Preference is always given to a single segment of greater saphenous vein (GSV) from the ipsilateral leg that is at least 2.5–3 mm in diameter, compressible, and free of thrombus throughout. Assessment of the contralateral GSV is useful in case ipsilateral vein is found to be of poor quality during operative exploration.
- Inflow artery selection is usually based on length of available conduit and location of proximal disease. The common, superficial, or deep femoral or popliteal arteries may all serve as suitable inflow arteries in circumstances where minimal or insignificant occlusive disease is present proximally. This determination is best made during diagnostic angiography. The need for concomitant inflow endarterectomy should also be evaluated at this time.

SURGICAL MANAGEMENT

Preoperative Planning

- Type of anesthesia to be used is determined by the type of cardiopulmonary comorbidities and the anatomic level of arterial occlusive disease. Preoperative consultation with anesthesiology and cardiology is customary in this patient population to assess the appropriate amount of surgical risk. General anesthesia, peripheral nerve block, and spinal anesthesia are all potential options in this group of patients. Intraoperative fluid administration should be used judiciously and preoperative preparation should include blood type determination and crossmatching as necessary. It is our practice to hold therapeutic anticoagulation for at least a few days prior to the procedure, but most patients remain on antiplatelet agents through the day of surgery and continue through the perioperative period.

Positioning

- Any lower extremity bypass might require intraoperative angiography and, as such, all such procedures should be performed on a radiolucent table. The patient is positioned supine, with the leg slightly abducted and externally rotated to provide optimal exposure of the ipsilateral GSV harvest site (**FIG 4**). It is our practice to localize the GSV by ultrasound to assist in incision planning. This also helps determine whether the contralateral leg should also be prepped as an alternative site for vein harvesting.
- Other items that should be available in the room include a sterile pneumatic tourniquet and surgical bump. Both are useful when the below knee popliteal artery or tibioperoneal trunk is used for arterial inflow for the graft. Open forefoot wounds are excluded from the operative field with adhesive or Ioban drapes.

A **B**

FIG 4 ● **A.** Positioning of the leg in gentle external rotation to facilitate exposure of the GSV medially. **B.** Identifying and marking the GSV under ultrasonography.

PERIMALLEOLAR BYPASS TO THE DISTAL POSTERIOR TIBIALIS ARTERY

First Step: Exposure of the Posterior Tibialis Artery at the Ankle

- Simultaneous dissection of the inflow and outflow targets increases the efficiency of the operative approach. The distal incision is marked by palpating posterior to the medial malleolus, taking care to avoid injury to adjacent GSV (**FIG 5**). Dissection is carried sharply through skin and subcutaneous tissues and through the flexor retinaculum. The tendons of the flexor digitorum longus muscle and flexor hallucis longus pass anteriorly and posteriorly, respectively, to the neurovascular bundle at this level. The paired tibial veins are often seen first as overlying the artery. The tibial nerve travels posterior to the artery and may not be seen clearly during this exposure. The tibial artery does not need to be dissected circumferentially if a pneumatic tourniquet is deployed for proximal control. Use of a tourniquet minimizes risk for venous injury at the dissection site and trauma to the arterial endothelium from vessel loops and vascular clamps. For exposure of the medial and lateral plantar arteries, the same incision is typically carried further distally onto the medial aspect of the foot.

Second Step: Exposure of the Inflow Artery

- Concurrent dissection of the arterial inflow should be performed while the tibial target is being exposed. If the common femoral artery is chosen, then a longitudinal vertical incision just below the inguinal ligament will allow for simultaneous exposure of the femoral bifurcation in addition to the saphenofemoral junction for dissection of the GSV (**FIG 6**). If the deep femoral artery is to be used as inflow, then division of the lateral femoral circumflex vein may be helpful in controlling the first-order branches past the origin. If the deep femoral origin is truly deep, the muscle bellies of the adductor longus and vastus medialis should be divided to limit the angle from which the graft originates from the arterial anastomosis. If the below knee popliteal artery is to be used as the inflow, which might be the case in diabetic patients with severe tibial disease not amenable to endovascular revascularization, this exposure is best obtained through a medial calf incision.

FIG 6 ● Incision for the exposure of the femoral bifurcation and start of the GSV harvest incision.

Third Step: Harvest and Preparation of Autogenous Vein

- The course of the GSV is marked on the skin prior to prepping. The shortest segment of suitable caliber and quality GSV is harvested. Incision placement is partially determined by the location of the arterial access incisions. Care should be taken to avoid creating skin flaps during

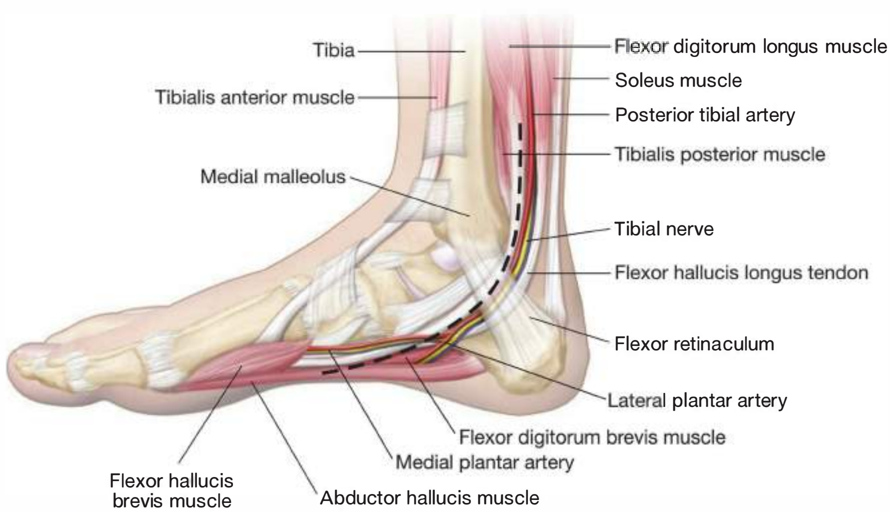

FIG 5 ● Incision for exposure of the posterior tibialis artery at the medial malleolus.

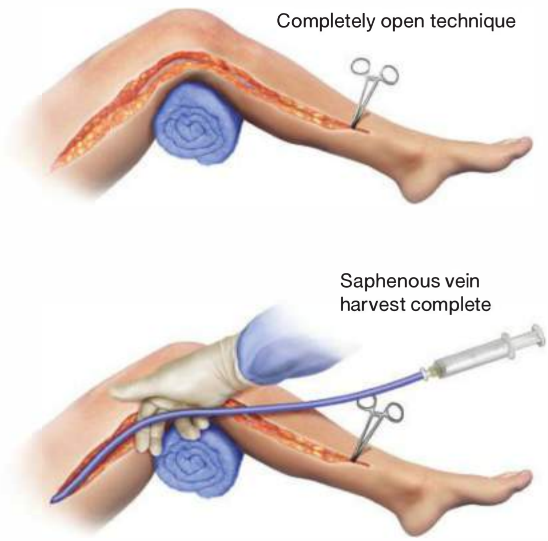

FIG 7 ● Preparation of the GSV.

vein exposure. Harvesting vein through skip incisions may help to minimize wound complications but is not necessary for a good result. Minimal vein manipulation, with care being taken to accurately ligate side branches with 4-0 braided permanent suture (or silk), is important. Minimal dissection of the vein is typically required when in situ bypass in planned. The vein can be left in its bed, with limited dissection of the anastomotic segments. Skip incisions provide access to ligate large side branches.

- After an adequate length of saphenous is exposed, it is removed from its bed for bypass placement or transposed into position after valve lysis for in situ bypass. When removed and repositioned, we generally try to use the largest diameter segment for bypass. The saphenofemoral junction is oversewn or suture ligated. The vein is then reversed and distended gently with heparinized saline or plasmalyte solution. Other vein preservative solutions can be used at the discretion of the surgeon. Any untied branches are carefully clamped and tied with silk suture. Small tears or holes are oversewn in a longitudinal fashion, taking care not to narrow the vein, using 7-0 polypropylene suture (**FIG 7**). Depending on institutional expertise, endovein harvest is an alternative method to minimize incisional length and potential wound complications.
- Once prepared, veins can be used in reversed or nonreversed configurations. We generally prefer reversed as to minimally disrupt the endothelium. If the distal portion of the vein is significantly smaller and concern exists regarding size mismatch at either end, then veins may be positioned in a nonreversed fashion by lysing the valve. To lyse the vein valves, a valvulotome is gently passed up the vein after the proximal anastomosis is complete and the vein is perfused and distended. It is critically important to have the first assistant provide gentle countertraction on the vein as the valvulotome is hooked on the valves in order to lyse them (**FIG 8A**). Care must also be taken to not hook the valvulotome on any ligated branches to avoid tearing the vein. Other commercially available valvulotomes can be used at the discretion of the surgeon.
- Tunneling the vein: The tunnel is created using a hollow tunneler (e.g., Gore, Scanlan, Jenkner) with a blunt appropriately sized tip (6 mm at least) in a subcutaneous plane away from the saphenectomy incision, if possible, to avoid wound complications. The vein is carefully inspected at the entry and exit site of the tunnel to ensure it is in a loose plane and not constrained by fascial or muscular bands (**FIG 8B**).

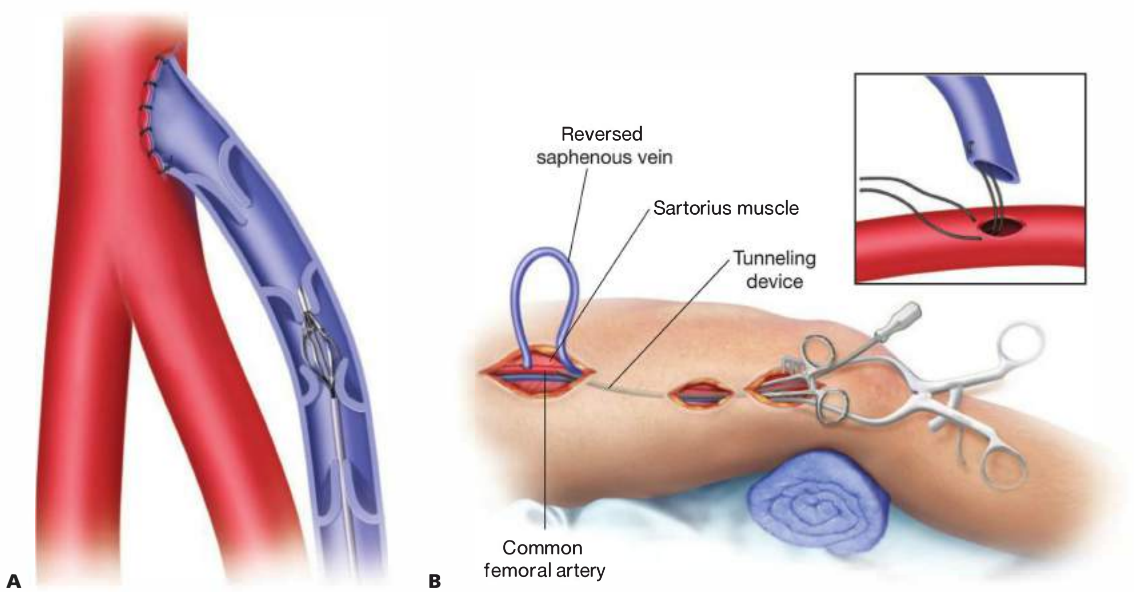

FIG 8 ● **A.** A valvulotome being used to lyse valves in a nonreversed vein under distension. **B.** Tunneling with hollow tunneling device through the subcutaneous tissues away from saphenectomy site.

- After systemic anticoagulation is achieved with unfractionate heparin, the proximal anastomosis is performed after controlling the inflow artery with vessel loops or vascular clamps. The loops or clamps are released and the anastomosis is confirmed to be hemostatic. Once this is assured, the vein is perfused and distended, the valves are lysed if applicable, and the vein is marked for orientation. It is then passed through the tunneler to exit the distal incision and clamped proximally with an atraumatic bulldog clamp or Yasargil clip. The length of vein needed is determined after the vein has already been tunneled and distended, with the leg in a maximally extended position. The leg can be manipulated in various positions with knee flexion to make sure any excess or redundant vein is appropriately trimmed prior to embarking on the distal anastomosis.

Fourth Step: Distal Anastomosis Creation

- If a tourniquet is to be used for distal control, then the lower leg is exsanguinated using an Esmarch bandage. The tourniquet is placed around the thigh if the inflow is at the level of the common femoral, profunda femoris, or proximal superficial femoral arteries. It is inflated to 250 to 300 mmHg. The target is then identified. Care is taken to identify the artery instead of the vein because they can appear deceptively similar when exsanguinated under tourniquet hemostasis. The distal anastomosis is created using a 6-0, 7-0, or 8-0 polypropylene suture depending on the size of the target artery. Loupe magnification is helpful and generally mandatory in this setting. The first assistant should sit beside the operating surgeon to maintain suture tension around the anastomosis and suction away blood and debris from the operative field (**FIG 9**).
- If the tourniquet fails to maintain sufficient hemostasis due to medial calcification in the larger proximal arteries, other options for hemostasis include vessel loops and vascular clamps for tibial control, use of vessel stoppers, or use of a carbon dioxide (CO_2) blower suction device. Circumferential tibial artery dissection must be done with care to avoid injury to the adjacent paired tibial veins, or venae comitantes, that give off several crossing branches above and below the target artery. Newer dissolving endoluminal occlusion gels are available for temporary hemostasis as well and may provide a less traumatic method of control in smaller arteries.
- Prior to completion of the anastomosis, the tourniquet is deflated and flushed. The proximal graft clamp or bulldog is released and the anastomosis is thoroughly flushed prior to tying down and completing the anastomosis. Topical agents such as thrombin/Gelfoam, Surgicel®, or Floseal® may be helpful in obtaining hemostasis following reversal of anticoagulation with protamine.
- Wound closure is a key component of the operation. Most of the morbidity from these procedures arises from wound complications. The vein harvest bed should be irrigated, inspected for hemostasis, and closed in multiple layers of running or interrupted absorbable suture. Care is taken to avoid injury to the saphenous nerve. At the ankle and around points of flexion, such as the knee, it is useful to use vertical mattress nylon suture. It is also important to close the ankle incision first before reperfusion edema makes tension-free closure challenging. It is often difficult to get more than one layer of subcutaneous tissue over the bypass and distal anastomosis at the perimalleolar level (**FIG 10**).
- The patency of the bypass is assessed intraoperatively by multiple potential methods. Feeling a strong bypass pulse in the tunnel and in the target vessel distal to the anastomosis is reassuring. Listening with a handheld Doppler to assess the quality of the Doppler signal of the artery distal to the distal anastomosis is also helpful. A multiphasic strong Doppler signal that augments significantly when the graft is first compressed and then released is suggestive of a patent bypass. In the absence of strong clinical signs of graft patency (e.g., palpable distal

FIG 9 ● Target artery is identified and anastomosis is created in an end-to-side technique.

FIG 10 ● Closure of the saphenous harvest site.

pulse), an intraoperative color flow duplex scan may be used to identify potential flow limiting defects, such as retained valves, focal velocity elevations, and low flow in the graft itself. However, intraoperative duplex scanning is not available in all operating rooms with sufficient resolution to recognize these defects. Finally, on-table arteriography also provides useful detail regarding potential problems, including the status of the anastomoses, tunneling issues, and the presence of retained valves, if any. Completion arteriography can be performed either through an up-and-over approach from the contralateral femoral artery or with a puncture in the ipsilateral inflow artery just above the proximal anastomosis (**FIG 11**). Some degree of spasm may be seen at the site of clamp placement or vessel loop manipulation. When tunneling concerns arise, dynamic arteriography with the leg flexed and extended in various positions can be helpful to prevent kinking of the bypass in the early postoperative period.

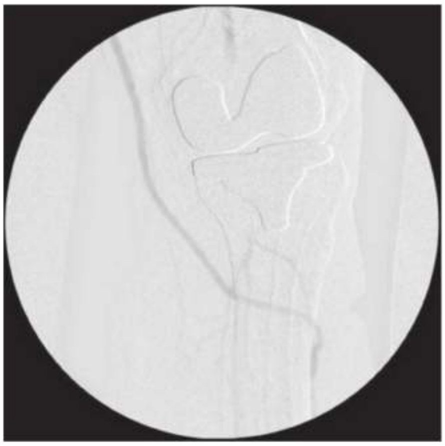

FIG 11 ● On-table angiography to assess the bypass following completion of the anastomoses.

PERIMALLEOLAR BYPASS TO THE DISTAL ANTERIOR TIBIALIS ARTERY

First Step: Exposure of the Anterior Tibialis Artery at the Ankle

- Simultaneous dissection of the vein and proximal inflow artery should occur while the distal bypass target is identified and controlled as described earlier. The distal exposure of the anterior tibial above the ankle is performed by identifying the tendon of the extensor hallucis longus and creating an incision just lateral to this and medial to the tibialis anterior tendon. Plantar flexing the ankle and palpating the space that opens between the two tendons often easily identify this groove in which the artery runs. The extensor retinaculum is divided at the malleolus and the vascular bundle should be easily identified at this level lying along the anterior surface of the tibia (**FIG 12**).

Second Step: Tunneling the Vein to the Anterior Tibialis Artery

- The GSV is harvested and either reversed or used in a nonreversed fashion depending on factors described earlier. The tunnel from the inflow artery to the anterior tibial can be maintained in a subcutaneous plane across the anterior surface of the tibia medial to the

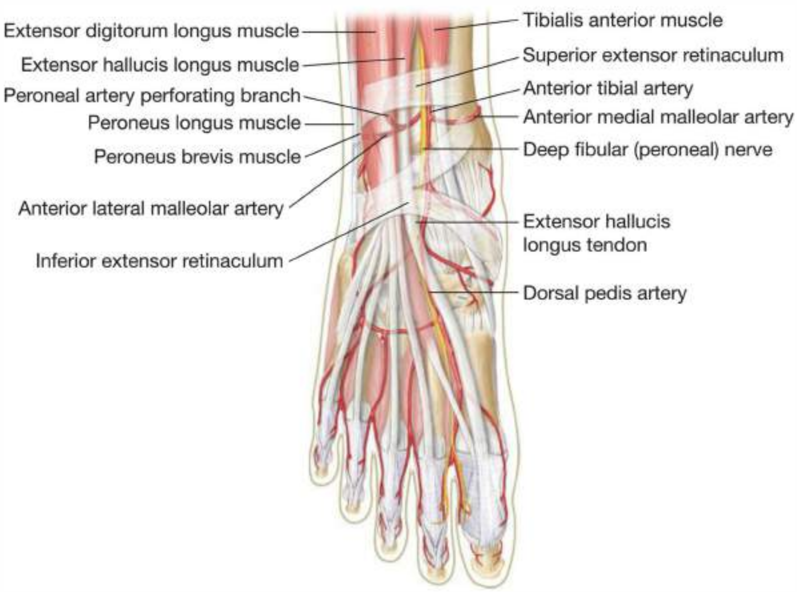

FIG 12 ● Exposing the anterior tibialis artery at the ankle.

exposure site. A counterincision may be needed at the ankle to allow for a gentler curvature of the vein graft toward the dorsum of the foot. If there is concern about potential compression of the vein graft in this region because of its superficial nature, the alternative is to tunnel through the interosseus membrane. This tunnel is created higher in the calf between the deep posterior and anterior compartments (**FIG 13**). Because the GSV harvest incision is already on the medial calf, the dissection can be extended deeper by retracting the gastrocnemius muscles posteriorly and partially dividing the soleus to reach the posterior tibial vessels. These are protected and gently retracted posteriorly while the fibers of the tibialis posterior muscle are separated and the tunneler is bluntly passed through the interosseus membrane here. Once the vein graft is in the anterior compartment, it can be tunneled in a subcutaneous or subfascial plane to reach the exposed anterior tibialis artery just above the ankle.

Third Step: Exposure of the Dorsalis Pedis Artery

- If the dorsal pedal artery is the target vessel, then the exposure distally is on the dorsum of the foot and the tunneling techniques remain similar to what is outlined earlier for the anterior tibial artery at the ankle. An incision is created on the dorsum of the foot just lateral to the extensor hallucis longus tendon and carried down through the fascia. The dorsal pedal artery lies lateral to the deep peroneal nerve here (**FIG 14**).

FIG 13 ● Tunneling through the interosseus membrane at the midcalf.

- Care should be taken to not leave self-retaining retractors in for too long in these smaller distal incisions to avoid tension on the wound edges and potential skin necrosis.

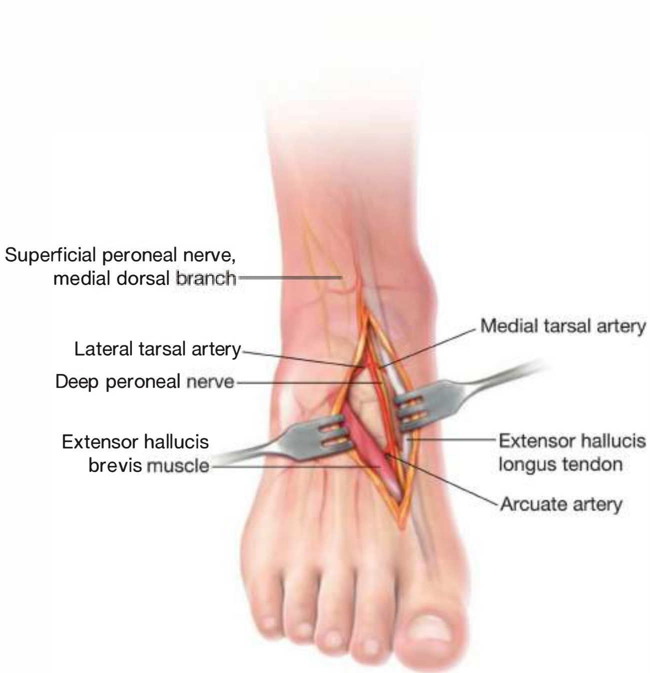

FIG 14 ● Exposure of the dorsalis pedis artery.

EXPOSURE OF THE PERONEAL ARTERY AT THE ANKLE

First Step: Peroneal Artery Anatomy

- The peroneal artery comes off the tibioperoneal trunk at the upper calf and then distally branches into two perforating branches, termed anterior and posterior perforating peroneal arteries, which supply the anterior and lateral compartments and communicate with the anterior tibial artery and some tarsal branches.

Second Step: Exposure of the Distal Third of the Peroneal Artery

- Because the proximal segment of the peroneal artery can be accessed easily from a medial approach, the perimalleolar or distal third of the artery needs to be approached from a lateral approach and requires resection of a portion of the fibula. An incision is created along the lateral border of the fibula and dissection is carried down through the fascia to the fibula after which the periosteum is cleared proximally and distally (**FIG 15**). The peroneal arteries are in close proximity to the fibula medially and care should be taken to avoid injury to the vascular bundle when clearing the bone medially (**FIG 16**). The bone can then be excised and the peroneal artery is identified behind the interosseus membrane. The bone can be transected using a Gigli saw or oscillating power saw. The advantage of either a traditional bone cutter or power saw is that the bone does not necessarily have to be circumferentially dissected.
- The peroneal artery can also be exposed posteriorly, but this is somewhat challenging to do when the patient is supine. An incision just above the ankle posterolaterally between the tendons of the flexor hallucis longus and the flexor digitorum longus reveals the artery in its most distal segment (**FIG 17**). This approach is favored when the small saphenous vein will also be harvested for the graft conduit.

Third Step: Additional Procedure: Spliced Vein

- Despite careful preoperative planning and efforts to fully interrogate adequate conduit, the greater saphenous vein may prove to be unsuitable for the intended purpose once exposed. If length of vein is a concern, then careful consideration should be given to either moving the inflow anastomosis more distally or moving the target artery more proximally. An additional alternative is to create a shorter tunnel, harvest the greater saphenous vein from the contralateral leg, or harvest arm vein when other options are not available or advisable.
- Occasionally, if no suitable autogenous vein conduit exists (especially in the case of redo bypass); consideration may be given to cadaveric cryopreserved vein or prosthetic bypass with vein cuffs or patches distally. The limitations of these nonautogenous options must be weighed against the known patency limitations of spliced vein or arm vein grafts.

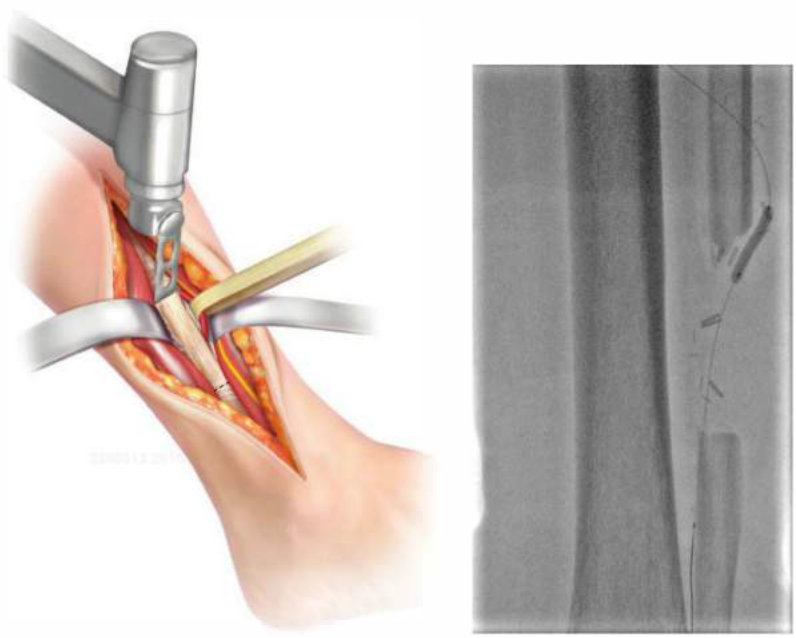

FIG 15 ● Clearing the fibular and resection for exposure of the distal peroneal artery.

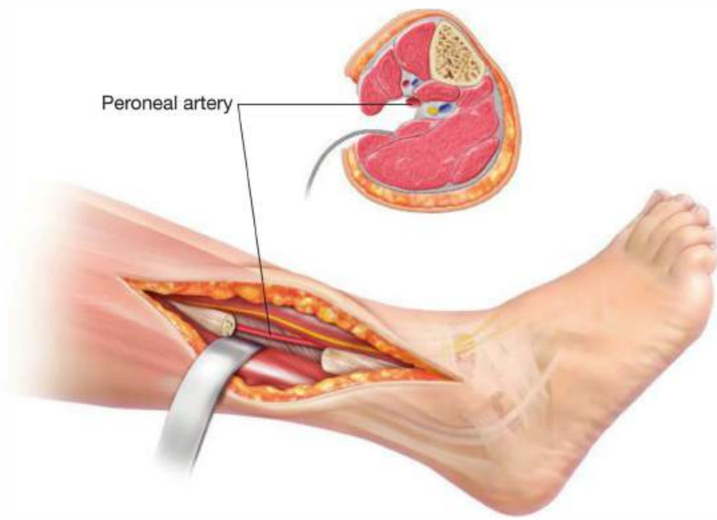

FIG 16 ● Exposure of the distal third of the peroneal artery.

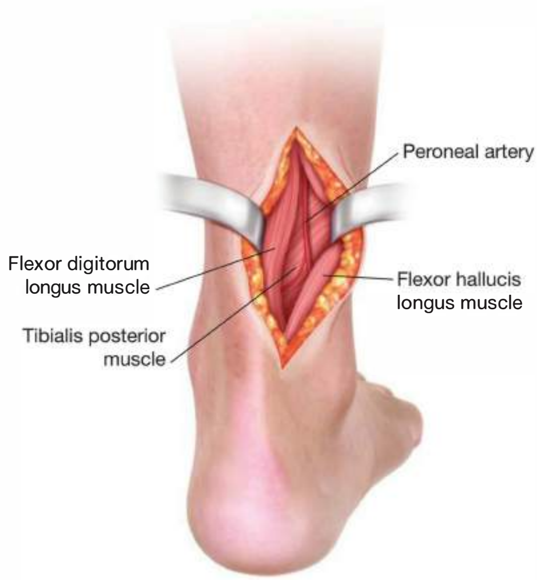

FIG 17 ● Posterior approach to the distal third of the peroneal artery.

PEARLS AND PITFALLS

Preoperative planning	▪ The bypass target is chosen to provide the best option for direct in-line perfusion to area of tissue loss on the forefoot.
Placement of incision	▪ Using ultrasound in the operating room to identify the GSV in relation to the proximal and distal incisions can help avoid raising flaps or creating postoperative wound complications. ▪ Use of a tourniquet above the knee can assist in avoiding unnecessary manipulation and potential injury to distal tibial vessels.
Tunneling	▪ Tunneling the bypass away from the vein harvest incision can help protect the bypass from exposure and infection in case of wound complications and wound dehiscence postoperatively.
Intraoperative assessment of bypass	▪ Manipulating the leg in slightly different positions can assist with evaluating the course of the vein bypass in the tunnel during intraoperative assessment with on-table angiography.

Wound closure	■ Avoid leaving self-retaining retractors in distal incisions for prolonged periods to avoid skin edge necrosis. ■ Closure of distal wounds is best accomplished with nylon suture in a vertical mattress fashion in order to avoid tension on the wound. Wounds over the dorsum of the foot can be closed with horizontal mattress sutures. Occasionally, a counterincision may be necessary to provide adequate coverage over the exposed artery at the ankle.
Postoperative care	■ A gently placed soft cast can prevent significant lower leg edema and subsequent wound breakdown in the immediate postoperative period. ■ Predischarge duplex assessment of the graft is important if intraoperative assessment of the bypass was not performed with angiography or duplex.

POSTOPERATIVE CARE

- Because of the length and location of incisions for inflow, vein harvest, and distal anastomosis, the patient will undoubtedly have significant edema postoperatively throughout the affected leg. To prevent blistering and potential wound breakdown, the foot, ankle, and lower leg may be wrapped in a soft cast consisting of an inner layer of Webril® and outer layer of gently compressive Coban®. Care needs to be taken to minimize external compression on the vein graft itself, especially in the areas around the ankle. The soft case is changed on postoperative day 3. The patient can ambulate starting on postoperative day 1, but the leg should be elevated when the patient is sitting or in bed. Patients are left on antiplatelet therapy perioperatively. There is some data supporting therapeutic anticoagulation in patients with high-risk vein bypasses (poor runoff, suboptimal conduit, etc.); however, this must balanced against the risk of bleeding in individual patients.
- For perimalleolar bypass patients who did not get an intraoperative assessment of their bypass with an on-table angiography, a predischarge duplex is performed to document patency and pedal perfusion. If a significant abnormality is identified on duplex (significantly low flows in the bypass or focally high velocities), then this should be addressed prior to discharge with angiography or exploration of the area with appropriate intervention.
- Once discharged, patients either return weekly for a change of their soft cast until their edema has sufficiently resolved or follow-up at the 1-month interval for formal duplex interrogation of the bypass. Certainly, more frequent visits may be warranted in patients with wound concerns.
- Surveillance duplex of vein bypasses is obtained at the 3-month, 6-month, 9-month, and 12-month postoperative time points with both ABI and graft duplex (**FIG 18**). After the 1-year time point, provided everything is stable clinically with the patient and there are no previous abnormalities on postoperative imaging, the surveillance can be moved to once a year. Occasionally, the surveillance interval is shortened for high-risk bypasses or prosthetic tibial bypasses.

OUTCOMES

- Primary patency of perimalleolar vein bypasses can be as high as 77% at 1 year, and limb salvage rates up to 85% at 1 year as well. Given the significant comorbidities in many patients with CLI, the rate of hospital readmission and poor functional outcome can be very high. Wound healing is adversely impacted by the presence of diabetes mellitus and renal failure.

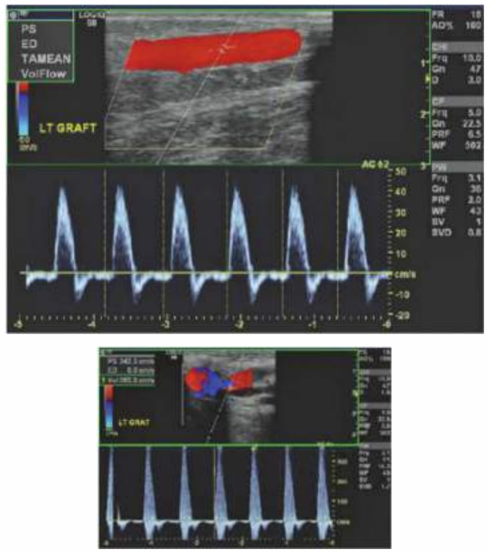

FIG 18 ● Surveillance duplex of vein bypass.

COMPLICATIONS

- Early complications of distal bypasses include bleeding, wound infection/breakdown, and graft occlusion. Late complications include graft stenosis, limb swelling, graft occlusion, and aneurysmal degeneration of the vein bypass. Most patients with CLI have concomitant coronary disease and the rate of perioperative myocardial infarction can be as high as 5%. It is very important to maintain patients on their cardiac medications in the perioperative period and manage fluids judiciously to avoid precipitating coronary events.

Chapter **34**

Acute Iliofemoral Deep Vein Thrombosis and May-Thurner Syndrome: Surgical and Interventional Management

Sharon C. Kiang   Brian G. DeRubertis

DEFINITION

- Acute iliofemoral occlusion is defined as complete or partial thrombosis of any part of the iliac vein and/or the common femoral vein (CFV), with or without associated femoropopliteal thrombosis, in which symptoms have been present for 14 days or less or for which imaging indicates that thrombosis has occurred within the past 14 days or less.[1] Acute iliofemoral occlusion may occur de novo following unprovoked deep vein thrombosis (DVT) or may occur (or reoccur) in the setting of prior ipsilateral DVT or external compression (May-Thurner syndrome or neoplasia). Treatment options include (1) systemic anticoagulation alone; (2) open surgical venous thrombectomy; or (3) percutaneous intervention, including catheter-directed thrombolysis, pharmacomechanical thrombectomy, and stenting of intrinsic or extrinsic obstructive lesions or masses.

DIFFERENTIAL DIAGNOSIS

- Iliofemoral DVT most commonly presents with unilateral leg swelling and pain. Although patient history and simple diagnostic testing can generally distinguish from other causes, differential diagnoses include cellulitis or worsening of chronic conditions such as venous insufficiency or lymphedema.

PATIENT HISTORY AND PHYSICAL FINDINGS

- There are three objectives in the treatment of iliofemoral thrombotic occlusion: (1) Prevent propagation of DVT and subsequent pulmonary embolism (PE), (2) provide symptomatic relief for the patient, and (3) prevent the development of postthrombotic syndrome (PTS).
- A thorough history must be obtained prior to treatment because decisions regarding choice of treatment modality are impacted by severity of symptoms as well as the patient's overall functional status.
- Specific risk factors that merit individualized questioning include history of trauma, current or past episodes of DVT or PE, history of thrombophilia, history or current diagnosis of cancer, and a history of tobacco or substance use. Family history of DVT or PE is important to ascertain. A thorough investigation of current medications should be undertaken, making note of any contraceptive therapy, hormone replacement therapy, or use of anticoagulation (i.e., warfarin, enoxaparin, etc.).
- Symptoms of iliofemoral occlusion can range from nondescript mild symptoms to severe disabling symptoms, and manifestations of symptoms can vary widely. Commonly reported symptoms of iliofemoral occlusion include limb edema, heaviness, pain, lifestyle-limiting venous claudication, stasis dermatitis, and in advanced cases, venous ulcerations.[2] Duration of symptoms and consideration of inciting events at the time of symptom development will help differentiate acute occlusion from exacerbation of chronic disease.
- Symptom severity is an important differentiating variable in the management rubric of acute iliofemoral occlusion; severe and persistent symptoms, especially those continuing following the initiation of therapeutic anticoagulation, increase the likelihood of long-term disabling sequelae. The more severe and persistent the symptoms, the more justified the indication for aggressive thrombus removal.
- A detailed physical examination is essential. Conditions that produce symptoms mimicking those associated with iliofemoral occlusion should be excluded. A thorough abdominal and lower extremity pulse examination, with noninvasive physiologic testing if necessary, will exclude possibility of arterial insufficiency. Comprehensive assessment of peripheral motor and sensory nerve function and of the spine and lower limb joints can rule out these confounding etiologies.
- The affected limb(s) should be examined for evidence of chronic venous insufficiency and/or stasis dermatitis, as well as signs and symptoms of acute DVT. Signs of acute iliofemoral occlusion may include pain, swelling, and bluish discoloration. Extensive thrombus propagation throughout the ipsilateral venous system may lead to phlegmasia alba dolens, characterized by profound painful swelling and a pale, milk-like skin hue. Further thrombus propagation from the deep to the superficial venous system increases outflow obstruction to the point of impeding arterial inflow, precipitating phlegmasia cerulea dolens, limb threat, and tissue loss.
- In patients with either acute or chronic venous disease, objective evaluation and prognostic stratification is best accomplished by using the CEAP (Clinical, Etiology, Anatomy, Pathophysiology) system and venous clinical severity score (VCSS).[3,4]
- Because multiple interventions may be required to optimize outcome in acute iliofemoral disease, patients' expectations should be managed accordingly. In addition, iliac and femoral venous intervention commonly requires extended periods of postoperative anticoagulation (warfarin and/or low-molecular-weight heparin) to ensure long-term procedural success. The likelihood of patient compliance thus represents an additional important prognostic indicator.
- Long-term functional outcomes are discouraging for patients who refuse interventional management of acute iliofemoral occlusive disease. Forty-four percent of patients treated with medical therapy alone will experience venous claudication, and up to 60% will develop PTS within 2 years.[5–7]

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging provides important prognostic and interventional guidance to surgical management of acute iliofemoral occlusive disease. Current modalities include duplex ultrasonography; catheter-based contrast phlebography; and reconstructed, cross-sectional, contrast-based whole body (computed tomography [CT] and magnetic resonance [MR]) imaging.

Duplex Ultrasonography

- In experienced hands, duplex ultrasonography (US) provides extremely sensitive and specific information regarding the chronicity and extent of infrainguinal venous obstruction. Diagnostic accuracy in the iliocaval venous system is less predictable due to the presence of overlying bowel gas and abdominal adiposity.
- Duplex-derived criteria for acute venous occlusion include incompressibility under direct vision, partial luminal obstruction within the normally echo-free lumen, and absent or abnormal venous flow characteristics with respiration or following a Valsalva maneuver or distal compression.[8]
- The primary advantages of duplex imaging include its noninvasive nature, avoidance of ionizing radiation or nephrotoxic contrast agents, easy reproducibility, portability, and accessibility in the outpatient setting. Additionally, substantial cost savings are realized compared to other imaging modalities. Other advantages include the ability of duplex scanning to differentiate hematomas, lymphatic system obstruction, superficial thrombophlebitis, and other soft tissue abnormalities from deep venous obstruction. Thus, duplex scanning is the initial imaging modality of choice in all patients with suspected iliofemoral DVT. When sufficient imaging parameters are met, definitive therapeutic intervention may be safely performed based on duplex-derived anatomic and diagnostic imaging alone.

Computed Tomography Venography

- CT phlebography is frequently ordered for assessment of limb swelling in the inpatient setting. Advantages of this modality include nearly universal availability day or night, less reliance on skill and experience of the technical staff performing the procedure, outstanding spatial resolution, reproducibility and sensitivity throughout the entire venous system, the simultaneous ability to image pulmonary arterial flow and lung perfusion, freedom from limb pain induced by direct probe compression during ultrasound examinations, and the ability to incidentally diagnose concurrent conditions (such as solid organ neoplasia) that may influence thrombogenicity or suitability for treatment with open versus endovascular techniques.
- The modern helical CT phlebogram provides a diagnostic sensitivity and a specificity of nearly 100% per year and was found to detect previously unsuspected venous thrombosis at a prevalence of 1.1%.[9,10]
- CT phlebography also provides useful information regarding thrombus density (and thus chronicity), the presence of residual luminal patency in obstructed veins, and the nature and severity of extrinsic iliac vein compression when present.
- The applicability of CT phlebography to the diagnosis of venous obstruction is limited by the volume of iodinated intravenous contrast required to obtain optimal spatial resolution in target vessels, as well as considerable whole-body radiation exposure inherent in CT imaging. On average, the radiation dosage delivered by diagnostic CT phlebography is equivalent to that of over 1,200 chest x-rays or over 10 years environmental exposure at sea level (dosage equivalents courtesy of Radiation Physics Department, Stanford Hospital & Clinics). This is particularly true in patients with reduced creatinine clearance, women of childbearing age who may be pregnant, or in children. For many reasons, including the considerable expense associated with the study, CT phlebography should not be considered a first-line study but rather reserved for patients in whom duplex scanning does not provide sufficient anatomic guidance or where additional diagnoses (e.g., pulmonary embolization, solid organ malignancy, or external iliac vein compression, etc.) merit evaluation or exclusion.

Magnetic Resonance Venography

- MR phlebography shares many of the advantages and disadvantages of CT-derived cross-sectional imaging, including the ability to obtain high-quality, high-resolution images of surrounding soft tissues and delineate the extent of accompanying lymphadenopathy, soft tissue sarcomas, venous aneurysms, malformations, and compression syndromes that may influence treatment and long-term management considerations. MR phlebography also provides a sensitivity and specificity of nearly 100%, respectively, in the diagnosis of acute iliofemoral venous occlusion.[11]
- However, unlike computed tomography venography (CTV), magnetic resonance venography (MRV) can be used during pregnancy and provide reduced risk of nephrotoxicity in patients with reduced creatinine clearance (although gadolinium is contraindicated in patients with an estimated glomerular filtration rate [eGFR] of more than 60 mL per minute).
- Contraindications for MR-based venous imaging include the presence of implantable pacemakers/defibrillators/infusion systems or other ferromagnetic devices and surgical clips/endografts, as well as claustrophobia in affected patients. MR studies are also expensive compared to duplex US, and dedicated personnel and equipment are less widely available than are modern, multirow-detector CT imaging capabilities. Thus, MR phlebography is considered most appropriate as a secondary examination in the absence of suitable duplex imaging or in the presence of contraindications to CT phlebography. MR phlebography may be particularly useful in the evaluation of coexisting or complicating ipsilateral or central venous vascular malformations.

Catheter-Based Contrast Phlebography

- Despite continuing improvements in the quality and widespread availability of noninvasive imaging, catheter-based contrast phlebography remains the gold standard for iliofemoral venous evaluation. Sensitivity and specificity are also nearly 100%, and in addition to anatomic information, physiologic venous pressure and flow information are also provided throughout the iliocaval system when accessed in a retrograde fashion from the CFV.

- Typical fluoroscopic findings include abrupt vessel cutoff in the case of total occlusion or visualization of a filling defect with residual luminal flow around the margins, a phenomenon known as "tram tracking."
- An obvious limitation is the relatively high degree of operator dependency, both in terms of physician and facility capabilities. Catheter-based contrast phlebography may be nondiagnostic in up to 18% of cases due to misinterpretations, artifacts, or superimposition of overlying structures.[12] Thus, experience and suitable infrastructure are necessary to ensure accuracy and precision.
- Other major drawbacks include the inherent invasiveness of the procedure and attendant procedural risk, radiation and contrast exposure (although significantly less than that required for CT imaging), and cost. Thus, contrast phlebography is also inappropriate as the initial diagnostic modality for most patients and best employed in conjunction with planned interventions directed at active thrombus removal.

Intravascular Ultrasound

- Intravascular ultrasound (IVUS) with the 9F Volcano IVUS catheter (Volcano Corporation, San Diego, CA) provides direct intraluminal visualization during catheter-based phlebographic assessment and intervention.
- IVUS-based imaging allows for precise measurement of cross-sectional area and maximum and minimum lumen diameter. Flow within the residual lumen may be determined, as well as precise analysis of residual luminal irregularities. The superior two-dimensional imaging characteristics of IVUS compared to contrast phlebography make this modality the measurement instrument of choice when assessing extrinsic iliac vein compression from tumors or overlying iliac arteries (e.g., May-Thurner syndrome).

INTERVENTIONAL AND SURGICAL MANAGEMENT

Preoperative Planning

- Serologic and hematologic evaluation should include the basic metabolic panel (to assess renal function and concomitant electrolyte abnormalities), complete blood count, and a coagulation profile. It is also important to ascertain the status of antiplatelet or anticoagulation therapies when present (e.g., dose, dosing frequency, prior complications, etc.).
- Prior to operative intervention, the index treatment limb should be marked as required for World Health Organization's preoperative checklist and "time-out" requirements and extent and severity of edema "baselined" for future comparison.
- When appropriate access requires multiple sites (e.g., bilateral femoral and/or internal jugular vein approaches), those should be marked and initialed as well.

Positioning

- Patients can be placed supine or prone depending on the site necessary for access. On the operating table, the patient should be placed supine, with their arms secured at the side to facilitate ancillary access from the groin or neck. When popliteal access is required, prone positioning is required.

PERCUTANEOUS MANAGEMENT OF ILIOFEMORAL DEEP VEIN THROMBOSIS (+/− VENOUS COMPRESSION SYNDROMES)

Duplex-Guided Femoral Vein Access

- Access site is chosen based on duplex US findings, proximal (peripheral) to the site of thrombotic occlusion. This may be the CFV in patients with isolated iliac DVT or the popliteal or tibial veins in patients with iliofemoral DVT.
- Under ultrasound guidance, a 0.018-in micropuncture set is used to access the target vein. In the setting of proximal obstruction, the vein is typically large and easily identified. Wire and catheter exchanged is performed to upsize to a 5-Fr interventional sheath.

Baseline Phlebography

- The initial phlebogram is performed either through the interventional sheath or through a diagnostic catheter advanced to the suspected site of occlusion. When using digital subtraction angiography, a mixture of 50% Visipaque and 50% saline provides adequate volume and visualization while minimizing contrast load.
- The ease with which guidewire passage is accomplished, as well as historical information regarding duration of symptoms, informs interventional decision making. Patients with symptoms of less than 7 days duration are frequently conclusively treated with single-session pharmacomechanical thrombectomy, whereas patients with longer duration will more frequently require pretreatment with multiday courses of catheter-directed thrombolytic therapy. The initial phlebogram is instrumental in determining the course of therapy in this regard. Regardless of approach, the goal of therapy is to achieve rapid thrombus removal, minimize venous obstruction, reduce the likelihood of venous valvular damage, uncover underlying venous compression syndromes, and at least theoretically, reduce likelihood of symptomatic recurrence.

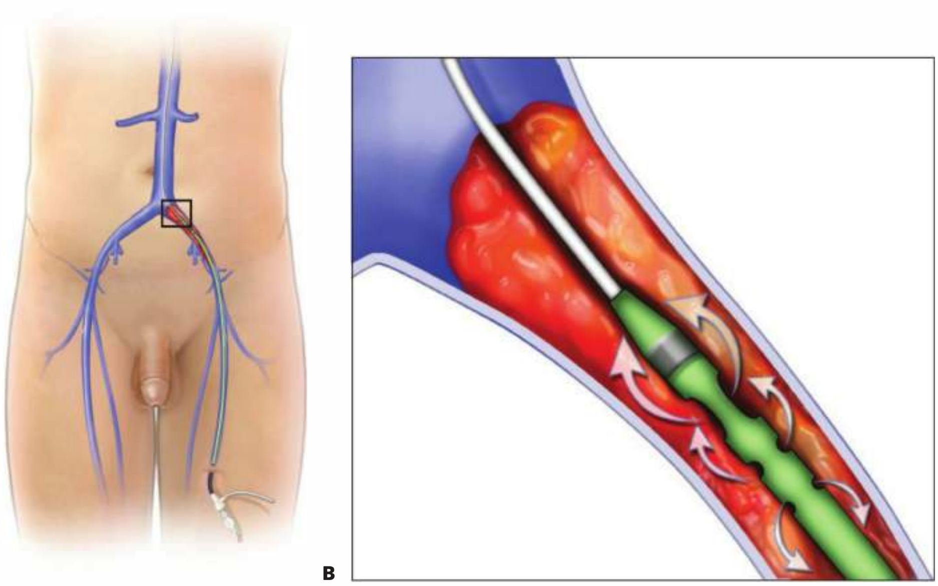
Catheter-Directed Thrombolysis

- Until recently, catheter-directed thrombolysis has been the mainstay of interventional management for iliofemoral DVT. Following guidewire traversal of thrombus, treatment length is determined via insertion of a marker catheter. Subsequently, an appropriately sized sidehole infusion catheter is positioned over the occluding thrombus. Infusion catheters come with infusion (perforated segment lengths) ranging from 5 to 50 cm or longer, and infusion segment length should be selected to direct infusate specifically into luminal thrombus only—for example, not into patent luminal segments where it will be rapidly dissipated into the venous and systemic circulation. Prior to initiating infusion, the multipurpose guidewire used to position the catheter is exchanged for a purpose and catheter-specific end-occlusion wire, which typically forces the infusate to exit through the side holes rather than leak out coaxially along the guidewire lumen.

- Once proper positioning is obtained, a continuous infusion of tissue plasminogen activator (tPA or alteplase, Genentech, San Francisco, CA) is initiated at the rate of 0.25 to 1.0 mg per hour, depending on the extent of thrombus burden and perceived chronicity. A concurrent, coaxial heparin infusion (400 to 700 units per hour) is administered through the sheath to prevent thrombus accumulation around the infusion system.
- Monitoring in a step-down or intensive care environment is an essential safety requirement during extended periods of catheter-directed intravenous thrombolysis outside of the cath lab. Fibrinogen levels, coagulation profile, and hematocrit are assessed every 4 to 6 hours. Typically, tPA infusion is halted if/when fibrinogen levels drop below 200 mg/dL or evidence of bleeding is present. Repeat phlebography is performed every 12 to 24 hours to assess therapeutic progress and residual thrombus load. As thrombus burden recedes, replacement catheters with shorter infusion segments are typically chosen to concentrate drug delivery within the remaining clot. Infusion rarely continues beyond 48 hours regardless of progress, as experience has demonstrated that complication rates vary directly with total tPA dosage and length of infusion. Also, infusion rates may be reduced when significant progress is noted during periodic phlebographic assessment, again to reduce risks of dosage-related bleeding complications while still pursuing complete dissolution of clot.
- Ultrasound-assisted thrombolysis using the EKOS infusion catheter (EKOS Corporation, Bothell, WA) may reduce the duration of infusion and total tPA dose. This 6-Fr catheter is also available in multiple infusion lengths and contains a core wire producing ultrasound energy that may disrupt fibrin bonds and increase tPA diffusion within thrombus. Clinical studies have demonstrated equivalent clinical outcomes with reduced infusion times using the EKOS system.

Pharmacomechanical Thrombectomy

- Pharmacomechanical thrombectomy (PMT) uses mechanical forces to assist tPA dispersion within the thrombus, typically during a single treatment session. Concurrent aspiration capabilities help remove thrombus fragments during treatment sessions. Devices currently used for this purpose in the venous system include the AngioJet catheter (MEDRAD, Warrendale, PA) and Trellis (Covidien, Mansfield, MA) infusion systems.
- The AngioJet systems comprise an infusion catheter and dedicated reusable drive unit. Radially oriented infusion ports generate high-pressure jets to disperse heparinized saline, with or without tPA, into the thrombus and an adjacent aspiration port to export fragments and debris.
- The AngioJet catheter is most commonly used in acute iliofemoral occlusion in the "power pulse" mode; in this setting, the aspiration function of the catheter is temporarily disabled, whereas tPA pulsation is delivered directly into the thrombus. Typically, 6 to 8 mg of tPA is delivered in this fashion at the beginning of a treatment session. With power pulse activated, the catheter is repeatedly advanced and withdrawn through the thrombus over the guidewire (FIG 1). After allowing the tPA to dwell for 10 to 15 minutes, the aspiration function is activated and thrombus removed to the greatest extent possible.



A B

FIG 1 ● **A.** The 6-Fr AngioJet thrombectomy catheter is useful in the treatment of DVT. This catheter is advanced through a sheath situated in the popliteal or femoral vein over a 0.035-in guidewire. The catheter has radially oriented infusion side holes that deliver saline and tPA directly into the thrombus **(B)** and aspiration ports that remove dissolved thrombus and debris.

FIG 2 ● The Trellis peripheral infusion system is an 8-Fr catheter with a single-use disposable drive unit. The catheter has compliant occlusion balloons that are inflated on either side of the treatment zone after advancing the catheter over the guidewire through the thrombus. The treatment zone of the catheter (either 15-cm or 30-cm length) contains both infusion side holes and aspiration ports. (Figure courtesy of Covidien, © 2014.)

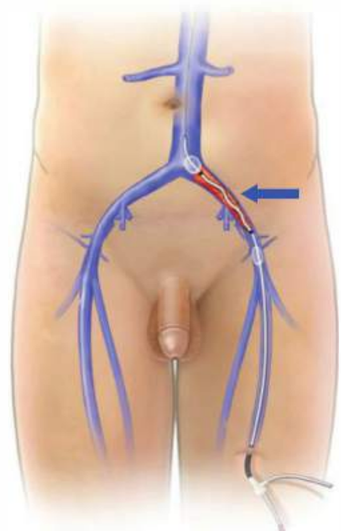


FIG 3 ● Once the Trellis catheter is in position, the guidewire is replaced by the mechanical dispersion wire, which is attached to the drive unit and enables the treatment portion of the catheter to oscillate back and forth *(arrow)* to facilitate tPA dispersion. During the 10-minute treatment time, tPA is infused through the infusion port at a rate of 1 mg (1 mL) per minute, and following treatment, the dissolved thrombus and remaining tPA is aspirated through the aspiration port.

- The Trellis system is composed of an infusion catheter of either 15- or 30-cm infusion length, with compliant occlusion balloons at either end of the infusion ports (**FIG 2**). Following placement over the guidewire, the end occlusion balloons are inflated in order to isolate the area of planned pharmacomechanical thrombolysis (**FIG 3**). A sinusoidal dispersion wire is then advanced through the core of the catheter and attached to a disposable drive unit, which when activated uses mechanical forces to disperse the tPA through the thrombus. After an infusion of 6 mg of tPA over the span of 10 minutes, aspiration of thrombus and debris is performed from the treated segment. The occlusion balloons concentrate tPA within the treatment segment, enabling multiple infusion and dispersal sessions during the same procedure with minimal systemic delivery of thrombolytic agent (**FIG 4**).

Stenting of Underlying Venous Stenoses or Venous Compression Syndromes

- Following clearance of acute thrombus from the iliofemoral system, underlying venous lesions that provoked DVT formation, or focal external compression may become apparent on completion phlebography. These lesions should be addressed during the same treatment session to minimize the risk of recurrence. IVUS may be particularly useful in this regard.
- Although fixed stenoses may occur throughout the venous system, the most common location for extrinsic compression occurs at the point where the left common iliac vein passes beneath the overlying right common iliac artery (RCIA) (**FIG 5**). After recognizing this compression and successful removal of thrombus proximal or distal to this lesion, the stenosis may be safely resolved with stenting (**FIG 6**). This is best performed by upsizing the interventional sheath to at least 10 Fr followed by

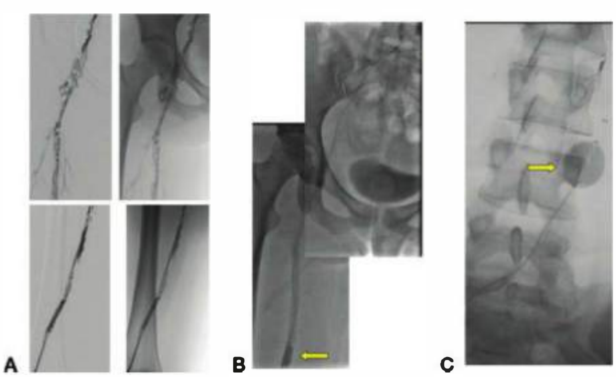

FIG 4 ● Patient with left iliofemoral venous thrombosis secondary to May-Thurner syndrome. Note the extensive thrombus within the iliac and femoral veins **(A)**. **B,C.** The patient is being treated in the prone position through popliteal vein access. The Trellis catheter has been inserted and advanced through the thrombus, and the occlusion balloons are inflated on either side of the treatment zone *(arrows)*. Note the oscillating dispersion wire that improves tPA delivery during infusion.

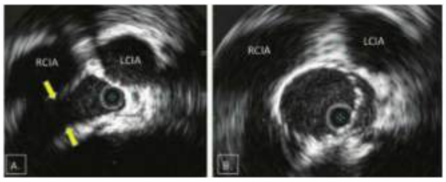

FIG 5 ● Intravascular ultrasound is the most sensitive assessment tool for detecting May-Thurner compression of the left common iliac vein. **A.** The RCIA is lying directly over and compressing the left common iliac vein (between *yellow arrows*). **B.** Following stenting of the left common iliac vein, there is complete resolution of the compression by the RCIA.

deployment of a self-expanding, braided, stainless steel Wallstent (Boston Scientific, Watertown, MA). In conjunction with completion venography, IVUS is then used to quantify the extent of residual compression.

- Stent diameter is chosen based on IVUS-obtained measurements, but diameters commonly chosen for common

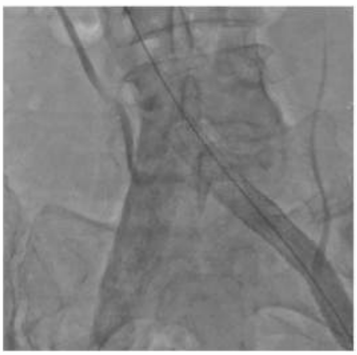

FIG 6 ● Stenting of the left common iliac vein for May-Thurner syndrome is performed with a braided self-expanding stainless steel stent, usually in diameters ranging from 16 to 20 mm.

iliac vein placement in May-Thurner patients range from 16 to 20 mm. In this application, it is important to choose longer stents that provide additional surface apposition in the common or even external iliac veins to present stent dislodgement and migration. Wallstents are particularly appropriate in this regard as they will shorten or extend in proportion to the ultimate treatment diameter and feature exposed wires at either end to optimize vein wall engagement.
- Once appropriately sited and deployed, poststent dilation is necessary to ensure optimal deployment and migration resistance. Some discomfort will be experienced by the "awake" patient during these procedures, and stenting molding should be guided by patient tolerance under these circumstances.

Completion Imaging

- Completion phlebography documents resolution of target stenosis and reciprocal reduction in collateral venous flow.
- The presence of persistent collaterals suggests residual venous stenosis or compression; IVUS should be reperformed in this circumstance to confirm wall apposition and stent expansion. Repeat balloon dilation may be necessary in these circumstances until sufficient expansion is achieved.

Closure of the Femoral Vein Access

- Following sheath removal, manual pressure is held over the venous puncture site. Closure devices are not appropriate or indicated for management of venous access.
- Patients need to remain supine for at least 1 hour following sheath removal.
- Therapeutic intravenous anticoagulation with unfractionated heparin is initiated at the completion of the procedure. Maintenance of full anticoagulation without interruption throughout the early postoperative period is imperative to procedural success.

OPERATIVE MANAGEMENT OF ILIOFEMORAL DEEP VEIN THROMBOSIS

Iliac Venous Thrombectomy

- For most clinical scenarios, open venous thrombectomy has largely been supplanted by the interventional, image-guided techniques described in the preceding sections. In patients with limb-threatening phlegmasia cerulean dolens or those with contraindications to lytic therapy or contrast administration, open surgical thrombectomy remains an effective and necessary treatment modality.
- Whenever possible, surgical thrombectomy is performed under general anesthesia with positive pressure ventilation to reduce the risk of intraoperative PE.
- A vertical inguinal incision is made to allow exposure and control of the CFV, femoral vein, saphenofemoral junction, and the profunda femoris vein. Once these venous structures have exposed, the patient is systemically anticoagulated with 100 units/kg of intravenous heparin.
- A longitudinal venotomy is made in the CFV, and a no. 8 or no. 10 venous thrombectomy catheter is then passed up to the level of the common iliac vein and thrombectomy is performed. Attempts are made to clear the majority of the iliac thrombus before passing the thrombectomy catheter into the vena cava in order to reduce the likelihood of pulmonary embolization.
- Back-bleeding may not be present due to competent iliac vein valves, or back-bleeding can occur from the hypogastric vein even without clearance of the thrombus within the common iliac vein. Therefore, back-bleeding should not be used as an indicator of effective thrombus clearance and venography should be performed as a routine after completion of iliac and infrainguinal thrombectomy.

Infrainguinal Femoral Venous Thrombectomy

- Following iliac venous thrombectomy, heparinized saline should be used to flush the iliac vein, the proximal external iliac vein (or distal CFV) should be clamped, and then any thrombus at the proximal (peripheral) aspect of the venotomy should be extracted with forceps.
- Infrainguinal thrombus can then be removed by manual massage or by exsanguinating the leg with an Esmarch bandage, sequentially applied from the foot to the groin, with sufficient overlap to provide continuous compression (**FIG 7**). Clot is delivered through the venotomy at the groin.
- Balloon thrombectomy can be performed using a no. 3 thrombectomy catheter passed from the venotomy in the CFV in a retrograde fashion down toward the popliteal and tibial veins. Following thrombectomy, the infrainguinal venous circulation should be flushed vigorously with heparinized saline before closure of the venotomy.
- If infrainguinal thrombus persists after thrombectomy, additional techniques for thrombus removal include on-table tPA administration. For on-table tPA administration, 6 mg of alteplase in 200 mL saline is infused retrograde into the femoral vein through the venotomy in the CFV, then the vein is clamped and the solution is allowed to dwell for 10 to 30 minutes.
- If the infrainguinal venous thrombectomy is not successful due to chronic thrombus in the femoral vein, the femoral vein is then ligated below the profunda, and balloon thrombectomy is then performed on the profunda vein and its branches.
- After open thrombectomy is complete, the venotomy is closed with running continuous monofilament suture, avoiding postclosure stricture of the CFV by precision suture placement. If narrowing is apparent, vein or bovine pericardial patch angioplasty may be performed as necessary to restore luminal diameter.

Adjunct Arteriovenous Fistula Creation

- Rates of rethrombosis following surgical thrombectomy can be as high as 80%. Creation of an arteriovenous fistula (AVF) may significantly reduce this risk and are incorporated in the procedure by most surgeons.
- The same groin incision may be employed for AVF creation, transposing the proximal segment of the ipsilateral greater saphenous vein to the superficial femoral artery (**FIG 8**).
- Surgical ligation or interventional occlusion of the AVF is ultimately required for optimal long-term outcome, usually employed within 6 weeks following the procedure. Documented patency of the venous system should be demonstrated on follow-up duplex imaging. Failure to close this fistula may result in significant long-term limb and cardiovascular complications, and follow-up is essential to ensure that this part of the procedure is completed.
- Open thrombectomy procedures by their nature are associated with significant blood loss from the central venous system, and preparations should be made both to crossmatch and bank sufficient packed red blood cells (RBCs), as well as employ operative scavenging systems to recycle and reinfuse lost blood to ensure that appropriate

FIG 7 ● Acute thrombus can generally be extracted during open surgical thrombectomy by exsanguinating the leg with an elastic Esmarch tourniquet. After performing the venotomy in the CFV in the groin, the tourniquet is wrapped from the foot up to the groin, expelling thrombus through the venotomy.

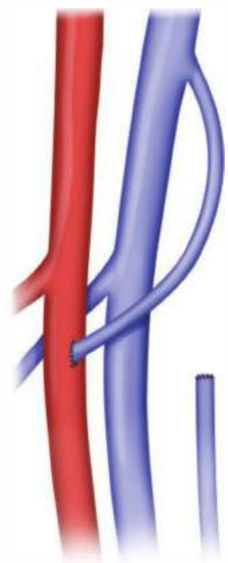

FIG 8 ● Patency rate following open surgical thrombectomy is significantly improved by creation of an AVF. Following thrombectomy of the iliac and femoral veins, the venotomy is closed with running monofilament suture and an end-to-side anastomosis is created between the saphenous vein and superficial femoral artery.

hemodynamic conditions may be maintained throughout the procedure.

Completion Imaging

- Completion venography of the iliac venous system should be performed following open surgical thrombectomy to assess the adequacy of the thrombectomy.
- Following closure of the venotomy and reestablishment of venous flow through the iliofemoral venous system, an 18-gauge access needle and guidewire can be used to puncture the CFV and place a 5-Fr sheath. Contrast injection directly through this sheath is performed to evaluate the iliac veins and assess for residual thrombus. Following venography, the sheath is removed, and a single monofilament stitch can be used to close the puncture site.

Wound Closure

- A careful search for any transected lymphatics should be conducted prior to wound closure.
- A closed suction drain should be placed in the groin wound to prevent seroma formation.
- The wound is then closed with multilayered running absorbable sutures for hemostatic and lymphostatic closure.

POSTOPERATIVE CARE

- Following open surgical thrombectomy, full therapeutic anticoagulation is imperative to prevent rethrombosis. An intravenous heparin infusion is immediately initiated and maintained for 24 to 48 hours before the patient is transitioned to oral anticoagulation with a low-molecular-weight heparin bridge prior to discharge.
- Ambulation should begin on the first postoperative day. Patients may usually be discharged within 48 to 72 hours following thrombectomy.
- On discharge, the patient should be placed in elastic compression stockings (30- to 40-mmHg ankle gradient), and the importance of compression should be stressed to the patient in the discharge instructions.

OUTCOMES

Endovascular Intervention

- Pharmacomechanical venous thrombectomy provides clinical success rates of 70% to 100% and may reduce the incidence of the PTS, although this latter conclusion remains controversial.
- Following successful procedures, long-term venous patency is reported at 84% in 5 years.
- Valvular competence is preserved at 80% in 5 years and 56% in 10 years in recent series.

Surgical Thrombectomy

- Surgical thrombectomy provides long-term iliac venous patency, with rates approaching 80% when combined with inclusion of a temporary AVF.
- At 5 years, over one-third of patients can be expected to be symptom free and have retained valvular competence.
